Clinical Findings

Patients with cryofibrinogenemia, as with cryoglobulinemia, typically present with cutaneous disease. The symptoms of cryofibrinogenemia are due to thrombotic occlusion of small- and medium-sized dermal vessels and resultant ischemia.[46] By definition, essential disease occurs in otherwise healthy individuals. Given the limited number of reported cases, the clinical presentation is not well defined, but likely emulates secondary disease. Patients presenting with cryofibrinogenemia typically report a temporal association between exposure to cold and an onset of symptoms. Non-specific general complaints of fever and malaise are common. The clinical phenotype of cutaneous lesions varies in severity from purpura, livedo reticularis, or ecchymoses to ulceration, ischemia, and gangrene. Cryofibrinogenemia may clinically simulate calciphylaxis, presenting in patients with end-stage renal disease (see Chap. 151). Any body site may be affected, but those maintaining a cooler temperature are more likely to be involved: hands, feet, buttocks, ears, or nose.

Non-cutaneous thrombotic events may also occur irrespective of the cryofibrinogen level (seen in approximately 25 percent of patients with secondary disease).[43] Cerebrovascular accidents, myocardial infarction, thrombophlebitis, pulmonary emboli, and retinal artery thrombosis have been reported, and correlate directly with the level of circulating cryofibrinogen. In contrast, spontaneous bleeding may occur in select patients due to depletion of clotting factors.

The histologic features of cryofibrinogenemia are similar in both cutaneous lesions and systemic disease,[54] with eosinophilic refractile deposits within vessel lumina and extension to the vessel intima, secondary to occlusive thrombi composed of cryofibrinogen precipitates. Distinction from type I cryoglobulinemia is difficult, but the presence of an accompanying granulomatous reaction, either extravascular granulomatous foci or granulomatous vasculopathy, is more characteristic of cryofibrinogenemia. Types II and III cryoglobulins, in contrast, typically elicit a lymphocytic or leukocytoclastic vasculitis. Cryofibrinogen precipitates may also be distinguished by their cylindrical configuration, which is often displayed within the vessel lumina.

Laboratory Testing

When cryofibrinogenemia is suspected, blood should be collected in tubes containing oxalate, citrate, or ethylenediaminetetraacetic acid as the anticoagulant. Tubes containing heparin should not be used given the risk of false-positives. On collection, the blood should be stored at 37°C (98.6°F) until centrifuged. Centrifugation performed after the sample has been allowed to cool results in false-negatives, as cryofibrinogens will precipitate with the red blood cell fraction. After centrifugation, plasma is stored at 4°C (39.2°F) and observed for the formation of a precipitate for up to 72 hours. A sample should also be drawn without anticoagulant, with the blood allowed to clot, to exclude the presence of precipitable cryoglobulinemia. As stated earlier, cryoglobulins form in both cooled serum and plasma and must be excluded when making a laboratory diagnosis of cryofibrinogenemia.

Differential Diagnosis (See Box 170-1)

Treatment

There is no regularly effective treatment for cryofibrinogenemia. Avoidance of exposure to cool environments is likely to be only partially effective. Various therapeutic interventions and pharmacologic agents have been proposed. Systemic steroids have shown limited benefit as monotherapy, but case reports cite improvement in clinical disease when combined with immunosuppressant therapy, most notably azathioprine.[55,56] Oral streptokinase has been reported to decrease disease activity; however, streptokinase is only available as an intravenous infusion in the

United States. Stanazolol is an androgenic steroid with fibrinolytic activity, presumed due to alteration of liver protein synthesis. It has been described to benefit patients in a few case reports.[57–59] Last, plasmapheresis, cryofiltration apheresis, and warfarin have been reported with varying success rates. The treatment of secondary cryofibrinogenemia should target the underlying disease or associated condition.

CHAPTER 171

Raynaud Phenomenon

John H. Klippel

EPIDEMIOLOGY

Studies of the epidemiology of Raynaud phenomenon are biased by under-reporting (most patients with primary Raynaud never seek medical attention) and studies done by investigators interested in the secondary forms of the disorder. Surveys indicate that Raynaud phenomenon affects up to 10 percent of the general population.[1,2] Primary Raynaud phenomenon is estimated to be approximately twice as common as secondary Raynaud.[3] Symptoms most often first develop in the teenage years, and most series show a female predominance of the disorder (female-male = 4:1). Increases in the frequency and severity of attacks during menses suggest that female sex hormones may be involved in the pathogenesis.[4] Differences in seasonal skin temperatures, marital status, alcohol use, age, and smoking between women and men have also been suggested to contribute to the sex differences.[5,6] Familial aggregation has been identified in a number of studies and suggests the contribution of genetic factors.[7] Other associations reported in epidemiologic studies include living in a cold climate, occupation, cardiovascular disease, low body-mass index, and use of vibratory tools.

ETIOLOGY AND PATHOGENESIS

The pathophysiology of the vasospasm is complex and only partially understood. Studies show significant reductions of peripheral blood flow throughout all phases of central body cooling and re-warming, suggesting impairments of central thermoregulatory control mechanisms.[8] The principal mechanisms thought to contribute to the development of Raynaud phenomenon include a local defect of a digital blood vessel, causing abnormal vascular reactivity or reduced blood flow; an enhanced localized production of vasoconstrictors or reduced production of vasodilators; hyperreactivity of the sympathetic nervous system; and abnormal properties of the blood that compromise distal perfusion.

The results of gross histologic examinations of digital arteries in patients with primary Raynaud phenomenon are normal. Structural abnormalities of the digital microvasculature are frequently seen in patients with secondary forms of Raynaud phenomenon, particularly in the connective tissue diseases. Studies show a range of pathology, including intimal hyperplasia, narrowing or total occlusion of arteries, or thrombi. In most patients with systemic sclerosis, there exists evidence of activation and damage of the endothelium, fibrinolysis, and platelet activation.[9] Microcirculatory flow studies with laser Doppler in patients with scleroderma have shown marked reductions in blood flow and hand temperature during an attack, with prominent abnormalities during re-warming—findings that suggest a failure of the arteriovenous anastomoses to open.[10]

Serotonin is also incriminated as an important mediator in the induction of ischemic attacks of Raynaud phenomenon. Patients have an increased sensitivity to intra-arterial infusions of serotonin, and S2-serotonergic antagonists relieve but do not prevent the induction of attacks.

The evidence of direct central sympathetic nervous system hyperactivity is strongest in vibration-induced injury, in which the use of a vibration tool in one hand produces vasospasm in the other hand.[11] Similarly, vasospasm can be inhibited by proximal nerve blockade in patients with vibration-induced injury. In general, most studies of the sympathetic nervous system in patients with primary or other secondary forms of Raynaud phenomenon have failed to detect evidence of sympathetic hyperactivity. The results of microelectrode studies of skin sympathetic nervous activity during cold pressor tests are normal, and plasma levels of catecholamines are not increased in the venous drainage of the hands of patients with Raynaud phenomenon.

RAYNAUD PHENOMENON AT A GLANCE

- Affects 10 percent of the population; 4:1 female-male ratio.
- Chronic episodic attacks of digital ischemia provoked by exposure to cold or emotional stress.
- Classified into primary (idiopathic) and secondary (underlying disease or cause present) forms; severity ranges from mild/benign to severe with loss of digital tissues.
- Connective tissue diseases—particularly systemic sclerosis—are the most common forms of secondary Raynaud.
- Both non-pharmacologic and drug therapies are used to reduce the frequency and severity of attacks.

▲ **FIGURE 171-1** Ischemic phase of attack of Raynaud phenomenon with marked pallor of the ring and little fingers of the left hand and little finger of the right hand.

Consistent abnormalities in plasma fibrinogen, cold agglutinins, platelets, or cryoglobulins have not been demonstrated in primary Raynaud phenomenon, but are important in certain secondary cases, particularly scleroderma. Levels of von Willebrand's factor and soluble thrombomodulin, thromboxane B_2 and β-thromboglobulin, and tissue plasminogen activator inhibitor-1 are increased in patients with scleroderma, when compared to levels in patients with primary Raynaud phenomenon.[9]

Genetic studies with microsatellite markers of extended families affected with primary Raynaud phenomenon have identified several potential candidate genes.[12]

CLINICAL FINDINGS

A careful history and physical examination are important in the evaluation of a patient with suspected Raynaud phenomenon.

History

The history is important to elicit a clear description of the attacks and to screen for evidence of signs and symptoms suggestive of a secondary cause. Patients complain of episodic attacks of well-demarcated, white or blue digits induced by exposure to cold and sometimes by emotional stimuli (Fig. 171-1). Often only a portion of the digit is affected, and the thumbs are typically spared. A classic tricolor change of pallor, cyanosis, and hyperemia described in most textbooks is rarely volunteered by patients; most describe only blanching of the digits accompanied by numbness. During the attacks, one or more fingers or toes may be numb and be described as "dead." On re-warming, the digits may become bright red, and throbbing pain may occur. When pain is a prominent symptom in the ischemic phase, a secondary cause should be suspected. Attacks last minutes to hours. The fingers and toes are most commonly involved; however, the attacks may involve the nose, earlobes, or nipples.

A careful review of systems is important to screen for symptoms of connective tissue disease (arthralgias, arthritis, dysphagia, heartburn, rash, photosensitivity, skin changes, muscle weakness, shortness of breath, or sicca), a drug-related etiology, symptoms of obstructive arterial diseases (intermittent claudication), and exposure to vibratory tools or continuous finger trauma.

Cutaneous Lesions

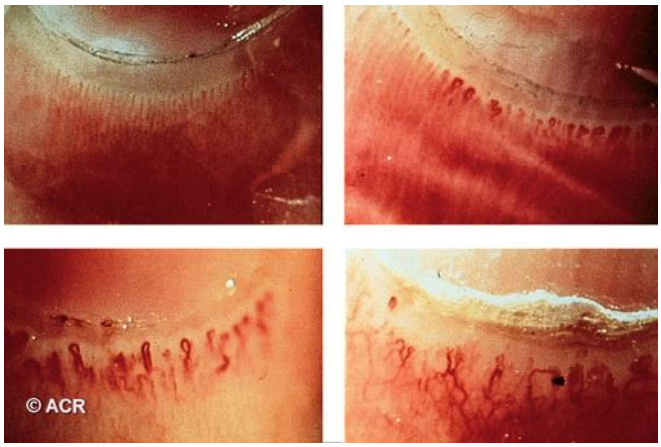
Attacks of Raynaud phenomenon, presumably stress induced, are commonly witnessed during the course of the history or physical examination. There is well-demarcated blanching or cyanosis of the digits extending from the tip to various levels of the digit (see Fig. 171-1). The digits distal to the line of ischemia are cold, while the proximal skin is pink and warmer. On re-warming, blanched digits may become cyanotic, because of the slow blood flow, and then bright red, because of reactive hyperemia. Persistent ischemic discoloration of digits suggests a secondary cause.

The digits should be carefully examined for trophic or ischemic changes, which are signs of prolonged or severe attacks of Raynaud phenomenon. The skin may become atrophic, thin, and tight (sclerodactyly), with loss of hair over the dorsal surfaces. The nails may become brittle and deformed. Ulcerations, which can be extremely painful, particularly at night, may develop on the finger pads or around the nail bed. The ulcers heal slowly, leave characteristic small, pitted scars (Fig. 171-2), and may become infected. Gangrene of the distal aspects of the digit is rare.

Related Physical Findings

The physical examination should pay attention to all pulses, and blood pressure should be obtained in both arms. Allen's test is useful to assess arterial and capillary function of the hands; abnormalities imply structural disease of the microcirculation and raise the suspicion of a secondary form of Raynaud phenomenon. The radial and ulnar arteries are simultaneously compressed by the examiner's thumbs while the patient opens and closes the fist to induce blanching of the palm. Selective arterial filling is judged by the rate of color return as pressure is sequentially released from the radial and ulnar arteries. Vascular

▲ **FIGURE 171-2** Loss of pulp of the pad of the digit with pitting scars and ulcerations from chronic, severe Raynaud phenomenon.



▲ **FIGURE 171-3** Nail fold capillary microscopy, in a patient with scleroderma, showing capillary drop out with enlarged, dilated, tortuous capillary loops.

obstruction from the thoracic outlet syndrome should be assessed by the Adson maneuver, which tests for diminution in the radial pulse with exaggerated movements of the neck and shoulder. A careful neurologic examination should be performed to detect evidence of sympathetic hyperactivity, abnormal reflexes, muscular weakness or atrophy, or compression of the median nerve within the carpal tunnel. Skin changes, such as telangiectases, changes in skin texture, rashes, or purpura, provide valuable clues to the presence of a connective tissue or hyperviscosity disorder.

LABORATORY TESTS

In all patients, a complete blood count, erythrocyte sedimentation rate, urinalysis, and anti-nuclear antibody test should be obtained. Additional laboratory studies should be directed by findings elicited by the history and physical examination. In patients with abnormal anti-nuclear antibody levels, tests for antibodies to specific nuclear antigens, such as Sm antigen or topoisomerase or centromere antigens, are helpful to detect early systemic lupus erythematosus or scleroderma (see Chaps. 156 and 158). A routine chest radiograph should be obtained to look for a cervical rib or evidence of interstitial lung disease.

Nail fold capillary microscopy is considered to be a useful procedure to distinguish primary from secondary Raynaud phenomenon.[13] Although mild capillary abnormalities may be observed in patients with primary Raynaud phenomenon, patients with connective tissue diseases may have enlarged, deformed capillary loops surrounded by avascular areas (Fig. 171-3).[14] Serial studies reveal progressive decreases in the total number of nail fold capillary loops in secondary, but not primary, forms of Raynaud phenomenon.[15] The patency of small arteries can be assessed by Doppler techniques. Digital subtraction arteriography should be reserved for selected patients with prolonged, severe ischemia for whom arterial reconstruction is a consideration.

DIFFERENTIAL DIAGNOSIS

Raynaud phenomenon is subdivided into primary (idiopathic) and secondary forms based on whether an underlying cause or disease association can be identified.

Primary Raynaud Phenomenon

Primary Raynaud phenomenon is a disorder in which known causes of attacks of peripheral vasospasm cannot be found. Criteria for the diagnosis of primary Raynaud phenomenon have been developed by Allen and Brown[16] and LeRoy and Medsger[17] (Table 171-1).

Several studies have examined the long-term outcome of patients with primary Raynaud phenomenon.[3,18,19] Progression to a secondary form of Raynaud phenomenon, most commonly a connective tissue disease such as scleroderma, occurs in approximately 15 percent of patients during the first decade after onset. Variables predictive of a transition to a secondary form include nail fold capillary abnormalities, hand swelling, positive Allen's test, and anti-nuclear antibodies.

Secondary Raynaud Phenomenon

CONNECTIVE TISSUE DISEASES The connective tissue diseases are the most common cause of secondary Raynaud phenomenon (Table 171-2). Among patients with scleroderma, 80 percent to 90 percent manifest Raynaud phenomenon and/or persistent vasospasm. It is the presenting symptom in about one-third of patients and may be the only manifestation of the disease for years. Raynaud phenomenon occurs in about one-third of patients with systemic lupus erythematosus, idiopathic inflammatory myopathies, and systemic vasculitis. Although patients with rheumatoid arthritis often complain of cold hands with mottled red and white areas, true Raynaud phenomenon appears to be no more common in persons with rheumatoid arthritis than in the general population. Arteriograms of patients with connective tissue diseases usually show digital and sometimes, ulnar or radial artery obstructions.

TABLE 171-1
Criteria for Primary Raynaud Phenomenon

- Vasospastic attacks precipitated by exposure to cold or emotional stimuli
- Bilateral involvement of extremities
- Normal vascular examination with symmetric peripheral pulses and normal nail fold capillary microscopy
- Absence of gangrene or, if present, limited to the skin of the fingertips
- No evidence of an underlying disease, drug, or occupational exposure that could be responsible for vasospastic attacks
- Negative anti-nuclear antibody test
- Normal erythrocyte sedimentation rate
- History of symptoms for at least 2 yr

Combined criteria of Allen and Brown[16] and Le Roy and Medsger.[17]

OCCUPATIONAL Raynaud phenomenon may be occupational in origin. It is especially common in individuals who use vibratory tools (e.g., air hammers, chain saws, rivet guns) and in those whose occupation requires prolonged exposure of the extremities to cold temperatures (e.g., butchers, ice cream workers, fish packers). Prevalence rates correlate with the vibration level of the tool and the duration of exposure; they can be as high as 90 percent in high-risk occupations such as logging or mining.[20]

NEUROLOGIC DISORDERS Any neurologic condition that produces permanent disuse of a limb can be associated with sympathetic nervous system disturbances to that limb. Patients often develop persistent vasospasm with coldness, paleness or cyanosis, and even ulcerations of the limb, and Raynaud phenomenon may occur. Thermoregulatory abnormalities may be

  - Intra-arterial injections

a prominent feature of reflex sympathetic dystrophy syndrome.[21] Nerve root pressure or nerve entrapment may produce Raynaud phenomenon. It is often present in patients with carpal tunnel syndrome and typically involves the first, index, and middle fingers, digits innervated by the median nerve. In addition, Raynaud phenomenon may occur as a result of neurovascular compression at the thoracic outlet. The compression may be caused by cervical ribs; abnormalities of the scalenus anticus muscle; bony abnormalities of the cervical vertebrae, clavicle, or first rib; or shoulder compression syndromes (the costoclavicular or hyperabduction syndrome).

DRUGS AND TOXINS Propranolol, one of the most widely used β-adrenergic blockers for cardiovascular diseases and migraine headaches, is probably the most frequently used drug responsible for Raynaud phenomenon. Ergot preparations and methysergide used to treat migraine headaches may produce vasospasm. Intra-arterial use of many medications and recreational drugs can result in toxicity to endothelial cells with irreversible structural damage to the microvasculature of the extremities and be responsible for severe Raynaud phenomenon. The chemotherapeutic agents bleomycin and vinblastine also may cause the phenomenon.[22]

HYPERVISCOSITY Patients with hyperviscosity from cryoglobulinemia, macroglobulins, cold agglutinins, and polycythemia can exhibit Raynaud phenomenon. Cryoglobulins are most commonly present in patients with multiple myeloma, but they also occur in patients with rheumatic diseases, chronic infections, leukemia, and lymphoma, and as an idiopathic condition.

MISCELLANEOUS The most common endocrine disturbance associated with Raynaud phenomenon is hypothyroidism; symptoms usually remit with thyroid hormone replacement. Raynaud phenomenon may be a feature of various infectious disorders, including subacute bacterial endocarditis, Lyme disease, and viral hepatitis, presumably a reflection of systemic vasculitis. Peripheral vasospasm may also occur in association with malignant tumors, including pheochromocytoma, carcinoid, and ovarian carcinoma.

The major forms of vascular ischemia that must be distinguished from Raynaud phenomenon are cold digits, chilblain (pernio), livedo reticularis, and acrocyanosis (see Chap. 93). Many patients complain of cold, sometimes painful digits without color changes. This condition likely represents one extreme of the spectrum of normal sympathetic nervous system activity. Chilblain is an inflammatory condition of the skin of the extremities induced by cold. Patients develop a bluish-red discoloration and edema, typically involving the lower limb and associated with warmth, erythema, and burning. In severe cases, hemorrhagic lesions, bullae, or ulcers may develop, and secondary infections may supervene. The lesions last from 7 to 10 days, often leaving a residual pigmentation of the skin. Livedo reticularis is a bluish discoloration of the skin of the extremities with a characteristic lacy, irregular appearance. The bluish discoloration becomes more intense on exposure to cold and may disappear in a warm environment. Most patients are entirely asymptomatic, although livedo reticularis may be a feature of the antiphospholipid syndrome, in which patients are at increased risk for venous and arterial thromboses, thrombocytopenia, and pregnancy losses. In acrocyanosis, the hands, and, less commonly, the feet, develop a persistent bluish discoloration. The blue color is intensified by exposure to cold and is converted into a purplish or red color by warming; a pallor phase is absent. The skin is cold, and the palms are often wet and clammy from sweat. Trophic changes or ulcerations are rarely observed.

TREATMENT

The management of Raynaud phenomenon is guided by the frequency and severity of attacks and the complications from ischemia (Table 171-3). Secondary forms of Raynaud phenomenon require treatment directed at the underlying medical disorder, discontinuation of drugs causing the vasospasm, or occupational modifications.

General Measures

Mild Raynaud phenomenon is generally easy to control with lifestyle changes to minimize exposure to the cold; dressing warmly with loose-fitting, layered clothing; and keeping the thermostat a few degrees higher than normal. Limiting time spent outdoors in winter, wearing insulated gloves, and using hand or foot warmers are usually helpful. Patients should be taught to recognize and terminate attacks promptly by returning to a warmer environment and applying local heat to the hands (e.g., by placing their hands in warm water or by using a hair dryer). Patients should be strongly encouraged to stop smoking and to avoid

TABLE 171-3
Management of Raynaud Phenomenon

Infrequent or mild attacks	Preventive measures
	Cessation of smoking
Frequent or severe attacks	Calcium channel blockers (nifedipine, diltiazem)
	Anti-adrenergic drugs (prazosin, reserpine)
	Topical nitroglycerin
Acute, severe ischemia	Intravenous prostaglandin E_1 or prostacyclin
	Digital sympathectomy
	Microvascular surgery
Digital ulcers	Antiseptic soaks, antibiotic ointments, occlusive dressing
	Calcium channel blockers (maximal doses)
	Intravenous prostaglandin E_1 or prostacyclin
Gangrenous, infected ulcers	Analgesics
	Antibiotics
	Surgical débridement
	Amputation

secondhand smoke, because nicotine induces cutaneous vasoconstriction. Stress modification and social support are valuable aspects of treatment to minimize vasoconstriction induced by hyperactivity of the sympathetic nervous system. Counseling, training in relaxation, or medications may be helpful. Some patients benefit from conditioning programs such as biofeedback training.

Digital ulcers from Raynaud phenomenon can be extremely painful and typically take weeks or months to heal completely. Pain control is an important part of therapy, because pain can lead to additional vasospasm and more ischemia. On occasion, narcotic pain medications may be necessary to control symptoms. The finger should be soaked in a tepid antiseptic solution (e.g., half-strength hydrogen peroxide) twice daily to soften or loosen the crust or eschar. After drying, an antibiotic ointment is applied to the ulcer, and the digit is covered with an occlusive dressing. Maximum drug therapy with a calcium channel blocker should be used throughout treatment. Infection is a common complication of digital ulcers and is typically manifest by increasing pain, erythema, swelling, or purulent drainage. Cultures usually demonstrate *Staphylococcus* sp., and treatment with dicloxacillin or cephalosporins is usually effective.

Drug Therapy

Various drugs have been used to treat Raynaud phenomenon, including vasodilators, platelet inhibitors, serotonin antagonists, and fibrinolytics. Drug therapy is usually reserved for patients with prolonged or frequent attacks that fail to respond to conservative measures. In general, improvements with drug therapy are more pronounced in patients with primary Raynaud phenomenon, presumably as a consequence of fixed, structural damage in patients with secondary forms.

Sympatholytic drugs, including reserpine, methyldopa, phenoxybenzamine, and tolazoline, have been used in management, although they have not been well studied. In a pilot study, the selective serotonin reuptake inhibitor fluoxetine reduced the frequency and severity of Raynaud attacks.[25] Additional drug therapies reported to be beneficial in the treatment of Raynaud phenomenon include low molecular weight heparin,[26] prazosin,[27] the angiotensin II receptor antagonist losartan,[28] and stanozolol.[29] The calcium channel blockers are by far the most widely used and effective drugs for treating Raynaud phenomenon.[23,24] Vasodilating properties vary among different agents. Nifedipine (10 to 20 mg tid or qid) reduces the severity and frequency of attacks; the long-acting preparation of nifedipine is better tolerated but may be less effective. Diltiazem (60 mg tid or qid) may be substituted if nifedipine is ineffective or not well tolerated. Side effects of calcium channel blockers include fluid retention, light-headedness, and heartburn; these may limit therapy.

Topical nitroglycerin paste (2 percent) and a sustained-release transdermal glyceryl patch are helpful in selected patients.[30] Intravenous prostaglandin E_1 and prostacyclin (PGI_2) and iloprost (a PGI_2 analog) have been shown to have beneficial effects in patients with severe Raynaud phenomenon; however, the vasodilatory effects are not sustained and long-term therapy is required.[31–34] Oral prostaglandins are currently available only as investigational agents.

Sympathectomy

Sympathectomy may be a consideration for the management of patients with refractory, disabling attacks or with an acutely ischemic digit that is unresponsive to other measures. A positive vasodilator response to a stellate ganglion block or epidural infusion should be documented before a permanent procedure is done. Lumbar sympathectomy has an important role in the management of severe Raynaud phenomenon of the feet, and selective digital sympathectomy may be used to relieve pain and heal digital ulcers in patients with ischemic digits.[35] The long-term effects of sympathectomy are poor, with up to two-thirds of patients reporting no benefit at the end of 1 year. Newer procedures for thoracic sympathectomy, including percutaneous radio frequency[36] and thoracoscopic procedures,[37] have been advocated as technically easier to perform with fewer complications and more promising long-term results.

Severe Vasospasm

Severe vasospasm with prolonged ischemia (dead-white finger) poses a threat of gangrene and amputation; it is considered a medical emergency. The patient should be hospitalized and the affected extremity put to rest. Nifedipine (10 to 20 mg tid) should be started immediately, as well as prostaglandin E_1 (6 to 10 ng/kg/minute) or PGI_2 (0.5 to 2 ng/kg), given by continuous intravenous infusion for several hours over 3 consecutive days. Intra-arterial phentolamine or tolazoline may reverse acute vasospasm, but monitoring of vital signs is essential, and these drugs need to be used with great caution. A digital (or stellate ganglion) block with lidocaine hydrochloride or bupivacaine hydrochloride (without epinephrine) relieves pain and produces a chemical sympathectomy that may reverse vasoconstriction. Sympathectomy (thoracic, lumbar, or digital) should be considered in patients who have a positive response. Arterial reconstruction should be reserved for patients with angiographically documented occlusive vascular disease.[38]

CHAPTER 172

Malignant Atrophic Papulosis (Degos Disease)

Dan Lipsker
Jean-Hilaire Saurat

In the early 1940s, Köhlmeier first described malignant atrophic papulosis, whereas Degos, Delort, and Tricot recognized it as a specific entity a year later.[1–3] We now know that the clinically distinctive lesion of the so-called *Degos disease* is a marker of a cutaneous thrombo-obliterative vasculopathy rather than of a specific disease per se. Indeed, such lesions can be found in at least two distinctive clinical settings: as an apparent idiopathic disease, either classic Degos disease or its benign variant, or as a surrogate clinical finding in some connective tissue diseases such as the anti-phospholipid syndrome, lupus erythematosus, dermatomyositis, and systemic sclerosis.

EPIDEMIOLOGY

Classic Degos disease is rare, with less than 200 reported cases. It almost always occurs in Caucasians, but cases have been observed in African American patients and in Japan. The disease most commonly presents between the third and fourth decades, but can occur at any age. Men are more often affected than women (ratio, 3:1). The majority of cases are sporadic, but familial cases have been described, and most of these cases are consistent with an autosomal dominant pattern of inheritance.[4]

ETIOLOGY AND PATHOGENESIS

The etiology of Degos disease is unknown. The histopathologic findings in patients with malignant atrophic papulosis suggest a primary vaso-occlusive process. Thus, a vascular coagulopathy and/or endothelial cell damage should be considered as the major pathogenic mechanism. A combination of prothrombotic factors possibly play a role in triggering the full-blown disease. Extensive studies of prothrombotic factors were performed in some patients with Degos disease, and no single abnormality was repeatedly identified. All patients should be screened for the presence of anti-phospholipid antibodies/lupus anticoagulant and cryoglobulins, although Assier et al. did not find the former in their series of 15 patients.[5] Inhibition of fibrinolysis and platelet abnormalities, including increased platelet adhesiveness and spontaneous aggregation, were reported in some patients.[5–8]

The lesions of Degos disease should be viewed as a cutaneous marker indicative of intraluminal thrombosis. Several disease processes may converge to produce those clinical and histologic findings.

CLINICAL FINDINGS (Fig. 172-1)

History

Patients seek medical advice for the appearance of small cutaneous lesions that usually are neither pruritic nor painful. In some patients, history and/or review of systems will reveal signs indicative of extra-cutaneous involvement: abdominal pain, diarrhea, melena, nausea, blurred vision, hemiparesis, paresthesia or any other sign indicative of an ischemic event. History can also give a clue to previous thromboembolic or obstetrical events suggestive of the anti-phospholipid antibody syndrome.

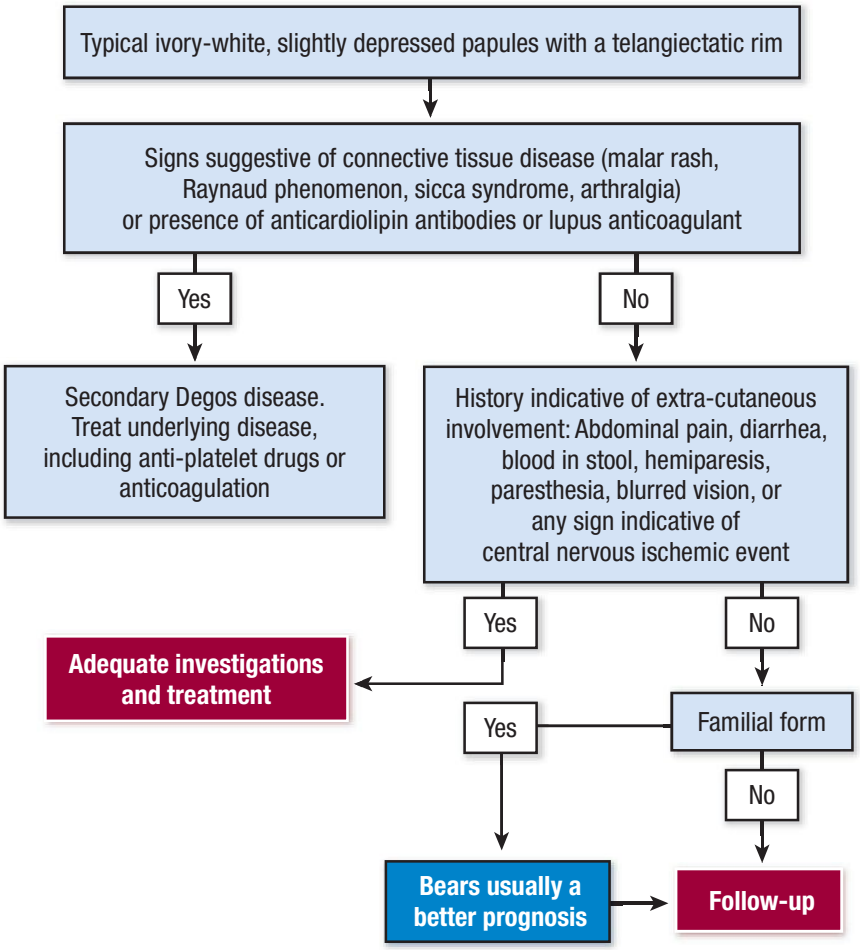
Cutaneous Lesions

Cutaneous lesions start as crops of 2 to 10 mm, largely asymptomatic or mildly pruritic, fleshy or rose-colored macules that soon become round, smooth, often dome-shaped firm papules (Fig. 172-2). Some lesions display central umbilication and/or necrosis (Fig. 172-3). These lesions evolve over days or weeks to porcelain-white, atrophic papules with a rim of rosy erythema and/or telangiectases (Fig. 172-4). A fully developed lesion therefore closely resembles lesions of atrophie blanche. In time, the reddish border disappears, and only a varicelliform white scar remains. Usually, the lesions are separated from each other, but they may coalesce, leading to polycyclic atrophic areas or to skin ulcerations.

The lesions are localized on the trunk and limbs. Palms, soles, face, scalp, and genitalia are usually spared, although there are exceptions. A linear distribution

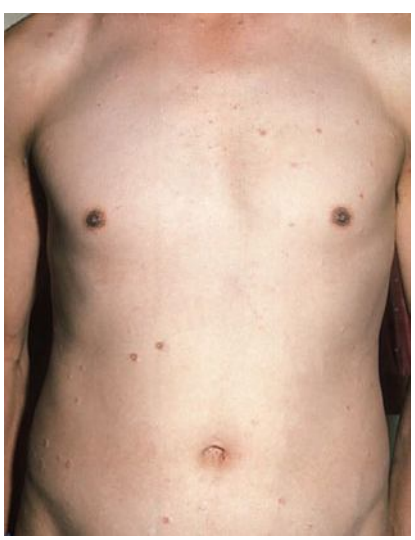
MALIGNANT ATROPHIC PAPULOSIS AT A GLANCE

- A rare, primary vaso-occlusive disorder, affecting mainly the skin, the gastrointestinal tract, and the central nervous system.
- Diagnosis relies on clinico-pathologic evaluation.
- Characterized by numerous typical porcelain-white, atrophic papules, with a rim of rosy erythema and/or telangiectases.
- Pathology shows a wedge-shaped area of dermal necrosis with edema and mucin deposition.
- Benign forms without extra-cutaneous involvement are possible.



▲ **FIGURE 172-1** Approach to the patient with malignant atrophic papulosis.

was reported.[9] Eye involvement is possible, and the most common manifestation is an avascular patch on conjunctivae, but sclerae, episclera, retina, choroids, and optic nerves may be affected (see eFig. 172-4.1 in on-line edition).



▲ **FIGURE 172-2** Numerous typical papules of Degos disease in a young man.

CLASSIC DEGOS DISEASE In classic Degos disease, the number of cutaneous lesions varies from a few to more than one hundred. Cutaneous findings usually precede the systemic manifestations that may involve the gastrointestinal tract, with bowel perforation and peritonitis, and/or the central nervous system, with hemorrhagic or ischemic stroke. Rarely, cutaneous lesions occur simultaneously or after gastrointestinal or central nervous system involvement. Postmortem studies have revealed small vessel thrombotic involvement of many organs, including kidney, bladder, prostate, liver, pleura, pericardium, lung, and eyes.[10] Some patients with classic Degos disease have anti-phospholipid antibodies, and this raises the possibility of a relationship with a primary anti-phospholipid syndrome.

BENIGN DEGOS DISEASE A benign form of Degos is now widely recognized. In this form, only skin involvement is found, and most of the familial cases are benign.[4] Development during pregnancy has been reported in a patient

▲ **FIGURE 172-3** Papule with central ulceration in patient with Degos disease.

with anti-phospholipid antibodies,[11] as well as a case occurring in a patient with acquired immunodeficiency syndrome.[12] A patient developing Degos disease after interferon injections, a drug known to induce atrophie blanche–like lesions[13] and microangiopathy,[14] is known to the authors (L. Thomas, personal communication). There is no clear-cut distinction between the classic and the benign form of Degos disease, and there is no way by which one can predict which patients will or will not develop visceral involvement.

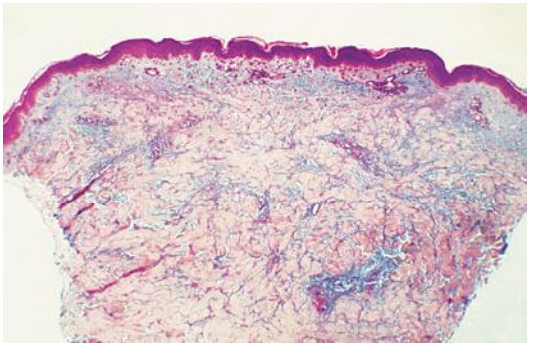
DEGOS DISEASE–LIKE LESIONS OR SECONDARY DEGOS DISEASE Degos disease–like lesions can occur in patients with known lupus erythematosus, especially those with anti-phospholipid antibodies, dermatomyositis, and systemic sclerosis.[15,16]

LABORATORY TESTS

Histopathology

Clinically, fully developed lesions reveal a cell-poor, wedge-shaped area of slight to severe dermal necrosis with dermal edema and copious mucin deposition, extending from the papillar dermis to the deep part of the reticular dermis

▲ **FIGURE 172-4** Typical pathognomonic papules of Degos disease with a porcelain-white center and an erythematous raised border.



◀ **FIGURE 172-5** A wedge-shaped area of dermal necrosis, poor in cells, with copious mucin deposition, extending from the papillar dermis to the deep part of the reticular dermis (hematoxylin-eosin-safran-Astra blue, ×40).

(Fig. 172-5). At the base of the lesion, occluded vessels with occasional thrombosis, thickened vessel walls, proliferating endothelial cells, and sparse perivascular lymphocytic infiltrate can be found (Fig. 172-6). Yet, a full-blown leukocytoclastic neutrophilic vasculitis is never found in patients with malignant atrophic papulosis. This entity should therefore not be classified as vasculitis. Numerous secondary, epidermal changes can be found: hyperkeratosis, interface dermatitis, scattered necrotic keratinocytes, and atrophy. An associated sclerosing panniculitis was reported in one patient.[17] Results of direct immunofluorescence studies have been inconsistent. Electron microscopy occasionally revealed tubuloreticular aggregates within endothelial cells of uncertain significance.

Because some of those histopathologic findings, such as mucinous infiltration of the dermis, interface dermatitis, and perivascular lymphocytic dermal infiltrate, are shared by lupus erythematosus and dermatomyositis, Degos disease is considered by some authors as a possible variant of lupus erythematosus.[18]

Other Laboratory Tests and Special Tests

There is no diagnostic or prognostic marker of the disease. A search for antinuclear antibodies, lupus anticoagulant, and anticardiolipin antibodies should be performed in each patient. An extensive exploration of hemostasis will sometimes reveal abnormalities.

Clinical evaluation can confirm secondary Degos disease if signs suggestive of connective tissue disease or antiphospholipid syndrome are present. If clinical evaluation reveals signs of intestinal or cerebral involvement (pain, diarrhea, hemiparesis, blurred vision, paresthesia), imaging studies including cerebral magnetic resonance imaging and/or endoscopic evaluation/laparoscopy are mandatory.

DIAGNOSIS

The diagnosis is usually established clinically, because of the distinguished lesion. A confirmatory biopsy should always be performed.

DIFFERENTIAL DIAGNOSIS

(Box 172-1)

COMPLICATIONS

Death related to an ischemic cerebral or gastrointestinal event is the major complication of Degos disease. Gastrointestinal hemorrhage, perforation, and peritonitis are the most frequent complications of the disease and are the major ominous events. Neurologic complications, including hemiparesis, aphasia, multiple cranial nerve involvement, monoplegia, sensory disturbances, and seizures, are less common. Rarely, progressive neurologic involvement can lead to death, especially in children. Exceptionally, death can result from respiratory failure or myocardial infarction.

Box 172-1

Differential Diagnosis

Most Likely

- Atrophie blanche

Consider (although unlikely, other diseases with white and/or necrotic papules)

- Cutaneous lichen sclerosus
- Pityriasis lichenoides
- Lymphomatoid papulosis
- Syphilids, tuberculids
- Cutaneous Kikuchi disease
- Clear cell papulosis
- Calcinosis cutis
- Fiboelastolytic papulosis of the neck
- White lentiginosis

Always Rule Out

- Connective tissue disease with Degos lesions

PROGNOSIS AND CLINICAL COURSE

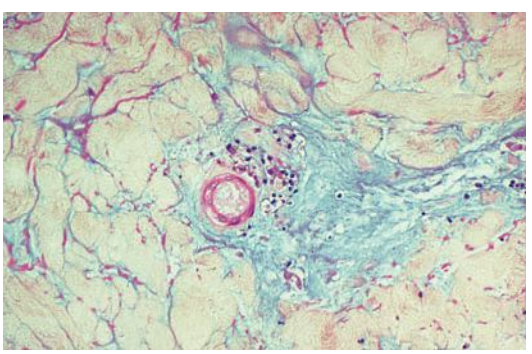
Although absence of visceral involvement 2 years after diagnosis portends a better prognosis, systemic involvement can occur up to many years after initial cutaneous lesions and thus, it is impossible to predict the outcome. Lethality is above 50 percent if patients present with extra-cutaneous involvement, and most of these patients die within 2 to 3 years mainly because of severe intestinal involvement. Familial Degos disease bears a better prognosis.[4]

TREATMENT

Due to the rarity of Degos disease, there are no controlled clinical trials, but only anecdotal reports. Yet, in some aspects, Degos disease resembles livedoid vasculopathy, and, therefore, some treatments reported to be efficient in patients with the former entity are worth trying.

Secondary Degos disease occurring in patients with known connective tissue disease should involve, in our opinion, the introduction of anti-platelet agents in addition to the standard treatments otherwise required by those patients.

Patients with classic Degos disease should be screened for all known preventable cardiovascular risk factors. Patients should cease smoking, and their lipid levels should be screened and lowered, if necessary, using statins.



◀ **FIGURE 172-6** At the base of the dermal lesion, in the deep part of the reticular dermis, important mucin deposition and a slight lymphocytic infiltrate around a blood vessel (hematoxylin-eosin-safran-Astra blue, ×200).

Box 172-2

Treatment of Malignant Atrophic Papulosis (Degos Disease)

First line	Aspirin (100–325 mg) and dipyridamole (3 × 400 mg)
Second line	Heparin and other anticoagulation strategies
Adjunctive measures	Control of cardiovascular risk factors

First-line treatment of patients with Degos disease should include platelet aggregation inhibitors (aspirin, clopidogrel, dipyridamole) (Box 172-2). A substantial number of patients responded to aspirin and dipyridamole.[6,7,12] A number of anecdotal treatments, including antibiotics, chloroquine, immunosuppressive agents, phenylbutazone, and fibrinolytics, have been reported with variable success. Systemic steroids have been reported to exacerbate the disease and should not be prescribed.[19] Heparin and other anticoagulation strategies such as anti-vitamin K (warfarin, fluindione) have variable success rates. Yet, by analogy to livedoid vasculopathy, low-molecular-weight heparin as well as the newer anticoagulants might warrant a trial in the acutely ill patient not responding to anti-platelet agents.[20]

CHAPTER 173

Vascular Malformations

Laurence M. Boon
Miikka Vikkula

EPIDEMIOLOGY

Vascular malformations are believed to be due to errors of development of vessels that occur during the fourth and tenth weeks of intrauterine life. Most vascular malformations are sporadic, although several families with inherited forms have been identified. They are very heterogeneous and affect about 0.3 percent of the population. Vascular malformations are mostly congenital, even if they may be diagnosed only later in life.

ETIOLOGY AND PATHOGENESIS

Although several genes have been identified as the cause of inherited forms of vascular malformations, the etiology of the most common sporadic lesions is unknown.[1,2] Histologically, vascular malformations consist of enlarged, tortuous vessels with quiescent endothelium. In contrast to hemangioma, there is no parenchymal mass nor cellular proliferation.

CLASSIFICATION

For many years, vascular anomalies were grouped under the term *angioma*, hampering precise classification and leading to incorrect diagnosis and improper management. For example, the term *hemangioma* has been used both for vascular malformations, often of the venous type (cavernous hemangioma) as well as for vascular tumors (strawberry hemangioma). This nomenclature changed in 1982 with the development of a biologic classification by Mulliken and Glowacki. It divided vascular anomalies into two major categories: vascular tumors (with cellular proliferation; hemangioma being the most common) (see Chap. 126) and vascular malformations (structural anomalies of blood vessels) that are subsequently subdivided, depending on the affected vessel type, into arterial, capillary, lymphatic, or venous malformations (VMs).[3,4] In 1996, this classification was adopted and further developed by the International Society for the Study of Vascular Anomalies (Table 173-1).[5] Vascular malformations mostly affect only one vessel type, yet combined malformations also exist. They are named according to the affected vessel types, (e.g., capillary-venous or veno-lymphatic malformation). In addition to isolated forms, vascular malformations occur in syndromes such as Klippel-Trénaunay (capillary-lymphatico-venous malformation with limb hypertrophy), Maffucci syndrome (multiple enchondromas associated with multiple venous anomalies and high incidence of malignancy)[6] or Parkes Weber syndrome (high-flow vascular malformation of the extremity with soft tissue hypertrophy).[7]

VASCULAR MALFORMATIONS AT A GLANCE

- Worldwide prevalence: Roughly 0.3 percent
- Congenital, diversified but localized and well-demarcated lesions of malformed vessels of various types: Capillary, venous, lymphatic, arteriovenous
- Histologically consist of enlarged, tortuous vessels of various types
- Can be isolated, combined, or part of a syndrome
- Management: Multidisciplinary approach

CLINICAL FINDINGS

Vascular malformations grow proportionately with the patient. Usually they do not regress. Most frequently, they are well demarcated and localized (Fig. 173-1). In rare instances, they can be the stigmata of deep lesions. Vascular malformations are rheologically divided into slow-flow (capillary, lymphatic, venous, and combined) and fast-flow (arterial, arteriovenous, and combined). Doppler ultrasound is the best non-invasive radiologic examination that provides

clues to the differentiation of the various types. Magnetic resonance imaging (MRI) details the extension and precise location of the lesion (Table 173-2).[8]

TREATMENT

Treatment of vascular malformations depends on the affected vessel type, the location of the lesion, and the symptoms. As many lesions are extensive, patients should be aware that a complete cure is often not possible. Treatment is difficult and can have severe complications. Extensive and/or complex lesions should always be managed by a multi-disciplinary team.

CAPILLARY MALFORMATIONS

Epidemiology

Capillary malformation (CM), commonly called *port-wine stain*, is a slow-flow vascular malformation with an incidence of 0.3 percent (Fig. 173-2).[9] Other blanchable pinkish patches, known as *stork bite*, *angel's kiss*, *salmon patch*, or *nevus flammeus neonatorum*, are often confused with CM. They are located on the nape of the neck (81 percent), the eyelids (45 percent), or the glabella (33 percent).[10] When located on the occiput, it is called *unna nevus* (see eFig. 173-2.1 in on-line edition.). These patches have a much higher incidence (42 percent) in white infants than in black infants (31 percent).[11] These lesions disappear spontaneously at around the ages of 1 to 4 years.

CMs are mainly sporadic, although there are well-documented pedigrees showing autosomal dominant inheritance.[12] When inherited, they are usually multiple and part of the CM-AVM phenotype, a newly recognized entity that associates atypical CM with arteriovenous malformation (AVM) (see Arteriovenous Malformations).[13–15] No sex preponderance is noted.

Etiology and Pathogenesis

Etiology of CM is currently unknown. Facial CM is thought to be due to clonal expansion of abnormal cells originating from the neural crest.[16] The identification of the affected gene (RASA1) in CM-AVM (see Arteriovenous Malformations) might help unravel the cause of the more common sporadic CM. Histologically, CM is characterized by dilatation of normal numbers of capillaries of the papillary and upper reticular dermis combined with areas of increased number of normal looking capillaries (see Fig. 173-2). Endothelial cells are flat. Factor VIII, fibronectin, and basement membrane protein are normal but S100 staining shows abnormal innervation.[17,18]

CAPILLARY MALFORMATIONS AT A GLANCE

- Worldwide occurrence: Roughly 0.1 percent to 0.2 percent of the population affected.
- Congenital no-flow malformations of the capillary bed.
- Pinkish-red to purple in color. Tend to darken and thicken with time.
- In most cases, a cosmetic problem.
- Can be part of syndromes, such as Sturge-Weber or Klippel-Trénaunay.
- Pathology: Capillaries that are increased in size and number with abnormal innervation.

Clinical Findings

CUTANEOUS LESIONS (Fig. 173-3; See Fig. 173-2) CM is a red homogenous congenital lesion that is often unilateral, sometimes bilateral, but usually not median. CMs involve skin and subcutis and, sometimes, mucosa. Their color varies from pinkish-red to deep purple with a geographic contour or a dermatomal distribution. Lesions are flat and painless, do not bleed spontaneously, and are never warm on palpation. They can extend throughout the entire body. Fifty percent of CMs are located on the face where they follow the distribution of the trigeminal nerve: ophthalmic branch V1 (front and upper eyelid), maxillary branch V2 (lower eyelid, cheek, and upper lip) (see Fig. 173-3B), or mandibular V3 (lower lip, chin, and mandible). In combination with another vascular malformation, CM can be part of a syndrome, such as Sturge-Weber, phakomatosis pigmento-vascularis, Klippel-

▲ **FIGURE 173-1** Vascular malformations of various vessel types: (**A**) capillary malformation of left lower extremity and genitalia; (**B**) subcutaneous lymphatic malformation invading the cubital nerve; (**C**) extensive venous malformation of right lower extremity causing pain, swelling, and coagulopathy; (**D**) arteriovenous malformation of sole; and (**E**) note nidus of the lesion on arteriography.

Trénaunay, Servelle-Martorell, etc. None of these syndromes is inherited. In rare instance, CM can be the cutaneous hallmark of occult spinal dysraphism, especially if located in the lumbosacral area.[19]

Sturge-Weber Syndrome. Sturge-Weber syndrome (SWS) is a neuro-oculocutaneous syndrome consisting of a CM located on the ophthalmic branch of the trigeminal nerve, a homolateral leptomeningeal capillary-venous malformation, often on the parieto-occipital area, and choroid "angioma" causing glaucoma and, sometimes, buphthalmos and retinal detachment (Fig. 173-4). Calcifications are frequently seen on the choroid plexus, and anomalies of the venous drainage of the encephalon can occur.[20] This malformation can cause epilepsy, leading to neural death, cerebral atrophy, and mental retardation.

Phakomatosis Pigmento-Vascularis.

Klippel-Trénaunay Syndrome. Klippel-Trénaunay syndrome (KTS) is an eponym used for the presence of a capillary-lymphatico-venous malformation located on the extremity with hypertrophy of the affected limb (Fig. 173-5). Venous varicosities on the lateral side of the leg, first described by Servelle, are very common and is specific for this syndrome in 80 percent of cases.[23] It is thought to be due to the persistence of embryologic veins. Valvular incompetence of deep venous system is common. Lower extremities are most commonly affected (95 percent), although upper limb, thorax, abdomen, and genitalia can also be involved. Lymphatic dermal vesicles cause frequent oozing. Lymphedema can be seen and tends to progress with time. Infection is common after trauma or secondary to small ulceration. VM is often seen in the underlying muscles. Hypertrophy of the limb is another sign of this disorder. It is already present at birth and occasionally evolves after puberty. Evolution towards ulceration, infection, bleeding, and thrombosis is common. Protein-losing enteropathy can be seen with abdominal involvement. Pulmonary embolism can sometimes lead to death.

IMAGING STUDIES No imaging studies are mandatory except in some rare situations. If a so-called *CM* is painful, warm,

TABLE 173-2
Clinical Characteristics of Vascular Malformations

	Capillary Malformation	Venous Malformation	Lymphatic Malformation	Arteriovenous Malformation
Skin color	Pinkish-red to purple	Normal–bluish-purple GVM: red (neonates) to dark blue-purple (adult)	Normal–yellowish-purple	Normal–red
Aspect	Flat	Flat–raised	Raised–vesicular	Flat–raised

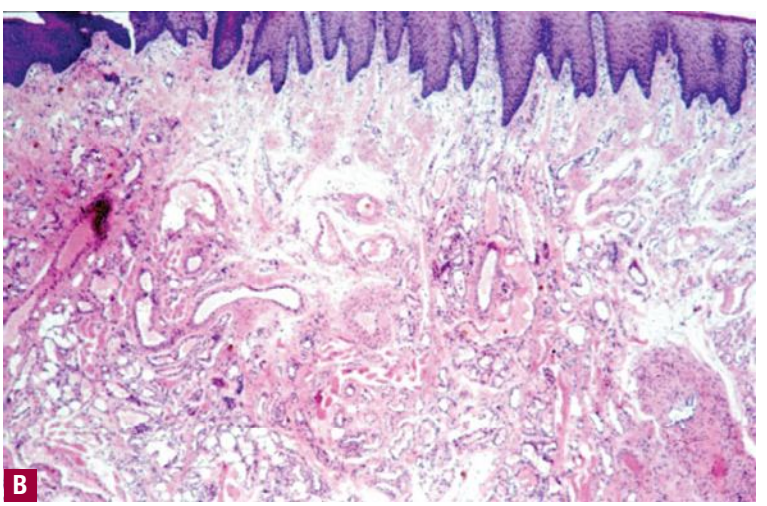
Palpation	Normal	Compressible GVM: Nodular, painful	Firm, non-compressible	Thrill, bruit
Associations	Hypertrophy	Phleboliths, deformation	—	Ulceration, deformation
Radiology	No-flow	Slow-flow	Slow-flow, cyst	Fast-flow
Histology	Dilated capillaries D2–40 negative	Thin-walled venous channels Relative lack of vascular smooth muscle cells GVM: glomus cells D2–40 negative	Cystic lymphatic channels D2–40 positive	Arterialized veins D2–40 negative
Etiology	?	VMCM: TIE-2 GVM: Glomulin	Lymphatic malformation: ? Primary lymphoedema: SOX18, VEGFR-3, FOXC2	Arteriovenous malformation: ? CM-AVM: RASA1
Treatment	Pulsed-dye laser	Sclerotherapy, surgery	Surgery, sclerotherapy	Embolization followed by surgical resection of nidus

CM-AVM = capillary malformation-arteriovenous malformation; FOXC2 = forkhead box C2; GVM = glomuvenous malformations; SOX18 = SRY-Box 18; VEGFR-3 = vascular endothelial growth factor receptor 3; VMCM = cutaneo-mucosal venous malformations.

or spontaneously bleeds, Doppler ultrasound is indicated to exclude the diagnosis of a fast-flow malformation such as an AVM, a Parkes Weber syndrome, or a proliferating hemangioma. CM located in the frontopalpebral area, especially if the inner part of the upper eyelid is involved, can be part of SWS. Therefore, a brain MRI and an ophthalmic examination have to be performed during the first months of life and repeated once a year until puberty, even if normal at younger age.[24] MRI of the spinal cord is needed in presence of a lumbosacral CM. In patients with phakomatosis pigmento-vascularis, ophthalmologic, neurologic, and orthopedic follow-up is mandatory due to the common association of CM with systemic lesion. In patients with KTS, leg length is evaluated radiologically after the age of 2 years and, if abnormal, followed once a year until the end of puberty. Doppler ultrasound evaluation of the venous status is



◀ **FIGURE 173-2** **A.** Extensive capillary malformation of upper extremity. **B.** Histologically, capillary malformation is characterized by dilated capillaries of normal number on the papillary and upper reticular dermis in combination with areas of increased number of normal-looking capillaries (hematoxylin and eosin staining).

▲ **FIGURE 173-3** Several aspects of capillary malformations: (**A**) light red lesions involving half of the body, (**B**) dark red lesions on the face with mucosal involvement and soft tissue hypertrophy, and (**C**) more localized on shoulder and arm.

mandatory to identify varicose veins in KTS. MRI is sometimes useful before management of the lesion.[23]

Differential Diagnosis (Box 173-1)

Complications

The major concern for a patient affected with CM is esthetic due to the visible discoloration. Hypertrophy of soft tissue can occur with time, especially when CM is located on V2 and V3 dermatomes or on the extremities. In rare instances, CM can be the stigmata of underlying anomalies such as lumbar dysraphism when located on the sacrum.

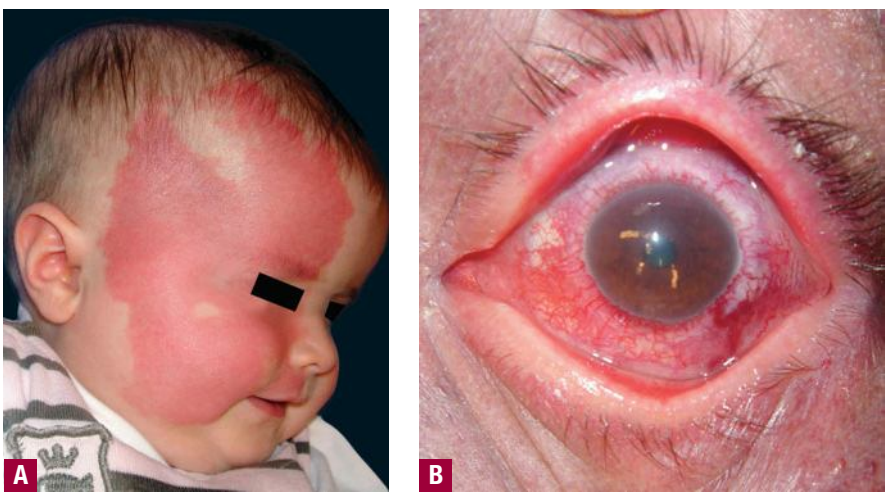
Prognosis and Clinical Course

CM never regresses. It is present at birth and slowly thickens and darkens with time. It often becomes raised and nodular.[31] Pyogenic granuloma can occur with time as well as soft tissue or bony hypertrophy (Fig. 173-6C).[32]

Treatment

Many treatment approaches have been used for CM, such as electrocoagulation, tattooing, dermabrasion, cryosurgery, and cosmetic makeup. Camouflage using Covermark is still effectively used (see eFig 173-6.1 in on-line edition). Laser treatment is the gold standard for most CM. Pulsed-dye laser with its specific wavelength (585 nm) and a short-pulse duration (400 ms) currently gives the best results in infants and children. There are few complications. Multiple sessions (6 to 12) are needed, and general anesthesia is usually necessary as the procedure is painful. Laser treatment is more efficient on the cervico-facial and trunk area than on the extremities. Early treatment during childhood does not reduce the number of laser sessions.[33] The use of a dynamic cooling system to avoid heating the epidermis allows increasing the laser fluences, resulting in optimal lightening of the lesion.[34] Recurrence can occur after cessation of therapy. Laser treatment has no impact on associated hypertrophy. Contour resection is needed mainly to treat complications such as pyogenic granuloma or lip hypertrophy.

Treatment of patients with KTS is conservative and mainly consists of



▲ **FIGURE 173-4** Extensive right facial capillary malformation (**A**) involving the ophthalmic and maxillary branches of the trigeminal nerve in a 6-month-old girl affected with Sturge-Weber syndrome. Choroid capillary-venous malformation (**B**) causing vision loss in a 50-year-old man with Sturge-Weber syndrome.

Box 173-1

Differential Diagnosis

DIFFERENTIAL DIAGNOSIS OF CAPILLARY MALFORMATION

Most Likely

- Faint pinkish median patch
  - Unna nevus
  - Nevus flammeus neonatorum
- Multiple, inherited
  - CM of CM-AVM
- Telangiectatic patch
  - CMTC[25]
  - HHT[26]
  - Essential telangiectasia
  - Unilateral nevoid telangiectasia
- Warm on palpation
  - Proliferating hemangioma
  - AVM
  - AVF
- Ulcerated or painful
  - AVM
  - AVF

Rule Out

- Small, multiple
  - Mastocytosis
  - CM of CM-AVM
  - Tufted angioma[27]

DIFFERENTIAL DIAGNOSIS OF CAPILLARY MALFORMATION (SITE-SPECIFIC)

Most Likely

- Occiput
  - Unna nevus
- Glabella, upper eyelid, nape of neck
  - Stork bite, angel's kiss, salmon patch

Consider

- Extremity
  - CMTC
  - Klippel-Trénaunay syndrome
  - Parkes Weber syndrome
- Faint on trunk
  - M-CM[28]

Rule Out

- Scalp
  - Adams-Oliver syndrome[29]
  - Multiple telangiectasia near canthus
  - Ataxia telangiectasia[30]

AVF = arteriovenous fistula; AVM = arteriovenous malformation; CM = capillary malformation; CM-AVM = capillary malformation-arteriovenous malformation; CMTC = cutis marmorata telangiectatica congenita; HHT = hereditary hemorrhagic telangiectasia; M-CM = macrocephaly cutis marmorata.

elastic stockings to alleviate pain due to venous congestion. Surgical resection of varicose veins cannot be done if the deep venous system is abnormal (aplasia, incompetence). In the presence of leg discrepancy, an early adapted shoe lift is needed to prevent scoliosis, and is followed by epiphysiodesis. If cutaneous bleeding occurs from capillary-lymphatic cutaneous vesicles, neodymium:yttrium-aluminum-garnet laser coagulation, sclerotherapy, or skin grafting can be helpful.

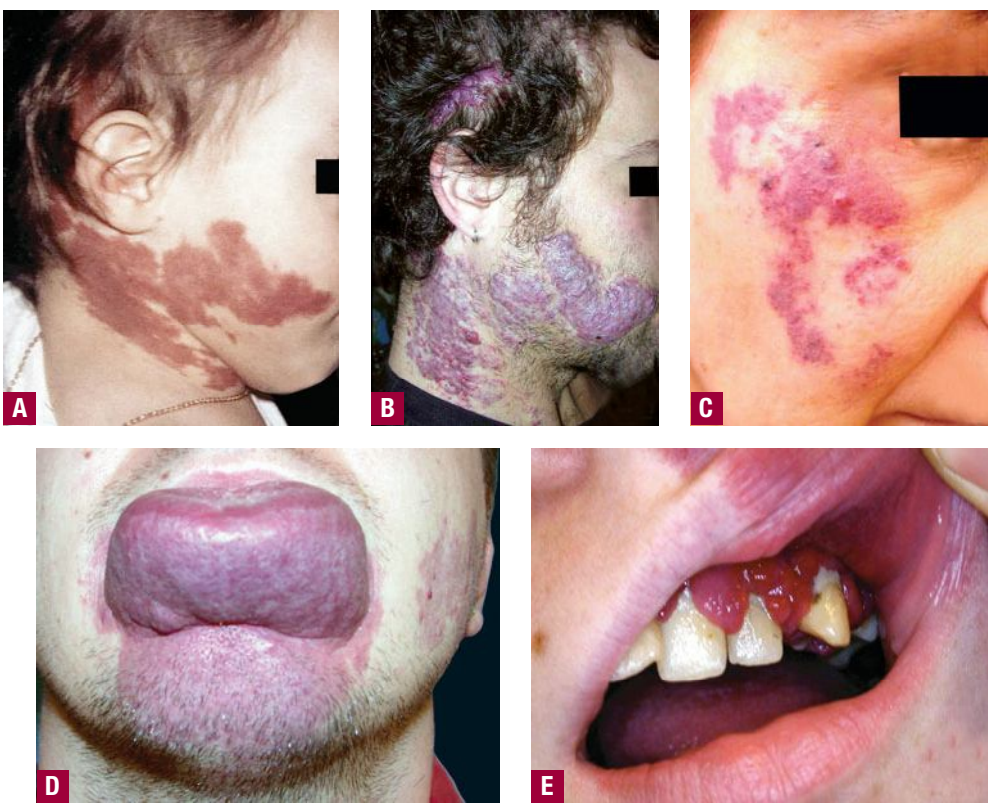
Prevention

In patients with SWS, ophthalmic follow-up, started immediately after birth and continued until the end of puberty, is essential, as visual impairment will depend on the promptness of treatment. Prophylactic anti-epileptic medication to prevent neural cell death has been advocated by some clinicians.[35,36]

VENOUS ANOMALIES

Epidemiology

Venous anomalies are the most common vascular malformations referred to specialized centers.[37] They are mainly sporadic, although 1 percent are inherited cutaneo-mucosal venous malformations



◀ **FIGURE 173-6** Clinical course of capillary malformation: Darkening and thickening with time: (**A**) at age of 6 months, and (**B**) at age of 33 years. **C.** Development of pyogenic granuloma, (**D**) soft tissue, and (**E**) mucosal hypertrophy.

VENOUS MALFORMATIONS AT A GLANCE

- Most common referrals to specialized centers for vascular anomalies. Incidence unknown, but lower than for capillary malformation.
- Congenital slow-flow malformation of the venous bed.
- Bluish in color, localized or extensive, solitary or multifocal.
- Compressible on palpation, presence of phleboliths.
- Histologically consists of ectatic venous-like channels with anomalies in mural cells.
- Mainly sporadic but can be inherited as an autosomal dominant trait.
- Inherited venous anomalies: Cutaneo-mucosal venous malformation (1 percent), glomuvenous malformation (> 5 percent).
- Syndromic venous malformation: Klippel-Trénaunay, blue rubber bleb nevus, Maffucci.

(VMCM), and 5 percent are inherited glomuvenous malformations (GVM). No sex preponderance is reported.[38] Both VMCM and GVM have an age-dependent variation in penetrance, which reaches its maximum by 20 years of age (87 percent for VMCM and 92.7 percent for GVM).[39] Large VMCMs and GVMs are present at birth. However, 17 percent of affected individuals develop new small lesions over time.[38]

VM is a congenital defect on the skin or mucosa, but can involve any structure (subcutis, muscles, bones, and nerves) and any organ, [central nervous system, gastrointestinal (GI) tract]. Fifty percent of VMs are located in the cervicofacial area and 37 percent on the extremities. VMs are mainly isolated, but can be part of complex vascular disorders of unknown etiology, such as KTS, and Maffucci and blue rubber bleb nevus (BRBN) syndromes.

Histology

VMs consist of ectatic vascular channels of venous type with flat endothelium and thin walls due to a variable number of mural smooth muscle cells that stain positive for smooth muscle cell-α-actin.[40] In contrast, GVM is characterized by distended venous channels surrounded by mural glomus cells that are aberrant smooth muscle cells. Glomus cells are round or polygonal instead of elongated like the normal vascular smooth muscle cells.[41] By immunohistochemistry, glomus cells stain positively for smooth muscle cell-α-actin and vimentin, whereas they are negative for desmin, von Willebrand factor and S100 neuronal marker.[42] By in situ hybridization, they are also negative for glomulin.[43]

Pathogenesis

The pathogenesis of sporadic VM is unknown. However, identification of the defective gene for inherited VMCM could help understand the cause of VM.[44]

Clinical Findings (Table 173-3; Fig. 173-7; and see eFig. 173-7.1 in on-line edition)

VMs are usually solitary, but can be multifocal, suggesting an inheritable disorder. Cutaneous VMs are congenital light-to-dark bluish lesions. Deep VM has a normal overlying skin color and is often diagnosed only at puberty or later in life with the onset of pain. Cutaneous VMs are detected early because they are usually clinically visible. Size varies from small spongy blebs to large lesions of several centimeters in diameter. VMs can easily be emptied by compression or by positioning in a nondependent position. Skin temperature is normal. There is no thrill or bruit. Depending on size and location, VMs can cause pain,

TABLE 173-3
Venous Abnormalities

	Venous Malformation	Cutaneo-Mucosal Venous Malformation	Glomuvenous Malformation	Blue Rubber Bleb Nevus	Maffucci Syndrome
Location	50% head and neck	Extremities, mucosa	70% extremities	Especially palms and soles	Extremities
Skin color	Normal–bluish-purple	Bluish	Bluish–red-purple	Bluish–dark blue	Normal–bluish
Aspect	Flat–raised	Raised dome-shaped	Raised, cobblestone, plaque-like, hyperkeratotic	Dome shaped, nipple-like	Exophytic

◀ **FIGURE 173-7** **A.** Venous anomalies: Extensive hemifacial venous malformation (VM) causing soft-tissue hypertrophy and lip deformation in a 6-month-old boy. **B.** Histologically, VM consists of ectatic venous-like channels with anomalies in mural cells (hematoxylin and eosin). **C.** Superficial glomuvenous malformation of the inner thigh. Note the presence of mural glomus cells on histology (hematoxylin and eosin). **D.** Mucosal VM involving the lower lip and the floor of the mouth.

particularly in the morning on awakening, anatomic distortion, and even threaten life because of bleeding, expansion, or obstruction of vital structures. Palpation is not painful unless thrombosis occurs.[38] Local thrombosis is responsible for acute pain that lasts for 10 days and causes phleboliths, which can be identified by palpation or by radiography. VM never cause pulmonary embolism. Facial VM is usually unilateral, causing asymmetry and progressive deformation and possibly dental malalignment (see Fig. 173-7 and eFig. 173-7.1 in on-line edition). Migraine is a common feature if VM is located in the temporal muscle. Oropharyngeal VM can impair speech whereas pharyngeal or laryngeal location will compromise the airway and cause snoring and even sleep apnea. On extremities, VMs often involve muscles and joints (see eFig. 173-7.1). They cause muscle weakness, hypotrophy, and sometimes, hypertrophy, resulting in leg length discrepancy which is less severe than in KTS. Intra-articular bleeding, if the malformation is located in the knee joint, leads to early-onset arthrosis.[47] Genital VM often occurs with limb VM and can be responsible for dyspareunia**.** GI VM is often diagnosed in patients with chronic anemia.

FAMILIAL CUTANEO-MUCOSAL VENOUS MALFORMATIONS

GLOMUVENOUS MALFORMATION (Fig. 173-8) Five percent of patients with venous anomalies seen at multi-disciplinary vascular anomaly centers are GVMs [Online Mendelian Inheritance in Man (OMIM) #138000]. GVM, previously known as *glomangioma* or *(multiple) glomus tumor*, is a vascular malformation of venous type. It should not be confused with solitary glomus tumor, a painful 3- to 6-mm papule commonly located in the nail bed (see Fig. 87-17). Clinically, these lesions resemble VM but can often be distinguished by color, appearance, consistency, and painfulness to palpation.[38] GVM varies from pink to purplish-dark blue in color. They are usually raised, nodular, hyperkeratotic, and multifocal (see Fig. 173-8). They are present at birth and slowly expand during childhood. Plaque-like GVM can be present at birth as a telangiectatic, red, flat lesion, which is only slightly bluish at the periphery. Thus, they mimic capillary-venous malformations. Within months, the lesion will become more raised and purple, like typical GVM.[48] GVMs are mainly located on the extremities (see Fig. 173-8), involve skin and subcutis, but rarely mucosa. In contrast to VM, GVM cannot be completely emptied by compression. They do not lead to intestinal hemorrhage, which distinguishes them from patients with BRBN syndrome (OMIM #112200).[49]

BLUE RUBBER BLEB NEVUS SYNDROME (BEAN SYNDROME) When a patient has both cutaneous and visceral VMs, the diagnosis of BRBN syndrome is most likely. This syndrome is usually sporadic, although some families with autosomal inheritance have been reported. They could be familial VMCM. The cutaneous VMs of BRBN are distinct, characterized by multiple, small (0.1 to 0.5 cm) spongy, and rubbery blebs often located on the palms and soles (Fig. 173-9).[50] Often a patient has one large VM that is present at birth and multiple small lesions disseminated all over the body. More lesions appear with time. The VMs are usually asymptomatic, but, occasionally, they can become tender and painful. GI lesions, commonly located in the small intestine, are sessile

◀ **FIGURE 173-8** Two glomuvenous malformations on the extremity: (**A**) small nodule, (**B**) extensive but superficial with cobblestone appearance, and (**C**) as seen on T2-weighted image.

or polypoid, causing chronic and severe iron-deficiency anemia. In rare instances, BRBN can involve other organs such as lungs, spleen, liver, kidneys, bladder, or even the brain.

FAMILIAL CEREBRAL "CAVERNOUS" MALFORMATION

MAFFUCCI SYNDROME Maffucci syndrome is a rare sporadic disorder that associates venous-type lesions with multiple enchondromas and a high incidence of malignancy (30 percent to 90 percent). There is no gender predilection. Enchondromas that are abnormal intraosseous and subperiosteal cartilaginous overgrowths in the hand, foot, and long bones, usually appear first, leading to an initial diagnosis of Ollier disease.[57] The venous-type lesions are multiple, located more commonly on the hand (89 percent) and foot (61 percent) but can be anywhere (Fig. 173-10). They are bluish exophytic nodules. These venous ectasias are often characterized as hemangioendotheliomas with spindle cells.[6] Skeletal deformation and spontaneous fracture as well as secondary dwarfism are common in patients with Maffucci syndrome.

CEREBRAL DEVELOPMENTAL VENOUS ANOMALY

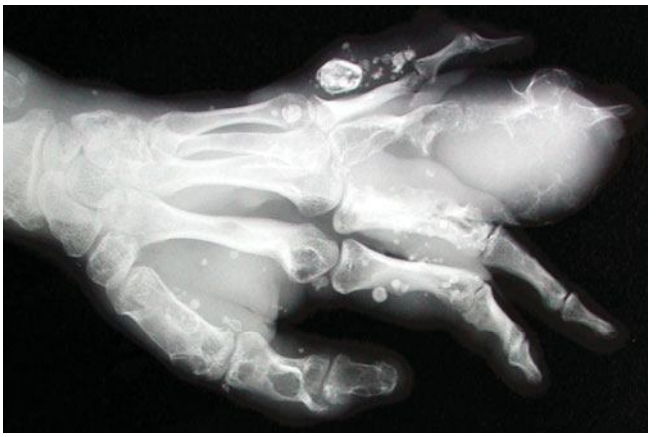
Laboratory Tests

Localized intravascular coagulopathy (LIC) can be associated with VM. It is characterized by elevated D-dimers and split fibrin degradation products, normal-to-low fibrinogen, and normal platelet counts. The phenomenon can decompensate into disseminated intravascular coagulation after, for example, surgery, sclerotherapy, pregnancy, and puberty, resulting in severe bleeding due to consumption of clotting factors.[60,61] This coagulation disorder is different from the Kasabach-Merritt phenomenon seen with kaposiform hemangioendothelioma (see Chap. 126).[62,63]

Imaging Study

Doppler ultrasound is the easiest way to confirm the clinical diagnosis of a VM by demonstrating a slow-flow, ill-defined vascular lesion that is compressible on palpation, in contrast to lymphatic malformation or hemangioma. Presence of phleboliths, easily identified on plain radiography, is the hallmark of VM and, in contrast, never present in GVM (see eFig. 173-10.1 in on-line edition).[64] Computed tomography scan detects skeletal defects that can be seen in about 20 percent of craniofacial VM. MRI with spin-echo T1- and T2-weighted sequences is the gold standard to evaluate extension and exact location of VMs (see eFig. 173-10.1 in on-line edition).[65] Arteriography is normal, as arteries are not affected by the malformation. The VM lesion is seen in late venous phase. Phlebography, always done before sclerotherapy, has limited diagnostic use compared with Doppler and MRI.

▲ **FIGURE 173-9** Hyperkeratotic, small, rubbery blebs characteristic of blue rubber bleb nevus syndrome.



▲ **FIGURE 173-10** Exophytic venous-like lesions of hand associated with multiple enchondromas (as seen on plain radiography) specific of Maffucci syndrome.

Differential Diagnosis (Box 173-2)

Cutaneous VMs are usually diagnosed by clinical examination on the basis of their bluish color and the fact that they are compressible on palpation. However, not all bluish lesions are VMs.

Prognosis and Clinical Course

VMs are present at birth and exhibit progressive ectasia with age. A rapid expansion can be observed after trauma, partial resection, or hormonal modulation at puberty, or during pregnancy or antiovulatory therapy. Deep VMs often become painful at puberty. If not treated, cervicofacial VM can cause chronic respiratory obstructive syndrome.

Treatment

Indications for treatment include esthetic preference, pain, or functional impairment. VMs can be treated conservatively or medically, and more aggressively with either sclerotherapy or surgical resection. VM in an extremity is conservatively managed by a custom-made elastic compressive garment. Aspirin (80 mg/day) can alleviate chronic pain due to local and painful thrombosis. Low-molecular-weight heparin is much more efficient in case of LIC (high D-dimer). The commonly used dosage is 100 anti-Xa/kg/day for adults and 30 anti-Xa/kg/day in children. Reduction of pain and D-dimers are seen within 10 days. The treatment can be continued for several months and is mandatory before any surgery to avoid decompensation into disseminated intravascular coagulopathy during or after surgery. It will also improve sclerotherapy results.

Small cutaneous VMs can be injected, at any site, with a sclerosant, such as 1 percent sodium tetradecylsulfate. For large VMs, fluoroscopic guidance and general anesthesia are mandatory during percutaneous sclerotherapy. Sclerotherapy is potentially dangerous and requires the skills of an experienced interventional radiologist.[66] Several sessions are usually necessary (see eFig. 173-10.2 in on-line edition). For GVM, sclerotherapy is less effective.

Small, well-localized symptomatic VMs can be surgically excised (see eFig. 173-10.3 in on-line edition). The risk of recurrence after subtotal surgery can be reduced by preoperative sclerotherapy.[44] Laser (argon, pulsed-dye, neodymium:yttrium-aluminum-garnet) has been used with variable results.[67] GI VM of BRBN can be managed by endoscopic cauterization, sclerosis, or bowel resection if necessary.[68] GVMs are best treated by surgical resection.[49]

LYMPHATIC MALFORMATIONS

Epidemiology

Lymphatic malformation (LM) is a congenital disorder of unknown incidence. It consists of vesicles or large cysts filled with lymphatic fluid. Macrocystic LM can be diagnosed in utero as early as the first trimester of pregnancy.[69] However, most LMs are diagnosed during infancy,

Box 173-2

Differential Diagnosis

DIFFERENTIAL DIAGNOSIS OF VENOUS MALFORMATION

Most Likely

- Bluish subcutaneous mass, non-compressible
  - Infantile hemangioma
  - Lymphatic malformation
- With multiple enchondromas
  - Maffucci syndrome

Consider

- Hyperkeratotic
  - GVM, if on extremity
  - HCCVM of CCM

Rule Out

- Superficial, collateral normal veins
  - Deep venous insufficiency iatrogenic stenosis or congenital agenesis
  - Bluish nonvascular lesion such as bluish nevus

DIFFERENTIAL DIAGNOSIS OF VENOUS MALFORMATION (SITE-SPECIFIC)

Consider

- Base of the nose
  - Normal prominent veins
- Scalp or forehead
  - Sinus pericranii
- Subungual
  - Solitary glomus tumor
- Cheek
  - Bluish nevus
- Brain
  - Developmental venous anomaly
  - CCM

Rule Out

- Neck; deep mass
  - Thyroglossal duct
  - Bronchogenic cyst

CCM = cerebral cavernous malformation; GVM = glomuvenous malformation; HCCVM = hyperkeratotic cutaneous capillary-venous malformation.

LYMPHATIC MALFORMATIONS AT A GLANCE

- Worldwide occurrence is unknown.
- Congenital sporadic no-flow malformations of the lymphatic vessels.
- Primary lymphedema can be inherited as an autosomal trait.
- Lymphatic malformations consist of micro- or macrocysts filled with lymphatic fluid.
- Infection is the most common complication that can lead to septicemia.
- Histologically consist of dilated lymphatic channels with flat endothelium that stains for D2–40.

before the age of 2 years. Some can manifest only at puberty or during adulthood. Macrocystic LMs are often located on the neck, axilla, chest wall, or groin, whereas microcystic lesions are commonly seen in the face. LMs occur sporadically in contrast to primary lymphoedema that can be inherited as an autosomal dominant trait in up to 20 percent of cases. Rare families with recessive inheritance have also been identified.[70] Primary lymphoedema is divided into congenital (present at or soon after birth) (Milroy disease, OMIM #153100) and late onset (present at puberty) (Meige disease, OMIM #153200). It can be isolated or part of a syndrome, such as Turner and Noonan syndromes.[71]

Etiology and Pathogenesis

LMs are errors in morphogenesis of the lymphatic vessels. The etiology is unknown. In contrast, several genes have been identified that lead to or cause lymphoedema. Milroy disease is caused by a mutation that leads to loss of phosphorylation of vascular endothelial growth factor receptor 3 (VEGFR-3),[72,73] whereas lymphoedema distichiasis is caused by loss of function mutations in the FOXC2 transcription factor. Hypotrichosis-lymphoedema-telangiectasia, which has an autosomal dominant or recessive pattern of inheritance, is caused by mutations in *SOX18*.[70]

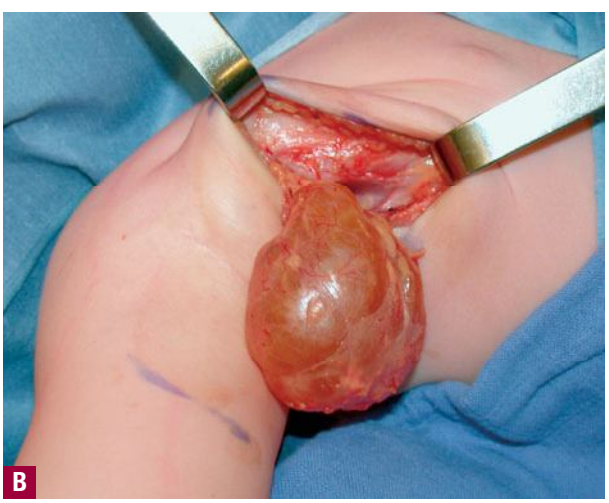
Histologically, LMs are characterized by dilated, flat, endothelium-lined channels of variable wall thickness. No blood cells are seen in these spaces, except after intracystic bleeding (Fig. 173-11) or in the presence of a combined lymphatico-venous malformation. Macrocystic LM shows single or multiple lymphatic cysts surrounded by thick fibrous membrane. These cysts do not communicate with each other. Endothelial cells express specific lymphatic markers, such as podoplanin, D2–40, VEGFR-3.[74] Lymphoedema is characterized by abnormalities in collecting lymphatic vessels in the affected limb (VEGFR-3 and FOXC2 patients) and extensive dermal fibrosis.

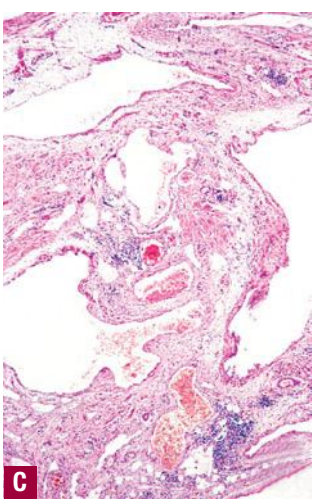
Clinical Findings

LMs are composed of microcysts (previously *lymphangioma circumscriptum*; Fig. 173-12) and/or macrocysts (larger than 1-cm diameter; previously known as "cystic hygroma") that grow proportionally with the child. They are filled with clear or serosanguineous fluid (see Fig. 173-12). Macrocystic LM manifests as a soft, multi-lobulated, well-defined mass, whereas microcystic LMs are ill-defined and often invade adjacent structures. Skin can be normal in color or, due to intracystic bleeding, have a bluish discoloration (see Fig. 173-12.1 in on-line edition). Dermal LMs can manifest as small millimeter-sized vesicles, clear (see Fig. 173-12 and eFig. 173-12.1 in on-line edition), or dark red (if intracystic bleeding) that can bleed and become purple and nodular (see Fig. 173-11A).

Facial asymmetry, especially of the mandible, is commonly associated with microcystic LM (see eFig. 173-12.1 in on-line edition). Intraorbital LM is responsible for ocular dystopia and exophthalmia as well as orbital enlargement. LM on the tongue impairs speech and produces oozing and halitosis. Airway obstruction is common when affecting the base of the tongue or the cervicofacial area.[75] Extension into the pleura can occur and cause chylothorax. Abdominal lesions are associated with chylous ascites. Extensive limb LM can cause elephantiasis.

ANGIOKERATOMA CIRCUMSCRIPTUM Angiokeratoma circumscriptum, or capillary-LM, is a combined, well-demarcated lesion often located on the extremity.





▲ **FIGURE 173-11** **A.** Microcystic, dermal lymphatic malformation (LM) consisting of clear and dark red vesicles. **B.** Intraoperative view of a macrocystic LM of the axilla showing a well-delineated cyst filled with clear lymph fluid. **C.** Histologically, LM consists of dilated lymphatic channels with flat endothelium (hematoxylin and eosin).

▲ **FIGURE 173-12** Lymphatic malformation. Frog-spawn–like confluent grouped "vesicles" filled with a serosanguineous fluid.

This lesion is pink to bluish-red in color, slightly raised, and usually hyperkeratotic (Fig. 173-13). Dilated capillaries and lymphatic vessels located on the superficial dermis and associated with hyperkeratosis can be seen histologically. Clinically, angiokeratoma circumscriptum (see Fig. 173-13), angiokeratoma of Mibelli (circumscribed, dark-red, and hyperkeratotic plaques on the distal extremities; see eFig. 173-13.1 in on-line edition), and angiokeratoma of Fordyce (very common hyperkeratotic, blue-black papules on the scrotum of elderly males; see eFig. 173-13.2 in on-line edition) are recognized (see Table 136-2). They have to be differentiated from the angiokeratomas of Fabry disease (see Chap. 136).

GORHAM-STOUT SYNDROME

LYMPHEDEMA Lymphedema is characterized by swelling of the affected body part, usually the lower extremity, and is caused by accumulation of lymphatic fluid into the extracellular space due to intrinsic lymphatic dysfunction (Fig. 173-14).

Congenital Lymphedema. Congenital lymphedema, or Milroy disease, is suspected in the presence of swelling of the dorsum of the feet with familial history of lymphedema. Lymphedema is present at birth, often bilateral, and affects the lower limbs below the knees.[77] Rare occurrence of pleural effusion and chylous ascites has been observed.[78] Other features can be associated with congenital lymphedema, such as hydrocele (37 percent of males), prominent veins (23 percent), upslanting toenails (14 percent), papillomatosis (10 percent), or urethral abnormalities in males (4 percent). Cellulitis is a common complication affecting 20 percent of cases.[77]

Meige Disease. Meige disease, or pubertal-onset lymphedema, represents 80 percent of primary lymphedema. It is usually isolated and more common in women. In two specific forms, the causative genetic alterations have been identified.

Lymphedema-Distichiasis Syndrome.

Hypotrichosis-Lymphedema-Telangiectasia Syndrome.

Turner Syndrome.

Lymphedema with Yellow Nails.

Imaging Studies

Doppler ultrasound shows anechoic or hypoechoic and homogeneous cysts that are not compressible. On MRI, macrocystic LMs are hypointense on T1- and hyperintense on T2-weighted sequences. In the presence of a large cyst, fluid level is seen, showing intracystic bleeding. Microcystic LM shows an ill-defined mass with abnormal enhancement.[65]

Laboratory Tests

For pure LM, no diagnostic test exists. In extensive, combined, lymphaticovenous malformation, LIC, as in VM, can be seen. Therefore, blood tests, including D-dimer levels, fibrinogen, and platelet counts, should be done for each patient.

Differential Diagnosis (Box 173-3)

Complications

LM can suddenly enlarge in response to fever, cough, or viral or bacterial infection or to intralesional bleeding (see eFig. 173-14.1 in on-line edition). Recurrent cellulitis is the major complication, as it can evolve into septicemia if not promptly treated. Local redness and warmth will appear, and the lesion will become painful. Visceral LM can cause protein-loosing enteropathy and hypoalbuminemia.

Prognosis and Clinical Course

LM usually grows with the child and often causes asymmetry with bony overgrowth. Increase in size can be seen during infection or intralesional bleeding. Episodic reports of spontaneous involution exist. As the regression is usually seen after local infection, it could be that this evolution is due to post-inflammatory sclerosis.

Treatment

Intralesional bacterial infection as well as early cellulitis should be managed with prolonged antibiotics first given in-

▲ **FIGURE 173-13** Capillary-lymphatic malformation (angiokeratoma circumscriptum) on the lower extremity, causing oozing. It is purple-red in color and slightly raised, with hyperkeratosis.

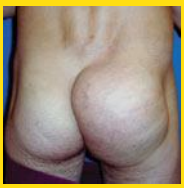
▲ **FIGURE 173-14** Various types of congenital primary lymphedema characterized by lymphedema of lower limb, below the knees (**A**), with papillomatosis (**B**), and with upslanting toenails (**C**), that can evolve into elephantiasis (**D**).

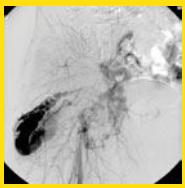
travenously. Pain medication and anti-inflammatory drugs may be required. Immune-modifying medications, such as interferon and corticosteroids, are not effective. Neodymium:yttrium-aluminum-garnet laser or carbon dioxide laser photocoagulation has been used to treat dermal LM vesicles that cause oozing (see eFig. 173-14.2 in on-line edition). Macrocystic LM is treated with fluid aspiration followed by percutaneous, intralesional injection of sclerosing agents performed by an interventional radiologist. Several sclerosing agents have been used, such as sodium tetradecyl sulfate, pure ethanol, OK432 (extract from a killed strain of group A *Streptococcus pyogenes*: Picibanil), doxycycline, or bleomycin. Side effects include fever, erythema, and edema.[83,84]

Surgical resection is another alternative for LM.[85] Results depend on the anatomical site and extension of the lesion (see eFig. 173-14.3 in on-line edition). Recurrence is frequent because it is difficult to differentiate LM from adjacent normal tissue. This leads to either incomplete resection or unnecessary sacrifice of normal structures. One should always try to treat completely one region at a time.[86]

Lymphedema is best treated with elastic stocking, massage, and pneumatic compression devices. Family and patient education regarding the etiology and treatment is necessary, as lymphedema can be inherited.

ARTERIOVENOUS MALFORMATIONS AT A GLANCE





- Worldwide occurrence: Rare, but exact frequency unknown
- Congenital fast-flow malformations that can be hidden until puberty
- Histologically consist of direct communications between arteries and veins
- Usually sporadic, but can have a genetic predisposition as in capillary malformation-arteriovenous malformation or hereditary hemorrhagic telangiectasia
- Can be part of syndromes such as Parkes Weber or PTEN hamartoma tumor syndrome
- Most difficult vascular malformations to treat; need a multi-disciplinary approach

ARTERIOVENOUS MALFORMATIONS

Fast-flow cutaneous vascular malformations are mainly AVMs and rarely arteriovenous fistula (AVF). AVF is usually traumatic. AVM is characterized by the presence of a "nidus," the epicenter of the lesion that is composed of direct communications between multiple feeding arteries and draining veins without intervening normal capillary bed. Histologically, AVM consists of distorted arter-

▲ **FIGURE 173-15** Extensive arteriovenous malformation deforming the right buttock (**A**). Arteriography showing the nidus of the malformation (**B**). Histology shows a direct connection between artery and vein, with thrombotic material secondary to the embolization procedure (**C**).

ies and veins with thickened muscle walls due to arteriovenous shunting and fibrosis (Fig. 173-15).

Epidemiology

The incidence of AVM is unknown. It is a rare, usually sporadic, fast-flow vascular malformation. It can affect any tissue and any organ. Seventy percent of AVMs are located on the head and neck area. AVMs are present at birth but often manifest later in life during puberty or after trauma. They never regress.

Etiology and Pathogenesis

The etiology of AVM is unknown. An underlying predisposing genetic defect exists for these fast-flow vascular malformations when part of CM-AVM (OMIM #608354), HHT (OMIM #187300), or PHTS (OMIM #153480 and #158350). The newly recognized CM-AVM entity associates multiple, small, atypical CMs with fast-flow lesions (AVM or AVF). CM-AVM is inherited as an autosomal dominant disorder with a penetrance of about 95 percent.[13–15] It is caused by loss-of-function mutations in the *RASA1* gene.[13] The high intrafamilial phenotypic variability could be explained by the necessity of a second hit, a somatic mutation, to occur. Prevalence of CM-AVM is unknown.

TABLE 173-4
Schobinger Classification of Arteriovenous Malformation

Stage 1	Local mass, blush or red stain Doppler ultrasound: Increased vascularization
Stage 2	+ Prominent draining veins, pulsation, thrill Doppler ultrasound: Arteriovenous shunting
Stage 3	+ Dystrophic changes
Stage 4	+ Congestive heart failure

Clinical Findings

During childhood, AVM is often mistaken for a CM or a hemangioma, as, at birth, AVM usually manifests as a faint, ill-defined macular red stain. However palpation reveals its fast-flow component as it is warm. About one-third of AVMs are present at birth, another one-third appear during childhood or at puberty, and the rest in adulthood. Puberty and trauma usually trigger the growth of an AVM. AVMs are staged using the Schobinger classification (Table 173-4). AVMs manifest as cutaneous, red-to-purple warm masses with a thrill, a bruit, or a pulsation of increased amplitude. They worsen with time, evolving from stage I to III or even IV, never regressing spontaneously (Fig. 173-16).

CAPILLARY MALFORMATION-ARTERIOVENOUS MALFORMATION CM-AVM manifests as multiple atypical CM associated with fast-flow lesions in 18 pecent to 20 percent of patients: AVM, AVF, or Parkes Weber syndrome. The expressivity is highly variable within families, from small, asymptomatic CMs to life-threatening AVM. In contrast to sporadic CM, CMs in CM-AVM are often multiple and randomly distributed. Their size is variable: from a few millimeters to several centimeters in diameter. They are round-to-oval, pink, red or brown, and sometimes with a narrow pale halo (Fig. 173-17). The lesions are well circum-

▲ **FIGURE 173-16** Stage 2 arteriovenous malformation (AVM) (**A**) evolving into stage 3 AVM (**B**).

◀ **FIGURE 173-17** Small atypical capillary malformations of capillary malformation-arteriovenous malformation (**A–D**). Note the pale halo (**D**).

scribed and blanch on pressure with a glass. Some of them are present at birth, whereas others appear later. They grow with the child and are asymptomatic. Fast-flow lesions (AVM or AVF) are either cutaneous, subcutaneous, with or without intramuscular and intraosseous involvement, or intracerebral.[13–15] About 10 percent to 15 percent of the CM-AVM individuals have Parkes Weber syndrome either on the lower (two-thirds) or the upper extremity (one-third). The AVMs can be asymptomatic but complications occur, depending on their location and size.

HEREDITARY HEMORRHAGIC TELANGIECTASIA Hereditary hemorrhagic telangiectasia (HHT) manifests as multiple cutaneous and mucosal telangiectasias that are associated with visceral, pulmonary, and cerebral fast-flow lesions. Epistaxis is a common clinical sign.[26]

PTEN HAMARTOMA TUMOR SYNDROME PTEN hamartoma tumor syndrome (PHTS) regroups patients with Bannayan-Riley-Ruvalcaba syndrome (BRRS) and Cowden syndrome, as 60 percent and 81 percent of them, respectively, have a mutation in the PTEN gene.[59] These patients typically have macrocephaly, penile freckling, multiple developmental venous anomalies in the brain, fast-flow vascular malformations (54 percent) and an increased risk of malignancy. The vascular malformations are often multifocal (57 percent) and musculoskeletal, and associated with ectopic fat deposition and disruption of the normal tissular architecture.[59]

PARKES WEBER SYNDROME Parkes Weber syndrome (OMIM #608355) was first described by F. Parkes Weber in 1918. This condition is characterized by a large, congenital, cutaneous, vascular stain on an extremity in association with soft tissue and skeletal hypertrophy of the affected limb, and with underlying multiple arteriovenous microfistulas.[7] The affected extremity is longer and larger than the contralateral one. The signs and symptoms worsen with age. When young, these patients can develop congestive heart failure.

BONNET-DECHAUME-BLANC SYNDROME

COBB SYNDROME

Imaging Studies

Ultrasonography and color Doppler show no mass, but an aggregation of high-velocity arterial and pulsatile venous flow with low resistance. Vessels are tortuous. On extremities, noninvasive follow-up is performed by comparing the arterial outflow of the affected limb with the unaffected one. Computed tomography-scan has been replaced by MRI, which better shows the extent of AVM and allows differentiation from hemangioma and VM. Flow voids, corresponding to fast-flow vessels, are pathognomonic of AVM. Arteriography is needed before any treatment to determine feeding arteries and the nidus (see Fig. 173-15).

Differential Diagnosis (Box 173-4)

Prognosis and Clinical Course

AVMs tend to worsen with time, causing local destruction and/or life-threatening bleeding. Puberty and trauma trigger growth. Bony hypertrophy is a common feature that causes common facial asymmetry. AVM of an extremity commonly causes peripheral ischemia due to blood flow steel phenomenon. Cardiac failure is rare (Schobinger stage IV), especially during childhood. Improper management due to misdiagnosis, or ligation of feeding arteries or partial resection of the nidus, can have dramatic consequences and expansion

of the AVM (see Fig. 173-16). The CMs in CM-AVM are harmless, and usually of only cosmetic importance.

Treatment

This fast-flow vascular malformation is the most complex and difficult vascular anomaly to treat. Its management is multi-disciplinary. AVM should be followed by periodic evaluation. In a limb AVM or multiple AVFs, elastic stockings can stabilize the lesion and protect the skin. The goal of cure of an AVM is based on obliteration (by embolization) and complete removal of the nidus or the epicenter. Early intervention for "quiescent AVM" (stage 1) is debatable but should be considered only if complete resection is possible. In contrast to AVF, superselective arterial embolization alone is only palliative and is done only in unresectable complicated AVM. The embolized particles need to reach the epicenter of the lesion to avoid refilling of the nidus through new collaterals.[92] Direct puncture of the nidus is another possibility in patients with previous arterial ligation or embolization.[93] Surgical resection is usually done only after embolization to minimize perioperative bleeding.[94] AVM needs to be widely excised. Reconstruction often necessitates microsurgical free flap transfer.[95] At least 5-year follow-up by annual Doppler ultrasound and/or MRI is mandatory after any treatment. For patients with Parkes Weber syndrome, the treatment should be as conservative as possible (e.g., elastic stockings). Epiphysiodesis may be necessary to control leg length discrepancy. However, this procedure can sometimes aggravate the AVM.[7]

CHAPTER 174

Cutaneous Changes in Peripheral Vascular Arterial Disease

Mandeep Dhadly

Robert T. Eberhardt

OBSTRUCTIVE PERIPHERAL ARTERIAL DISEASE

Epidemiology

Although atherosclerotic obstructive peripheral arterial disease (PAD) has a prevalence of only 3 percent in patients age 40 to 59 years old, this rises to 15 percent in the age group older than 65 years. Nationwide, this translates into approximately 9 million cases in the United States in 2005, and this number is expected to increase along with the aging demographics of our population.[1,2] PAD is often unrecognized clinically and almost one-half of all patients are asymptomatic. Gender predisposition shows preponderance in males, although the incidence in females rises rapidly after menopause. Anatomically, superficial femoral artery disease predominates, with development of symptoms typically in the seventh decade. Interestingly, symptoms from aorto-iliac disease usually present a decade earlier.

Etiology and Pathogenesis

Atherosclerotic risk factors are similar to those identified for coronary artery disease. Diabetes mellitus and smoking are the most significant and are associated with a fourfold and doubling of relative risk, respectively. Patients with diabetes mellitus develop the disease at an earlier age than non-diabetics and have more severe and progressive disease. The anatomic distribution of obstruction differs from non-diabetics with less aorto-iliac involvement and more extensive disease of the runoff vessels below the knees; however, superficial femoral artery disease is similar in both populations. Approximately 50 percent of patients have hyperlipidemia. PAD is also more commonly encountered in patients with hypertension.

The pathologic findings in atherosclerosis occur in large- and medium-sized arteries, and are morphologically diverse, with focal accumulation of lipids and lipoproteins, mucopolysaccharides and collagen, smooth muscle cells and macrophages, and calcium deposits in variable quantities. Localized areas of intimal thickening secondary to smooth muscle cell proliferation and lipid-laden macrophages are seen in early stages with disruption of the internal elastic lamina. The media is often atrophic with thin strands of smooth muscle, lipid pools, collagen tissue, and calcium deposits. Enlarging plaques encroach on the lumen despite dilation of the artery, and the plaques may ulcerate. Hemorrhages occur in the arterial wall. Thrombi may form and occlude the narrowed arterial lumen.

The etiology of atherosclerosis is complex and multifactorial, but progressive buildup of plaque narrows the vessel lumen, and complete occlusion may develop acutely secondary to thrombosis. Because disease progression is usually over an extended time period, collateral blood vessels have time to develop and are usually robust. Tissue perfusion to the affected limb is often adequate at rest, but the blood pressure distal to the occlusions decreased secondary to high resistance and limited flow through collateral vessels. Dermatologic changes imply severe compromise of tissue perfusion, often secondary to tandem high-grade stenoses or occlusions present at multiple levels in the arterial tree.

Clinical Findings (Fig. 174-1)

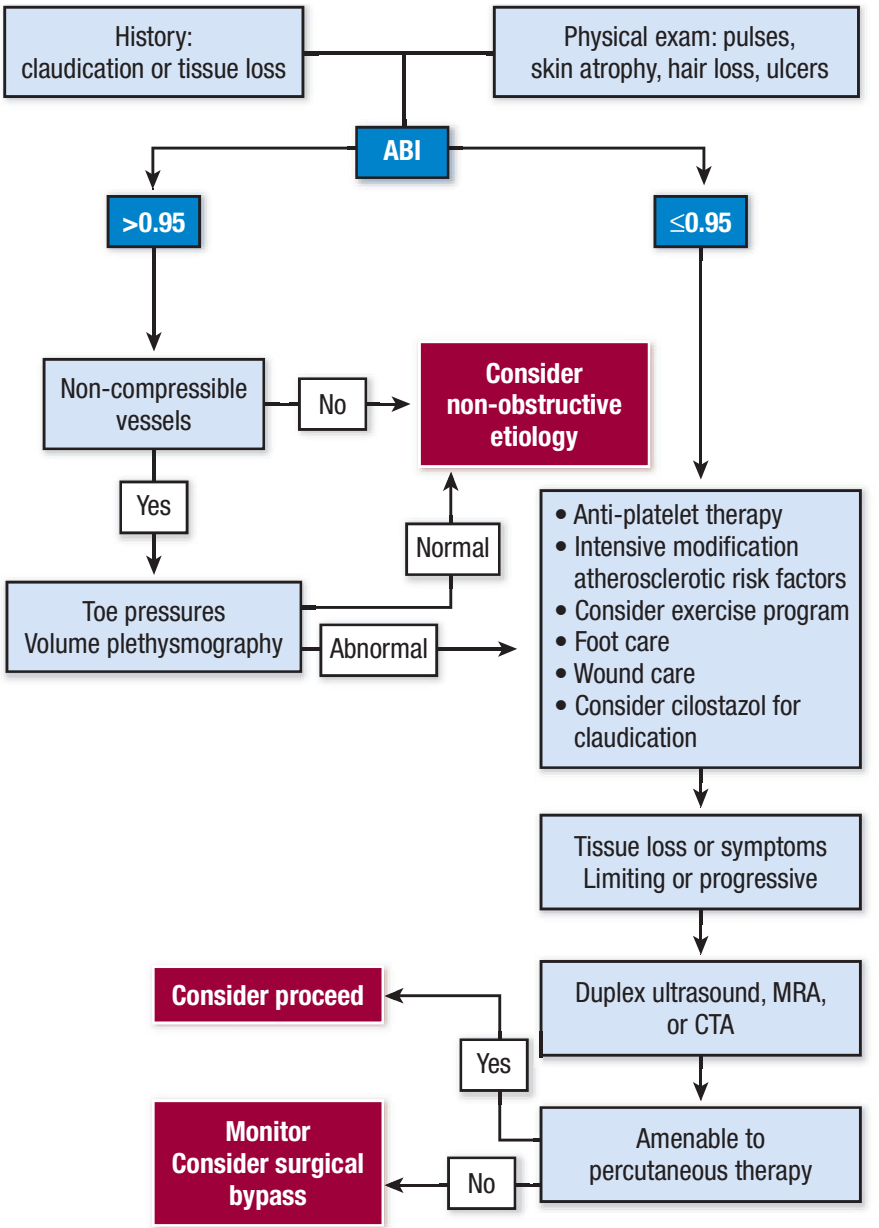
HISTORY The classical symptom of intermittent claudication is usually described as pain, fatigue, or tiredness in the muscles distal to the diseased vascular segment on walking. The discomfort tends to be highly reproducible and precipitated by the same level of exertion. Resolution within several minutes of rest is an expected finding. Patients with inadequate collateral circulation may complain of cold extremities, hyperesthesia, rest pain, discolored toes, or skin breakdown. Rest pain typically affects the foot and may interfere with sleep or necessitate sleeping with the leg in a dependent position. Peripheral edema may then occur.

Acute limb ischemia secondary to vessel thrombosis or embolism presents more dramatically with severe pain, usually persistent at rest, pallor, pulselessness, paresthesias, and paralysis (the five Ps). Poikilothermia (a cold extremity) may be added to this pentad of clinical findings (Box 174-1). The presence of neurologic symptoms indicates severe ischemia and need for emergent evaluation.

CUTANEOUS FINDINGS The cutaneous findings in PAD will vary depending on the severity of arterial obstruction and tissue ischemia (Table 174-1). Limbs in patients with intermittent claudication may appear normal although associated clinical findings include hair loss, coldness, and cyanosis, or thickened and malformed toe nails. In patients with severe ischemia, the skin is apt to be atrophic, dry, and shiny. In patients with rest pain, the foot is usually bright red and cold in dependency. Ulcerations most often start at the tips of the toes or on the heel of the foot and are extremely painful except when diabetic neuropathy is also present (Fig. 174-2). Ulcers occasionally start on the lower calves or lateral aspect of the heel. They frequently demonstrate irregular borders and a pale base. The heels may show cracks in the skin with nu-

OBSTRUCTIVE PERIPHERAL ARTERIAL DISEASE AT A GLANCE

- Most commonly due to atherosclerosis of the vessels supplying the lower extremity
- Affects 15 percent of the U.S. adult population over the age of 65 years
- Stenosis or obstruction of the large arteries to the lower extremities leading to supply demand mismatch, initially with exertion but may progress to occur at rest
- Intermittent claudication with exertional muscle pain or fatigue, critical limb ischemia with rest pain or tissue compromise, and acute limb ischemia
- Cutaneous findings from hypoperfusion ranging from dry skin, hair loss, and malformed toenails to ulceration and gangrene



▲ **FIGURE 174-1** Approach to patient algorithm for suspected peripheral arterial obstructive disease. ABI = ankle-brachial index; CTA = computed tomographic angiography; MRA = magnetic resonance angiography.

merous fissures. When gangrene occurs, usually one or more toes become black, dry, and mummified (Fig. 174-3). Superimposed infection is a major concern, and important associated signs include purulent discharge or decay (wet gangrene) or surrounding tissue erythema and swelling.

Box 174-1

Acute Limb Ischemia: Six Ps

- Pain
- Pallor
- Pulselessness
- Paresthesia
- Paralysis
- Poikilothermia

RELATED PHYSICAL FINDINGS The hallmark characteristic is decreased or absent pulses distal to the stenotic arterial segment, and there may be bruits on auscultation over the diseased segment of vessel secondary to turbulent flow. The collateral circulation to limbs affected by PAD can be evaluated by simple bedside exam. With the patient supine, elevation of the limb at a 45° angle for 2 minutes should not produce pallor. Collateral circulation is deemed inadequate if the toes and feet become pale. The patient then assumes a sitting position with the legs dependent and the times for filling of the foot veins and flushing of the feet measured. The veins should fill within 20 seconds and the feet flush immediately in a warm environment. When these times exceed 30 seconds, the collateral circulation is deemed inadequate, and the patient must be observed frequently for the development of rest pain, ulcers, or gangrene. Venous filling times are of limited value when varicose veins co-exist.

- Brittle toenails
- Absence of sweating
- Ulceration
- Gangrene
- Tenderness
- Regional edema

Special Tests

A simple objective test comparing systolic blood pressure in the arms and ankles is sufficient to document the severity of arterial obstruction. The ankle systolic pressure in the supine position should be equal to or greater than the brachial artery systolic pressure. An ankle-to-arm systolic pressure ratio is calculated (ankle-brachial index, or ABI); values greater than 0.95 are considered normal, whereas those less than 0.4 are indicative of severe disease. This information is of prognostic use for determination of wound healing or the need for revascularization. One important caveat to note is that occasional patients with heavily calcified or "non-compressible" vessels, most commonly diabetics, may have falsely elevated ABIs despite the presence of significant PAD. Under this circumstance, alternate tests, including toe pressures (as smaller vessels are rarely affected) or segmental volume plethysmography, are helpful. Duplex ultrasound scanning can be time-consuming, but further helps to define physiology. Magnetic resonance imaging (MRI) or computed tomography angiographies are competitive technologies used to demonstrate precise anatomic location and extent of disease in the arteries but supply limited hemodynamic information. MRI is usually preferred because of

lack of ionizing radiation or need for iodine-based contrast dye, but may not be tolerated by claustrophobic individuals. Conventional catheter-based arteriography is usually reserved for definitive evaluation in patients about to undergo vascular surgery or as a necessary component of percutaneous angioplasty or stenting procedures (Fig. 174-4).

Differential Diagnosis

The diagnosis of PAD can usually be made by the typical history of intermittent claudication and palpation for diminished or absent pulses in the limbs. The ABI is usually diminished, although occasional patients may have normal values at rest. When the diagnosis remains in doubt, a helpful provocative maneuver to increase blood flow is to exercise the patient. Post-exercise blood flow may be limited by the arterial obstructive disease, and repeat ABI will then be diminished. The differential diagnosis of PAD includes both local factors and systemic disorders (Box 174-2). Arterial obstructive disease is just one of several potential etiologies for the development of a foot ulcer (Box 174-3). In some patients with diabetes mellitus or other disease resulting in neuropathy, ulcers may develop on the heel, toes, or anterior calf in the presence of normal pulses. These painless (neurotropic) ulcers are due to repetitive trauma not noticed by the patient because of the peripheral neuropathy. Surrounding callus formation is a typical finding.

Thromboangiitis obliterans also causes intermittent claudication, ulcers, and gangrene. It occurs in a younger age group (onset of symptoms before age 45 years old) and is often associated with superficial thrombophlebitis and vasospasm. In contrast to PAD, it affects medium and smaller arteries and the upper extremities more commonly.

Occlusive vascular disease confined to focal anatomic locations in young patients with minimal traditional risk fac-

Box 174-2

Differential Diagnosis of Obstructive Peripheral Arterial Disease

LOCAL FACTORS
- Trauma (including iatrogenic)
- Arterial dissection
- Cystic adventitial disease
- Thrombosed popliteal artery aneurysm
- Arterial entrapment syndromes
- Extrinsic compression

SYSTEMIC DISEASE
- Primary thrombotic disorder (thrombophilia)
- Embolism
- Thromboangiitis obliterans
- Fibromuscular dysplasia
- Vasculitic disorders (particularly giant cell arteritis or Takayasu arteritis)

tors for atherosclerosis should raise suspicion for alternative etiologies. For example, popliteal artery occlusion may occur secondary to entrapment by calf muscles or cystic adventitial disease. In the latter condition, adventitial cysts of unclear etiology compress the vessel lumen, most commonly in the popliteal artery (85 percent) or rarely, in the external iliac or femoral arteries, presenting as intermittent claudication. Surgical excision of the cysts usually alleviates symptoms although, in the event of complete vessel occlusion, an interposition graft may be necessary.

Neurogenic claudication (pseudoclaudication) is often a difficult diagnosis to distinguish and is due to compression or intermittent ischemia of the lower spinal cord or cauda equina with exercise. Etiologic factors are prolapsed intervertebral discs, congenital stenosis, or hypertrophic bony ridging of the spinal canal. In contrast to PAD, leg pain may occur in the erect position without exercise and be affected by changes in posture, neurologic signs may be present before or after exercise, and peripheral pulses are normal. Dilemmas in diagnosis and management can occur when both conditions co-exist. MRI or computed tomography scan of the spine is used to confirm the diagnosis.

Box 174-3

Differential Diagnosis of Foot Ulcers
- Obstructive peripheral arterial disease
- Microvascular disease
- Chronic venous insufficiency
- Neuropathic (particularly diabetic)
- Infection (diabetes or fungal)
- Trauma

Box 174-4

Treatment of Obstructive Peripheral Arterial Disease

	SYMPTOM RELIEF	RISK REDUCTION
First line	Exercise regimen Cilostazol (Pletal)	Smoking cessation Statin therapy (target low-density lipoprotein < 100 mg/dL) Aspirin Glycemic control Antihypertensive therapy
Second line	Pentoxifylline (Trental) Percutaneous revascularization (angioplasty, stent, atherectomy, cryotherapy) Surgical revascularization (endarterectomy or bypass)	Other lipid therapy Clopidogrel (Plavix)

Complications

The major direct complications of PAD relate to limb loss from progressive severe ischemia or superimposed infection. In patients with rest pain or tissue loss, the risk of infection is high and wound healing slow or absent. Under these circumstances, the need for revascularization is more urgent to avoid the need for amputation. Superimposed infection needs to be aggressively treated with antibiotics, wound débridement, and local foot care and, if rapidly progressive, presents a medical emergency.

Prognosis and Clinical Course

Peripheral vascular outcomes in patients with intermittent claudication as a consequence of PAD tend to be relatively benign, with studies showing that 60 percent to 90 percent of such patients remained stable over a period of 5 to 9 years. Occasional patients show spontaneous improvement in symptoms, most likely secondary to enhanced collateral blood flow, although plaque regression is possible. Patients with diabetes mellitus, however, tend to have progressive disease, and their amputation rate is fourfold greater than for patients without diabetes. In patients with diabetic neuropathy, trauma to the limbs must be avoided, and special shoes may be required. Ongoing smokers also have greater amputation and vascular graft occlusion rates than nonsmokers.

In contrast with the limb-related outcomes, because patients with PAD often have advanced atherosclerosis present in multiple vascular beds, the risk of associated cardiovascular morbidity and mortality is high.[1,2] The 5-year mortality in patients with intermittent claudication is 30 percent, with death largely attributed to cardiovascular causes. In addition, another 20 percent of patients will incur a nonfatal myocardial infarction or stroke.

Treatment

For patients with intermittent claudication, an exercise program is the treatment of choice (Box 174-4).[2] Patients are instructed to exercise to the threshold of tolerable pain, briefly rest, and then exercise again for a total duration of 30 to 60 minutes a day in excess of their normal activity. The exercise period must be performed in one session, with walking being the preferred modality. Drawing on data from several studies, approximately 80 percent of patients may be expected to show significant improvements in exercise tolerance through these techniques. Patients should be further instructed to keep their feet warm, clean, and dry; and extremes of temperature should be avoided because ischemic tissue is more susceptible to burning and to frostbite than normal tissue. Cuts or severe bruises of the limbs or feet should be treated immediately. Conventional vasodilators appear to have no value in treatment.

Two agents have been approved for the indication of intermittent claudication in the United States. Cilostazol, a phosphodiesterase inhibitor with antiplatelet and vasodilatory properties, has been shown in several studies to have consistent benefits on treadmill walking distance and quality of life.[2] However, its benefits are limited by high frequency of side effects, principally gastrointestinal symptoms or headaches. Furthermore, it is contraindicated in patients with congestive heart failure. Pentoxifylline affects red cell deformability and blood viscosity but has been shown

to be ineffective in the treatment of claudication in recent studies.[2] Propionyl-L-carnitine is an agent with metabolic effects, actively under study in the United States for this indication.

Endovascular intervention with angioplasty or stenting is highly effective for aorto-iliac disease and is often indicated for moderate, or lifestyle-limiting claudication. Angioplasty or stenting of the superficial femoral artery is technically feasible but limited in applicability by high restenosis rates, particularly in the setting of long occlusions, a common scenario in this location. Despite this limitation, it is a valid therapeutic option for patients with focal disease, severe claudication, or tissue loss. Endovascular management of infra-popliteal (below the knee) disease is associated with extremely high restenosis rates, and is usually a temporizing measure to allow increased blood flow for wound healing. Surgical bypass techniques are effective but are generally high-risk procedures in a population with frequent co-morbidities and are usually reserved for patients with severe intermittent claudication or rest pain, or to allow healing of ulcers and gangrene. Sympathectomy is not of value for intermittent claudication, but may allow small ulcers or areas of gangrene to heal. In patients with rest pain, ulcers, or gangrene who are technically unrevascularizable or very high risk for surgery, treatment options are limited. A period of rest with legs dependent may improve some patients, but amputation is a frequent outcome. Parenterally administered prostacyclin or prostaglandin E_1 despite some favorable reports of success, has not yet been thoroughly evaluated and is an expensive mode of therapy.

Dry gangrene of the digits or lower limbs should be allowed to spontaneously demarcate. Soaking or ointments are unnecessary. The edges of the gangrenous areas should be kept open if possible and observed frequently for infection. Pain medication is usually necessary for 2 to 3 months with digital gangrene. A conservative approach and patience will save many digits and extremities. Infected (wet) gangrenous areas must be actively débrided and appropriate antibiotics administered. Amputations may be necessary.

Prevention

The grim statistics regarding cardiovascular outcomes in these patients emphasize the need for aggressive secondary prevention by modifying appropriate cardiovascular risk factors when possible. Tobacco smoking is absolutely contraindicated. Hypertension and diabetes mellitus should be controlled, and hyperlipidemias should be treated with a target low-density lipoprotein < 100 mg/dL (or < 70 mg/dL with uncontrolled or multiple risk factors) as per recent guidelines for secondary prevention. Evidence is accumulating that aggressive lipid management will prevent progression of PAD, in addition to prevention of myocardial infarction and stroke. Similarly, anti-platelet use with aspirin is well established for prevention of cardiovascular events. The use of thienopyridines such as clopidogrel (Plavix) may be of additional benefit, but may be associated with higher bleeding rates (particularly with combined therapy) and expense. Use, therefore, must be individualized.

ATHEROMATOUS EMBOLISM

Epidemiology

The epidemiology of atheromatous embolism is poorly defined due to underreporting and difficulties establishing a clinical diagnosis.[3] Routine autopsy series of the adult population suggest an incidence of atheromatous embolism of between 0.15 percent and ~4 percent. The incidence increases dramatically in the presence of severe atherosclerotic disease. Atheromatous embolism has been found in more than 20 percent of deaths following cardiac surgery or angiography. However, it should be emphasized that the rate of clinically detected atheromatous embolism appears to be reasonably low (less than 1 percent).

Etiology and Pathogenesis

The pathogenesis of atheromatous embolism involves the occlusion of small arteries and arterioles by atheromatous debris (or so-called *cholesterol crystals*) that are dislodged from a proximal atherosclerotic plaque, with this material inciting an inflammatory cascade characterized by leukocyte infiltration followed by monocytes. This inflammatory process leads to further occlusion with thrombus formation, endothelial cell proliferation, and intimal fibrosis, which may result in ischemia, infarction, and necrosis. The clinical picture is characterized by impaired perfusion of the skin and muscle due to small vessel occlusion, although nearly any organ of the body may be involved.

ATHEROMATOUS EMBOLISM AT A GLANCE

- Atheromatous embolism is the embolization of small pieces of atheromatous debris from the more proximal arteries to the smaller arteries.
- Synonyms include *cholesterol embolism*, *atheroembolism*, *blue toe syndrome*, and even *pseudovasculitis syndrome*.
- More common with advanced age and after invasive procedures.
- Manifestations include blue or discolored toes, livedo racemosa, gangrene, necrosis, ulceration, and fissure.
- Renal failure and stroke from systemic involvement.
- Diagnosis confirmed by cholesterol clefts in skin or muscle biopsies.
- Treatment focuses on prevention during invasive procedures and elimination of the embolic source. Medical therapy may include anti-platelet therapy and statin agents, while the use of anticoagulation is controversial and often avoided.

The major risk factor for the development of atheromatous embolism is atherosclerotic disease of the thoracic or abdominal aorta. The risk is higher with more extensive atheroma burden (defined by increased thickness above 4 mm) or unfavorable plaque features such as protruding mobile plaque. Co-existent vascular disease including coronary artery disease, PAD, and even an abdominal aortic aneurysm is a risk factor. The more traditional atherosclerotic risk factors also increase the risk of atheromatous embolism, with older age (more than 60 years old) being prominent.

Atheromatous embolism often occurs after an invasive procedure. Angiography, endovascular procedures, and both cardiac and vascular surgeries may create mechanical trauma to the vessel and destabilize an atherosclerotic plaque. Anticoagulation, primarily with Coumadin, and even thrombolytic therapy are potential risk factors. It has been postulated that anticoagulation may de-

lay the healing of irregular or ulcerated plaque. Embolic events may occur spontaneously although minor stressors such as coughing or straining may be provocative factors.

Clinical Findings

HISTORY There is a wide spectrum of clinical manifestations depending upon the affected organs. The clinical presentation ranges from subtle clinical findings to catastrophic systemic embolic complications. However, lower extremity involvement is extremely common with manifestations of discolored or ulcerated painful toes and tender calf muscles. This is more common after invasive cardiovascular procedures. Depending on the source for the embolization, nearly any organs of the body may be involved. Involvement of the ascending aorta may result in systemic complications including transient ischemic attacks, strokes, or other retinal manifestations, while involvement of the descending or abdominal aorta may lead to renal failure, mesenteric ischemia, or hemorrhagic pancreatitis. In addition, constitutional symptoms including fever and weight loss may be seen due to hypermetabolism associated with the inflammatory process.

CUTANEOUS LESIONS The dermatologic manifestations are often the presenting complaint (Table 174-2). The most common of these findings are related to tissue or digital ischemia and include cyanosis, necrosis, gangrene, ulcerations, and fissures. The finding of tender, cool, blue, or purple toes with normal pulses, found in the "blue toe syndrome," is common (Fig. 174-5A). About 50 percent of patients will have livedo racemosa, which typically involves the foot and leg but may extend into the trunk or buttocks. Erythematous lesions are often seen on the lateral aspect of the foot and calcaneal region. Although advance ischemic manifestations such as ulcers or gangrene may be present (see Fig. 174-5B), the surrounding areas are normally perfused tissue. There may be other cutaneous manifestations, often hemorrhagic in nature, including petechiae, ecchymosis, purpura, and splinter hemorrhages. Raised painful erythematous nodules may occur that are probably inflammatory in origin.

▲ **FIGURE 174-5** **A.** Typical appearance of blue toes due to multiple atheromatous emboli to the lower limbs in a patient with extensive atheromatous disease of the aorta. **B.** Development of ulceration of the tip of the toes due to atheromatous embolism with a faint reticular pattern on the forefoot typical of livedo racemosa.

TABLE 174-2

- Blue or purple toes
- Livedo racemosa
- Gangrenous digits
- Ulcers
- Fissures
- Nodules
- Petechiae
- Purpura
- Splinter hemorrhages

RELATED PHYSICAL FINDINGS Examination of the vascular system often reveals normal pedal and proximal pulses, but systolic bruits may be heard on auscultation over the aorta or common femoral arteries. Tenderness of skeletal muscles, particularly in the calf, may be detected. Funduscopic examination revealing Hollenhorst plaques is a specific but insensitive finding because most atheromatous emboli arise from a source distal to the aortic arch. Fever may be present.

Laboratory Tests

The laboratory tests are typically nonspecific and depend upon the organ involved and the severity of disease. An elevated erythrocyte sedimentation rate, thrombocytopenia, hypocomplementemia, leukocytosis, and anemia may all been seen due to the systemic inflammatory response. With renal involvement azotemia, proteinuria, microscopic hematuria, eosinophilia, and even eosinophiluria may be seen. Transient eosinophilia has been reported in up to 80 percent of those with renal involvement. Involvement of the gastrointestinal tract may lead to anemia and blood in the stools. Injury to the liver, gallbladder, or pancreas may lead to abnormal liver function tests and elevated pancreatic enzymes.

Special Tests

Contrast angiography may demonstrate diffuse atherosclerotic involvement of the vessels proximal to the lesions but is typically avoided due to the risk of precipitating further embolic events. Noninvasive imaging techniques such as computed tomographic angiography or magnetic resonance angiography are useful to evaluate for atherosclerotic disease within the aorta or other large vessels. Although stenotic atherosclerotic disease is the most common finding, aneurysmal disease may also be present. Transthoracic echocardiography is often helpful to evaluate for a cardiac source, but the more definitive transesophageal echocardiography can also assess the thoracic aorta for plaque.

Histologic findings are useful to confirm a suspected diagnosis. Cholesterol crystals are birefringent under polarized light. However, due to the solubility of cholesterol with typical solvents used in processing of tissue for histopathology, cholesterol crystals appear as empty clefts. Skin, muscle, or renal biopsies may reveal these characteristic elongated, needle-shaped clefts in small arterial vessels. There may also be inflammatory infiltrates, intimal thickening, and perivascular fibrosis as well as giant cells. The sensitivity of the biopsy depends upon the site. Muscle biopsy seems to be the most sensitive test, reportedly being positive in > 95 percent of cases, but is technically difficult, painful, and risky to obtain. The sensitivity of skin biopsy has varied from 40 percent to 90 percent. Skin biopsies offer maximum yield when

- Thrombocytopenia, polycythemia
- Thrombotic embolism
- Vasculitis
- Warfarin-induced skin necrosis

obtained directly from areas of suspected emboli, such as those with livedo racemosa, but should be cautiously obtained or avoided in areas of more overt ischemic injury.

Differential Diagnosis

The diagnosis of atheromatous emboli is suggested by blue or ulcerated painful digits, livedo racemosa, petechiae, and tender calf muscles in the presence of normal pulses. Definitive diagnosis can be made by skin, muscle, or even renal biopsies. Several other entities must be considered in the differential diagnosis of atheromatous embolism (Box 174-5).

Complications

There are numerous ischemic complications depending upon the organ involved. These include the kidneys, mesenteric circulation, and central nervous system. Renal atheroembolic disease is a consequence of showering of emboli to the renal parenchymal branch vessels. An intense inflammatory process may ensue, producing glomerular sclerosis, tubular atrophy, and interstitial fibrosis. Although there is a variable timing of onset and progression of disease, there typically is a several-week delay after the inciting event before the development of renal dysfunction. New onset of hypertension or overt renal failure may ensue. It is rare to develop gross hematuria or frank renal infarction. The development of renal failure is one of the more ominous complications with a high mortality in affected individuals.

The central nervous system is another feared site of involvement with atheromatous embolism. There is the obvious concern for ischemic manifestations such as transient ischemic attacks, stroke, and paralysis. However, other less readily apparent manifestations may result, such as a confusional state or a progressive neurologic decline.

The gastrointestinal tract is perhaps the third most common organ system involved with atheromatous embolism. The manifestations may be non-specific abdominal complaints such as abdominal pain, nausea, vomiting, or diarrhea. More overt ischemic manifestations may be seen with gastrointestinal bleeding or bowel infarction. The colon is the most common site in the gastrointestinal tract to be affected. Establishing a diagnosis may be difficult as endoscopy findings are often non-specific, and biopsy may miss the classic findings. Splenic infarction, cholecystitis, gangrene of the gallbladder, pancreatitis, and pancreatic necrosis have also been reported.

Prognosis and Clinical Course

The outcome depends upon the organ system affected with the emboli. Early reports suggested an extremely poor prognosis with a mortality of more than 50 percent. This figure appears to have been an overestimation as more recent estimates range from 20 percent to 30 percent for 1-year mortality. The poorest outcomes have been reported in those with emboli arising from a suprarenal location.

The syndrome usually subsides, and lesions heal following successful surgical or medical treatment, although spontaneous resolution may occur. Recurrent embolism may result in limb loss in the absence of surgical or interventional management options. In the "malignant multisystem" disease, most patients die within 1 year if treatment is unsuccessful. The prognosis is extremely poor in the presence of systemic complications, particularly renal failure or stroke. The development of end-stage renal disease due to atheromatous embolism is a strong predictor of death.

Treatment

Early recognition is essential to minimize end organ damage and improve the clinical outcomes.[3] Preventing further ischemic insult, supportive care, and removal of the atheromatous source are the mainstays of therapy. Elimination of the source of the emboli can often be accomplished by surgical bypasses or endarterectomy although many of these patients have contraindications to major surgery. Endovascular procedures with covered stents may also be considered; however, this approach may carry significant risk with the potential to exacerbate further embolization.

Medical therapies have not been well studied, and recommendations are based on the results from small series or anecdotal reports. Anti-platelet agents such as aspirin and dipyridamole are most often tried and, if successful, therapy should be continued long-term. Antithrombotic therapy such as subcutaneous heparin or low-molecular-weight heparin may be beneficial with some, suggesting that these agents may reduce the secondary small vessel thrombosis. Warfarin is usually avoided due to potential for exacerbating the process, but this concern has limited basis. There is even a proposed beneficial effect of long-term anticoagulation to prevent embolic events in those with extensive mobile aortic atheroma. The use of statins may aid in plaque stabilization and has clear established benefits in prevention of cardiovascular ischemic events in those with vascular disease. Other agents such as iloprost and cilostazol have limited evidence to suggest benefit but have been tried in those with renal dysfunction and cutaneous lesions, respectively. Systemic corticosteroids are not recommended.

Prevention

Primary prevention in high-risk patients, targeted to avoid the development of atherosclerotic plaque, should be performed. Once atherosclerosis develops, avoiding unnecessary invasive procedures is advised. When angiography is necessary, newer techniques with the use of soft-tipped guidewires and more flexible catheters help to reduce the risk. In addition, protective devices such as filters, baskets, and balloon occlusion have been used. Surgical techniques have also been refined with less aortic manipulation and circulation arrest, which may help to minimize the chance of developing this disorder.

THROMBOANGIITIS OBLITERANS (BUERGER DISEASE)

Epidemiology

The prevalence of this disease is greatest in the Mediterranean, the Middle

THROMBO-ANGIITIS OBLITERANS

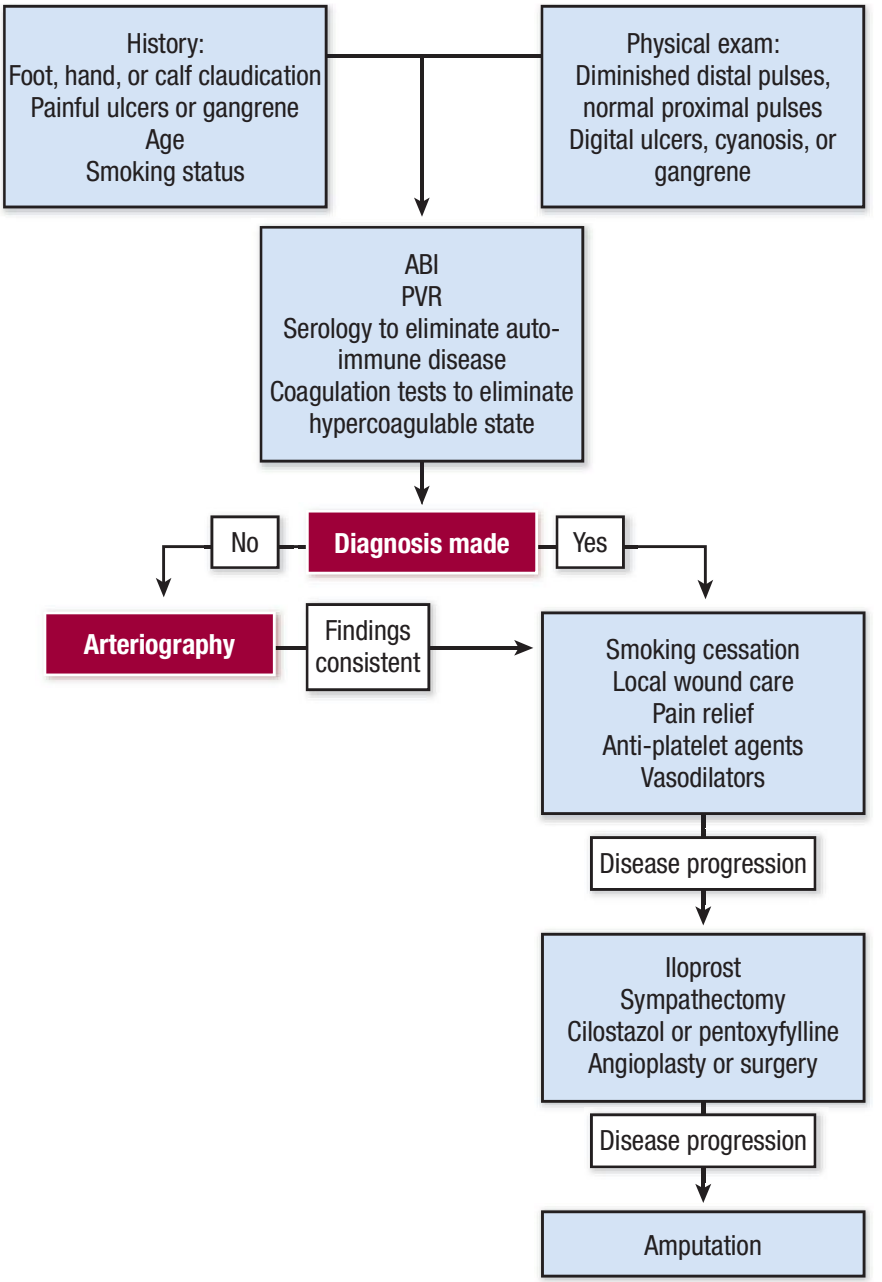
AT A GLANCE

- Rare inflammatory occlusive disease affecting medium and small arteries and veins, most commonly in the extremities.
- Predominantly affects males, age 20 to 40 years old.
- Extremely strong association with smoking; often abates with smoking cessation.
- Clinical manifestations include ischemia, cold sensitivity, or claudication of foot, leg, or hand.
- Ischemic ulcers, peripheral cyanosis, gangrene, or superficial thrombophlebitis.

East, and Asia.[4] Males are afflicted with a higher prevalence than females, although an increased incidence in females has occurred in recent years, likely reflecting the pattern of tobacco use. Patients are usually between the ages of 20 and 40 years old. Over the last three decades, there has been a marked decline in the reported prevalence of thromboangiitis obliterans in the United States, possibly reflecting the impact from adoption of strict diagnostic criteria for this disease entity, although declining smoking prevalence may also play a role.

Etiology and Pathogenesis

The etiology of thromboangiitis obliterans remains unknown.[4] The disease almost exclusively occurs in smokers and often abates with the cessation of tobacco smoking. An increased cellular sensitivity to types I and III collagen has been reported in comparison to a group of normal individuals and patients with atherosclerotic disease. Tissue ischemia is produced by an inflammatory reaction involving medium and small arteries of the extremities and superimposed obstruction by thrombi. Despite the inflammatory process, thromboangiitis obliterans is considered serologically silent, and even during active disease, erythrocyte sedimentation rate and C-reactive protein levels are usually normal. In one report, serum anti-endothelial cell antibody titers were found to be high, and impaired endothelial-dependent vasodilation to acetylcholine has been demonstrated to occur even in non-obstructed limbs. Veins may also be involved. Occasionally, cardiac, intestinal, and cerebral vessels are involved.



▲ **FIGURE 174-6** Approach to patient algorithm for suspected thromboangiitis obliterans. ABI = ankle-brachial index; PVR = pulse-volume recording.

Clinical Findings (Fig. 174-6)

HISTORY The most common initial complaints are claudication of the foot or lower calf, digital cyanosis or gangrene, or rest pain. Involvement of multiple limbs is usual. Patients may present with ulcers of the toes or fingers. Although the lower extremities are affected most often, more than one-third of patients have upper-extremity involvement. Ulcerations or gangrenous areas are characteristically extremely painful. Superficial thrombophlebitis, often migratory, may occur in up to 40 percent of patients. Cold sensitivity or even classical Raynaud phenomenon may be observed.

CUTANEOUS FINDINGS The cutaneous findings of thromboangiitis obliterans are sim-

▲ **FIGURE 174-7** Necrotic toe in a patient with thromboangiitis obliterans; this appearance may be seen with other arterial occlusive processes.

ilar to that of PAD. Common findings include ulceration or gangrene of digits (feet worse than hands) (Fig. 174-7), peripheral cyanosis or Raynaud phenomenon, and superficial thrombophlebitis, often migratory, with indurated red nodules.

RELATED PHYSICAL FINDINGS Physical examination may reveal cyanotic, ulcerated, or gangrenous, and very painful digits. The dorsalis pedis, posterior tibial, and ulnar pulses are often absent. During episodes of thrombophlebitis, small indurated red, tender nodules will be found, which follow the course of superficial veins and are common on the thigh or calf. Typical changes of Raynaud phenomenon, with well-demarcated pallor or cyanosis of the digits, may be seen on exposure to cold; one or more extremities may be involved. Sensory abnormalities reflecting ischemic neuropathy have been observed in advanced cases. Nail fold examination with capillaroscopy may reveal multiple dilated capillary loops.

Laboratory and Special Tests

There are no specific blood studies. Classical findings on contrast arteriography include segmental occlusions of medium and small blood vessels interspersed with normal appearing wall segments. Corkscrew configuration of collateral vessels originating from the occluded vessels are a classic finding; however, this is non-specific, as it may be seen with other disorders. More proximal and larger caliber vessels are usually spared.

Pathology

In the acute stage, there is a pan-vasculitis of arteries and veins; the diagnostic finding is arterial thrombi with foci of microabscesses and giant cells. In contrast to systemic vasculitis (see Chap. 165) and atherosclerosis, normal architecture is usually well preserved, and there is no early disruption of the internal elastic lamina.[5] In the chronic stage, only fibrotic obliteration of the arteries may be observed. The diagnosis can then only be surmised in the absence of hallmark pathologic changes to support atherosclerosis.

Differential Diagnosis

The same differential diagnoses as for PAD must be considered in thromboangiitis obliterans (see Box 174-2). In particular, the disease must be distinguished from distal arterial obstructive disease often seen in diabetes mellitus or end-stage chronic kidney disease. Other considerations include autoimmune disease, particularly scleroderma or CREST syndrome (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia), and ergotamine abuse.

The diagnosis should be considered in young male smokers presenting with symptoms and signs of distal extremity ischemia, migratory thrombophlebitis, or Raynaud phenomenon. An abnormal Allen test (with compromised perfusion of the fingers and blanching secondary to an occluded ulnar artery or incomplete palmar arch following manual compression of the radial artery) in a young smoker with lower extremity ulceration is very suggestive of this disease. The distal nature of disease and associated upper extremity involvement are particularly helpful clues to differentiate from atherosclerotic PAD. Arteriographic findings may support the diagnosis but only biopsy of an artery or vein during the active phase of the disease showing the characteristic pathologic picture is truly diagnostic. Atherosclerosis is the major differential but tends to occur in an older age group, usually more than 45 years of age, and larger vessels are involved. Raynaud phenomenon (see Chap. 171) is infrequent, and upper extremities are rarely involved. Occasional patients with long-standing diabetes mellitus or end-stage renal disease may exhibit arteriosclerosis affecting medium-sized and distal vessels, but these diagnoses are usually obvious. Raynaud phenomenon associated with scleroderma or CREST syndrome may present with a similar picture, but systemic symptoms, proximal skin changes, and presence of anti-nuclear antibodies will assist in the diagnosis.

Complications

Major clinical complications of this disease include amputation or superimposed infection of ischemic tissue. Rarely, involvement of other vessels may result in myocardial infarction, stroke, or mesenteric ischemia.

Prognosis and Clinical Course

The disease often continues to progress unabated in patients who continue to smoke. Amputations of digits or even extremities may be necessary. The course of the disease is marked by exacerbations and remissions, but usually becomes quiescent after many years. However, in those who manage to quit smoking, remission is common and progression to amputation unusual unless critical limb ischemia with tissue loss is already present. Patients generally have a normal life expectancy.

Treatment

There is no specific treatment (Box 174-6) other than smoking cessation. Local wound care is imperative, and adequate analgesic therapy is emphasized. In the absence of data from large randomized

Box 174-6

Treatment of Thromboangiitis Obliterans

	IMPROVE BLOOD FLOW	SYMPTOM RELIEF
First line	Smoking cessation	Local wound care Analgesics
Second line	Anti-platelet agents Oral vasodilators Cilostazol (Pletal) Pentoxifylline (Trental)	
Third line	Iloprost Angioplasty Surgical endarterectomy or bypass	Sympathectomy Amputation

trials, anti-platelet agents and vasodilators may play a role and are usually initiated. Similarly, pentoxifylline or cilostazol, both agents used for improving walking distances in claudicants with atherosclerotic disease, may be tried. In one study, daily infusions of iloprost, a prostaglandin analog, were shown to relieve rest pain, heal ulcers, and prevent amputation more frequently than aspirin. Bypass surgery or angioplasty have been reported but are suboptimal therapeutic options because of the small size and distal location of the vessels affected. Sympathectomy may help patients with a prominent vasospastic component. Vascular endothelial growth factor gene therapy may prove of value, but has not been well studied yet.

Prevention

The only preventive measure is never to smoke.

LIVEDO RETICULARIS AND LIVEDO RACEMOSA

Epidemiology

Livedo reticularis is typically a primary disorder that affects young to middle-aged females (20 to 50 years of age) who are otherwise healthy.[6,7] Amantadine-induced livedo reticularis is also more common in females. The epidemiologic factors of livedo racemosa are dependent on the underlying condition. The distinction between livedo racemosa and livedo reticularis is an evolving concept, which is not universally quoted, and is not referenced in most of the older literature.

Etiology and Pathogenesis

In both disorders, the characteristic ring-like mottling results from (patho)physiologic changes with the cutaneous microvascular system. Anatomically, the dermis is perfused via perpendicularly oriented ascending arterioles. Individual arterioles arborize into a capillary bed at the skin surface. Ultimately, the capillary beds empty into a conical appearing, peripherally located subpapillary venous plexus.

Pathophysiologically, livedo arises from either deoxygenation or venodilatation within the venous plexus. Decreased arteriolar perfusion is the predominant cause of deoxygenation within the venous plexus. Diminished arteriolar flow can result from vasospasm, hyperviscosity, and/or thrombosis. Physiologic arteriolar vasospasm produces the reversible cutaneous discoloration of livedo reticularis. Protracted arteriolar vasospasm, thrombosis and/or hyperviscosity underlie the pathologic skin changes of livedo racemosa. Venodilatation of the venous plexus may be provoked by hypoxia or autonomic dysfunction.

Amantadine-induced livedo reticularis has traditionally been ascribed to catecholamine provoked arteriolar vasospasm; however, an interaction between amantadine and *N*-methyl-D-aspartic acid receptors in the skin may be responsible in some unexplained fashion.

Livedoid vasculopathy is a rare ulcerative sub-type of livedo racemosa due to fibrinolytic abnormalities and microcirculatory thrombosis.

LIVEDO RETICULARIS AND LIVEDO RACEMOSA AT A GLANCE

- Livedo is an ischemic dermopathy characterized by a violaceous reticular or "net-like" mottling of the skin.
- Imperative to differentiate benign livedo reticularis from pathologic livedo racemosa.
- Livedo reticularis is a primary disorder affecting young to middle-aged females that is benign. The livid conical discoloration is symmetric, reversible, and uniform.
- Livedo racemosa is a secondary disorder that is pathologic and permanent. The livid conical discoloration is asymmetric, irreversible, and "broken."
- Anti-phospholipid antibody testing should be obtained on all patients presenting with livedo racemosa.

Clinical Findings

HISTORY With the exception of a subjective feeling of coldness, the majority of patients with livedo reticularis are asymptomatic. Patients often present with concerns regarding their skin discoloration. A minority describe mild pain and numbness. Livedo racemosa–associated symptoms are related to the causative secondary disorder (e.g., livedoid vasculopathy provokes painful ulcerations).

▲ **FIGURE 174-8** Symmetric and relatively uniform, conical rings of primary, reversible livedo reticularis (cutis marmorata).

CUTANEOUS LESIONS In livedo reticularis, a symmetric, fishnet-like red or purple mottling surrounds a pallorous conical core (Fig. 174-8). This discoloration is aggravated by cold exposure and may completely dissipate with warming. The livid rings are most pronounced on the lower extremities yet the abdomen and upper extremities can be affected.

In contradistinction to the symmetric and uniform reticular pattern of livedo reticularis, the discoloration of livedo racemosa is asymmetric, irregular, and "broken" (Fig. 174-9). Although it may improve with warming, it does not resolve. Attendant skin manifestations of livedo racemosa may include purpura, nodules, macules, ulcerations, and/or atrophie blanche type scarring.

In both livedo reticularis and racemosa, the skin is palpably cool.

RELATED PHYSICAL FINDINGS Livedo reticularis and livedo racemosa are often associated with vasospastic digits or acrocyanosis. With exception of the characteristic skin changes, the examination in livedo reticularis is otherwise unremarkable. Patients with livedo racemosa may have concurrent abnormal physical findings related to their underlying disease (e.g., aphasia and lateralizing neurologic signs associated with Sneddon syndrome).

Laboratory and Special Tests

In livedo reticularis, laboratory testing is typically negative and consequently is un-

▲ **FIGURE 174-9** Permanent and "broken" rings of secondary livedo racemosa on the buttocks and thighs in a woman who had cerebrovascular thrombosis. This is an example of Sneddon syndrome.

warranted. An anti-phospholipid antibody panel should be obtained on all patients presenting with livedo racemosa. A complete thrombophilia panel is warranted in the rare patient with livedoid vasculopathy (see Chap. 164). The need for additional laboratory analysis in a patient with livedo racemosa should be directed by the clinical assessment.

A skin biopsy is not required in livedo reticularis as the findings are non-specific. A large punch or wedge biopsy of the deep reticular dermis and subcutaneous fat is sometimes helpful in identifying the secondary cause of livedo racemosa. The biopsy findings are highly variable and reflect the associated livedo racemosa etiology. For instance, cholesterol clefts suggest atheroembolic disease, calcification of the vessels and interstitium indicate calciphylaxis, non-inflammatory arteriolar obstruction occurs with Sneddon syndrome, livedoid vasculopathy is associated with extensive fibrin deposition and microthrombi (see Chap. 164), whereas fibrinoid necrosis is present in polyarteritis nodosa (see Chap. 165).

Differential Diagnosis

The diagnosis of livedo is easily made by identifying the characteristic mottled skin discoloration. It is paramount that the clinician distinguish between livedo reticularis and livedo racemosa. Once a diagnosis of livedo racemosa is established, the secondary cause should be sought (Table 174-3).

Prognosis and Clinical Course

The prognosis for livedo reticularis is excellent as this is primarily a cosmetic condition. Livedo racemosa–associated prognosis is less favorable and parallels the associated disease. Of interest, livedo racemosa has been identified as a marker for predicting multisystem thrombosis in the anti-phospholipid antibody syndrome. Additionally, up to 40 percent of patients manifest livedo racemosa as the initial sign of the anti-phospholipid antibody syndrome.[7] Livedoid vasculopathy tends to be a relapsing condition marked by recurrent painful ulcerations and subsequent atrophie blanche type scars.

Treatment

Other than cold avoidance, medical treatment for primary livedo reticularis is typically unwarranted. As a last resort, vasodilator therapy may be tried in the patient that is socially inhibited by the cosmetic appearance of the disorder.

Therapy of livedo racemosa should be directed towards the underlying disorder. Patients with livedo racemosa and the anti-phospholipid antibody syndrome with thrombosis require anticoagulation. Treatment of livedoid vasculopathy is often unsatisfactory but potentially beneficial medications include anticoagulants, anti-platelet agents, immunosuppressants, pentoxifylline, danazol, and tissue plasminogen activator. Alternatively, hyperbaric oxygen and psoralen and ultraviolet A light therapy have also been successfully utilized to treat livedoid vasculopathy.

TABLE 174-3
Conditions Associated with Livedo Racemosa

- Anti-phospholipid antibody syndrome
- Sneddon syndrome
- Livedoid vasculopathy
- Vasculitis (especially polyarteritis nodosa)
- Collagen vascular disease
- Myeloproliferative syndromes (polycythemia vera, essential thrombocytosis)
- Paraproteinemias
- Cryoglobulinemia/cryofibrinogenemia/cold agglutinin disease
- Atheroembolic disease
- Calciphylaxis
- Hyperoxaluria
- Atrial myxoma
- Erythema ab igne
- Chronic pancreatitis
- Infections

ERYTHROMELALGIA (ERYTHERMALGIA)

Epidemiology

This is a rare disorder with limited epidemiologic data available.[8] In Norway, the incidence is estimated to be 0.25 for 100,000 population with a prevalence of 2 per 100,000. Primary erythromelalgia has a greater male prevalence and may occur at any age. In contrast, secondary erythromelalgia has an equal sex distribution and occurs mostly after the third decade.

Etiology and Pathogenesis

The etiology and pathogenesis of the erythromelalgia are unknown. Several mechanisms have been postulated for

ERYTHRO-MELALGIA AT A GLANCE

- Intense, burning pain with marked erythema, typically of the lower extremity.
- Typically intermittent. May be precipitated by exercise.
- Primary disorder or secondary to a myeloproliferative disorder.
- Cutaneous manifestations are often a result of attempts to alleviate the symptoms with immersion and thermal injury.
- Aspirin may be effective for secondary erythromelalgia.

primary erythromelalgia, including arteriovenous shunting and a small fiber neuropathy. It has been speculated that precapillary sphincters may be constricted while arteriovenous shunts are open, leading to an increased total perfusion but a deficient nutritive blood flow. Substances produced by local hypoxia lead to increased local blood flow, warmth, redness, and pain. In contrast, the genetics of erythromelalgia appears to be supporting a neuropathic basis. A mutation in a voltage-gated sodium channel of sensory nerves has been reported in inherited erythromelalgia.

Secondary erythromelalgia occurs in polycythemia, thrombocythemia, and autoimmune disorders and is hypothesized to be caused by platelet breakdown products based on the response to aspirin therapy.

Clinical Findings

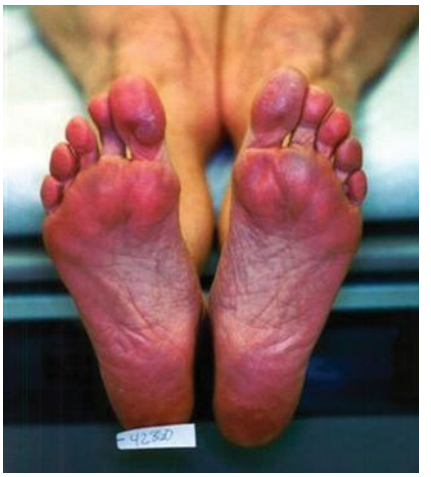
HISTORY The disorder is characterized by red, hot, painful extremities with characteristic intense burning pain. It most commonly affects the lower extremities but may affect the upper extremities as well as other body parts, such as the face and ears. Involvement is usually symmetric although it can be unilateral in secondary cases. The symptoms are typically intermittent in nature but may be constant. Their onset may be gradual or abrupt, precipitated by activities, such as exercise or dependency of the limb, or ambient temperature or the use of heavy blankets at night. In contrast, cold exposure (e.g., standing on a cold floor) or immersion in ice water often relieves flares.

A few patients have been described who have both erythromelalgia and Raynaud phenomenon. During the hyperemic phase of Raynaud phenomenon, patients often complain of erythromelalgic-like symptoms. It is postulated that both syndromes have a common basis in a dysfunction of the regulation of vasomotor tone.

CUTANEOUS LESIONS Examination during attacks reveals warm, red, extremely sensitive extremities with normal pulses (Fig. 174-10). Between flares, the extremities may appear normal. The constant use of ice water leads to maceration of the skin, secondary infection, ulcers, and necrosis.

Pathology

The pathology of the primary disease is unknown. In the secondary syndrome caused by thrombocythemia or polycythemia fibromuscular dysplasia, internal elastic membrane splitting, and thrombotic occlusions of arterioles are present.



▲ **FIGURE 174-10** Intense erythema of the feet with associated burning pain typical of erythromelalgia.

Laboratory and Special Tests

There are no confirmatory tests. It has been reported that warm water immersion at 32° to 36°C (89.6° to 96.8°F) may induce attacks. Secondary disease must be evaluated with a complete blood cell count and anti-nuclear antibodies, to help distinguish autoimmune diseases. Nerve conduction studies may be necessary to rule out neuropathies.

Differential Diagnosis

The diagnosis must be made from the history and clinical manifestations. Skin injury is sometimes present from the constant cold-water immersion. The main differential diagnosis is regional complex pain syndrome (or reflex sympathetic dystrophy) during the early warm phase, but this is usually unilateral, and there is a history of trauma.

Complications

Complications are often related to treatment used by patients to provide relief of symptoms. Immersion or thermal injury may ensue due to prolonged soaks in ice water. This may lead to trophic changes of the skin, ulcers, and infection and even the need for amputation.

Prognosis and Clinical Course

The natural history of erythromelalgia is extremely variable.[9] Symptoms may be mild for several years or totally disabling within weeks. It has been reported that with long-term follow-up, symptoms were worse in 32 percent, unchanged in 27 percent, improved in 31 percent, and resolved in 10 percent of patients. Many patients become unable to work or carry on daily activities. As a result of the profound impact upon their life with intractable symptoms, patients have been known to commit suicide. There is a decrease in survival compared with age- and gender-matched controls.

Treatment

There are limited data available to guide therapy, primarily based upon case reports or small series.[9] Behavioral modifications should include efforts to keep the limbs cool and avoid the use of ice water or prolonged soaking. Additional measures including biofeedback and even hypnosis have been tried. Pharmacologic therapy has varied but often has focused on vasoactive drugs and drugs that affect the nervous system. Most vasoactive drugs, including calcium-channel blockers and β blockers, have been minimally effective in treating this disorder. Drugs used to treat neuropathy, such as serotonin reuptake inhibitors, tricyclic antidepressants, and gabapentin, have been used and may provide some relief. Aspirin is often of great benefit but only in secondary cases. Topical therapies, such as lidocaine patch or capsaicin cream, may reduce the pain. The prostaglandin E_1 analog misoprostol has been evaluated in a double-blind, crossover trial and found to be superior to placebo. Numerous other agents, including lorazepam, cycloheptadine, methysergide, piroxicam, and pizotifen, have been tried in selected cases. Surgical or medical sympathectomies have also been tried but have been found to have mixed results.

Prevention

There are no established measures to prevent the development of erythromelalgia. The focus has been to prevent flares once the disorder occurs. The key to prevention is to avoid exacerbating factors and to prophylactically cool the involved extremity. The other preventive measures are to prevent the development of secondary complications often as a result of prolonged soaking in ice water. It is important to limit the duration of soaking and to use cool, not ice-cold, water.

CHAPTER 175

Cutaneous Changes in Venous and Lymphatic Insufficiency

Claude S. Burton
Craig N. Burkhart
Lowell A. Goldsmith

CHRONIC VENOUS DISEASE

Chronic disease of the peripheral veins includes a spectrum of diseases ranging from edema and tenderness to venous ulceration (Table 175-1).

Anatomy

Epidemiology

Chronic venous disease is extremely common. Although estimated costs and time lost from work have not been objectively assessed in over two decades, estimates state that 6 to 7 million people in the United States have evidence of venous stasis and that it accounts for 1 percent to 3 percent of the total health care budgets in countries with developed health care systems.[1]

Risk factors for chronic venous disease include heredity, age, female sex, obesity, pregnancy, prolonged standing, and greater height.[2]

Etiology and Pathogenesis

Venous ulcer occurs after failure of the calf muscle pump (Fig. 175-1). The heart pumps blood down to the foot; the calf muscle pump (when upright), returns venous blood to the heart. Venous blood from the skin and subcutis collects in the superficial venous system including the greater and lesser saphenous veins and its tributaries, moves through the fascia in a series of "perforating" or "communicating" veins, and fills the muscle-enveloped deep venous system. With muscle contraction, the deep veins are compressed; one-way valves in the deep system allow the now high pressure flow to move against gravity, and one-way valves in the perforators close to prevent pressure injury in the skin (see Fig. 175-1). In all patients with venous disease there is failure of these one-way valves and this can result in varicose veins (Fig. 175-2). The severity of venous disease is influenced by the number and distribution of incompetent valves and is worsened by any impairment of leg muscle function or ankle joint range of motion—all critical components of the calf muscle pump.

TABLE 175-1
Common Signs and Symptoms of Peripheral Venous Disease

Symptoms
- Leg fullness
- Aching discomfort
- Heaviness
- Nocturnal leg cramps
- Bursting pain on standing

Signs

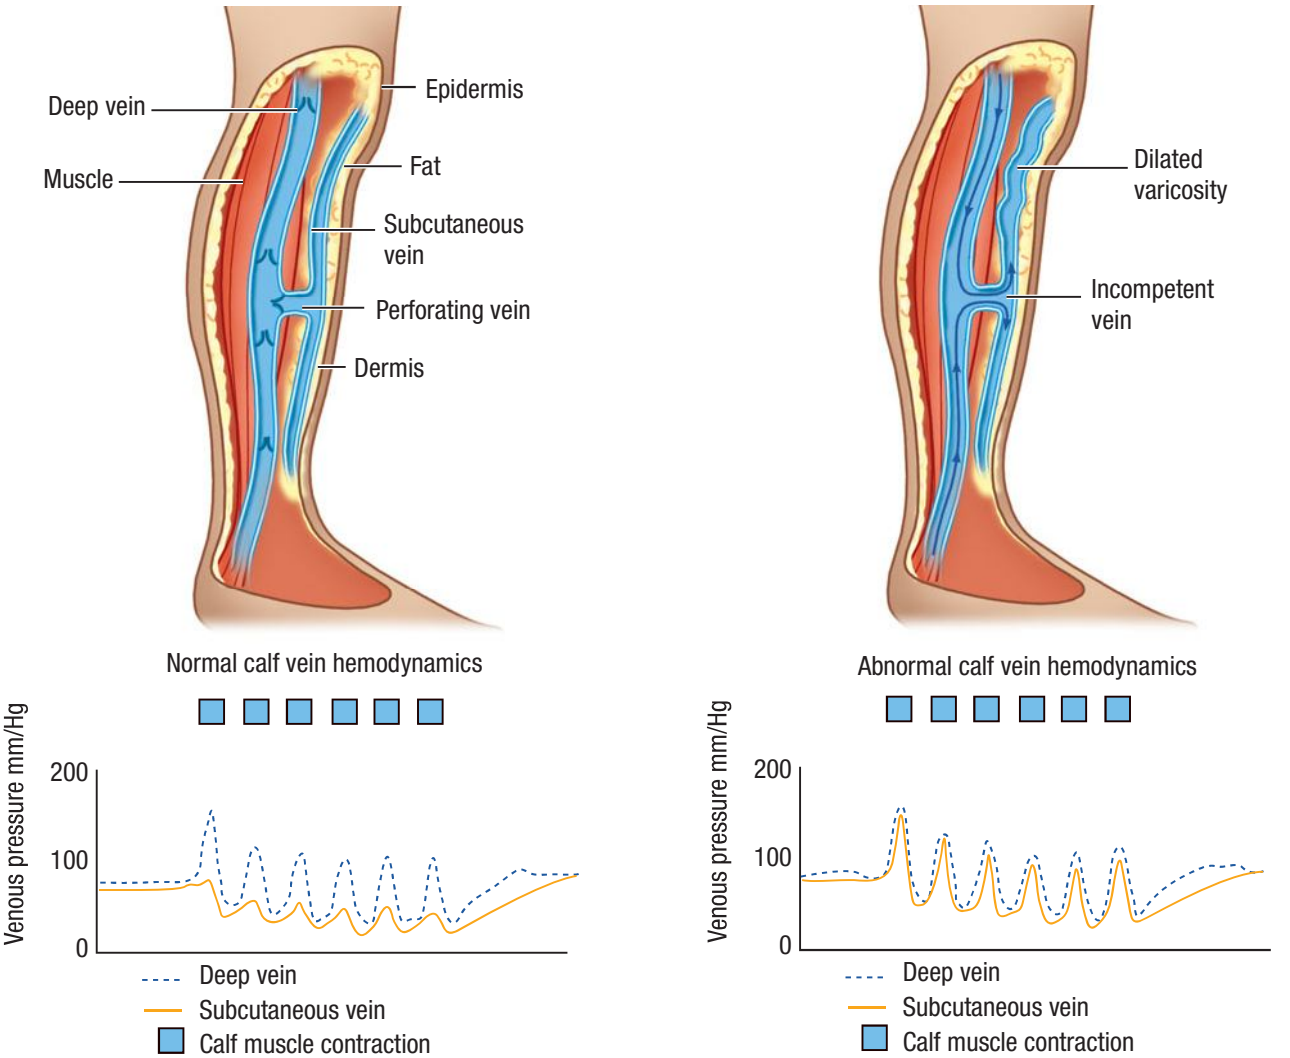
Very early
- Tenderness to palpation

Early
- Edema
- Hyperpigmentation
- Stasis dermatitis
- Varicose veins

Late
- Venous ulcers
- Atrophie blanche
- Lipodermatosclerosis
- Acroangiodermatitis of Mali
- Post-phlebitic syndrome

VENOUS DISEASE AT A GLANCE

- One percent to 3 percent of U.S. health care expenses are for peripheral venous diseases and their complications.
- Venous ulcers are the most common chronic wound in humans.
- Risk factors include genetics, obesity, female gender, pregnancy, occupations requiring prolonged standing, surgery, trauma, and malignancies.
- Peripheral venous disease should be considered part of a spectrum including
  - Early signs: Tenderness, edema, hyperpigmentation, and varicose veins.
  - Late signs: Atrophie blanche, lipodermatosclerosis, and venous ulcers.
- Venous ulcers are located exclusively below the knee after venous pump failure, most often secondary to prior thrombosis.
- Treatment for all stages includes leg elevation, compression, treatment of infection, and dermatitis.
- Deep venous disease is associated with thromboembolism.



▲ **FIGURE 175-1** Anatomy and hemodynamics of the calf muscle pump in normal individuals and in patients with venous insufficiency. The latter is characterized by high pressure reflux from deep veins into the superficial veins and small vessels of the skin.

Any obstruction to venous return (thrombosis, radiation fibrosis, etc.), or elevation of tight atrial pressure (pulmonary hypertension, heart failure, etc.), further compromises venous return. A detailed description of the anatomy and hemodynamics of the venous system of the lower extremities is found in Chap. 250.

The most common cause of valvular failure is thrombosis. The nidus for venous thrombosis is typically the valve cusp, and when the thrombus is lysed by plasmin, valve function is often lost as well. Calf muscle pump failure after deep venous thrombosis (DVT) is often referred to as the *post-phlebitic syndrome*.[6]

Once valves fail, especially those in the perforators, high pressure blood in the deep system refluxes into the unsupported veins of the skin, leading to soft tissue injury, inflammation, and eventually fibrosis, as the subcutaneous fat is replaced by scar in a process described by the term *lipodermatosclerosis* (see the section Cutaneous Lesions).

Clinical Findings

HISTORY An approach to the analysis of patients with ulcers is in Fig. 175-3.

Trauma frequently triggers the nonhealing venous ulcer. The events preceding ulceration happen insidiously over many years and may be ignored by the patient. A history of thrombosis may be missing because most episodes of lower extremity venous thrombosis are clinically silent. Relevant inquiry related to thrombosis risk should include a family history of similar problems (suggesting perhaps a familial thrombotic tendency), any episode of leg immobilization including knee or hip surgery and fractures, and any head injury associated with loss of consciousness.

Most patients complain of leg swelling, and many have been given diuretics, though the edema of venous disease, unlike the edema in salt-retaining states, like heart failure, cirrhosis, and nephritic syndrome, does not respond to diuretics. An edematous leg not responsive to diuretic therapy is a strong clue to the diagnosis. Venous ulcers may or may not be painful.

CUTANEOUS LESIONS All of the clinical syndromes described are secondary to the initial valvular syndrome and are grouped into clinical categories. Once there is venous valvular failure, a rather predictable series of changes occur in the skin. The earliest (though not universal) physical finding is soft tissue tenderness, even of normal appearing skin, discovered when checking for the presence of edema by palpation. Its association with other cutaneous signs of chronic venous disease is common.

The soft tissue injury that precedes ulceration begins in the subcutis, and visible changes may not appear for some time. Frequently one notes the ap-

▲ **FIGURE 175-2** Extensive varicose veins on the calf and thigh.

pearance of petechial lesions, which have the appearance of cayenne pepper sprinkled about the gaiter area. As the hemoglobin in the petechial lesions breaks down, the iron remains in the skin as hemosiderin and may lead to impressive discoloration (Fig. 175-4).

Stasis dermatitis, characterized by erythema, scaling, pruritus, erosions, oozing, crusting, and occasional vesicles may occur during any stage of chronic venous insufficiency (see Fig. 175-4). It typically occurs in the medial supramalleolar region where microangiopathy is most intense. Over time, lesions may lichenify. As 58 percent to 86 percent of patients with venous leg ulcers develop contact sensitization to topical therapies, it is important to evaluate for coexisting allergic contact dermatitis.

In lipodermatosclerosis (sclerosing panniculitis, hypodermatitis sclerodermiformis) pliable subcutaneous fat is gradually replaced by fibrosis, and the skin begins to feel indurated. This is a fibrosing panniculitis (see Chap. 68) characterized by a bound-down, indurated plaque that begins at the medial ankle and extends circumferentially around the entire leg.[7] As the fibrosis increases, it may constrict and strangle the lower leg further, impeding venous and lymphatic flow and leading to brawny edema above and below the fibrosis. These late changes resemble an inverted champagne bottle (Fig. 175-5).

Varicose veins, especially noticeable when the patient is standing, and smaller

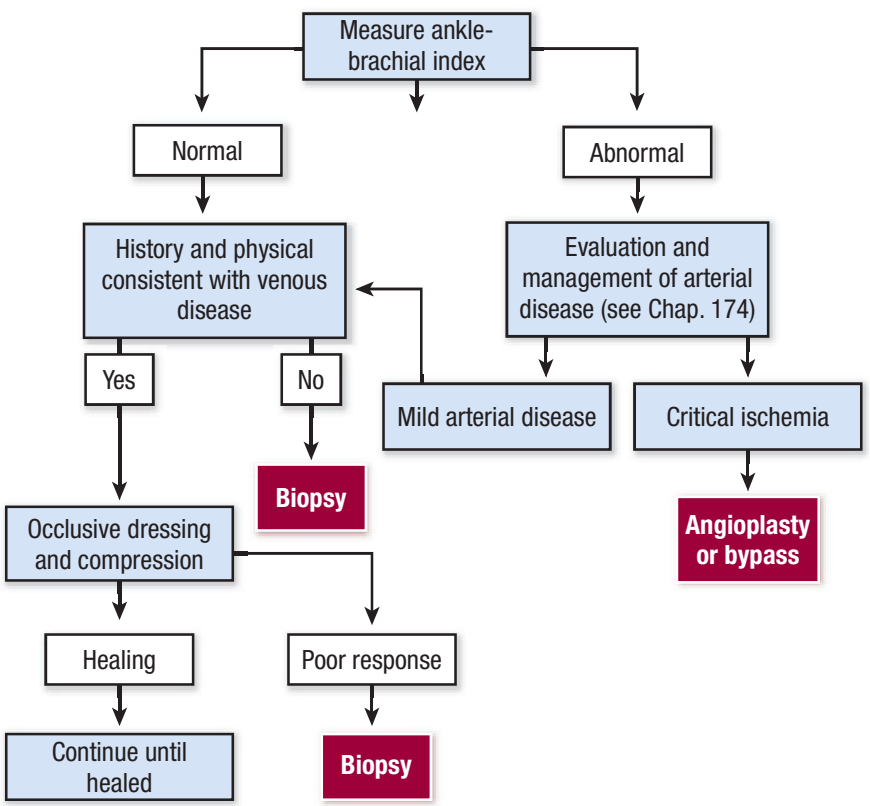
▲ **FIGURE 175-4** Bilateral venous disease with dermatitis and extensive hemosiderosis.

varicosities appear about the dorsum of the foot and ankle (see Chap. 250). Although they are usually asymptomatic, patients may complain of symptoms of aching, cramping, itching, fatigue, and swelling that are worse with prolonged standing (see Fig. 175-2).

Atrophie blanche (livedo vasculitis, segmental hyalinizing vasculitis) refers to skin overlying areas of fibrosis that often appears porcelain white and atrophic. Fully established lesions of atrophie blanche consist of irregular, smooth, atrophic plaques with surrounding hyperpigmentation and telangiectasias (Fig. 175-6). Although mostly related to venous stasis, atrophie blanche may also be associated with an underlying disorder of coagulation (e.g., antiphospholipid syndrome, inherited coagulopathies) or autoimmune disease (e.g., scleroderma, lupus erythematosus).[8]

Occasionally, acute inflammation of the subcutaneous fat develops in patients with venous disease, and histologically one finds an acute septal panniculitis in this setting (see Chap. 68).

Though ulceration is classically located in the gaiter area (see Fig. 175-5), *venous ulcers* have been described anywhere below the knee. Venous ulcers are typically tender, shallow, irregular, red-based ulcers that are always located below the knee (Fig. 175-7). They are usually located on the medial ankle or along the line of the long or short saphenous veins. Clinical distinction should be made with other common ulcers of



▲ **FIGURE 175-3** Approach to patient with lower extremity venous insufficiency.

the lower extremity as discussed later in this chapter and as shown in Box 175-1.

Histopathology

Laboratory Tests and Imaging Studies

It is crucial to evaluate arterial blood flow. A useful bedside screening test is to calculate the ratio of the systolic blood pressure in the ankle (as measured by Doppler) to the systolic pressure in the brachial artery (also measured by Doppler). This "ankle/brachial index" is greater than or equal to one in normal individuals. Anything less than one is an indication of peripheral arterial disease. The lower the ratio, the more severe the arterial obstruction (see Fig. 175-3). An ankle/brachial index is reliable except in the presence of calcified vessels, which are non-compressible and therefore a true systolic pressure cannot be measured. Having excluded arterial disease as a cause of ulceration, a clinical diagnosis is sufficient for the initiation of empiric therapy in most cases. When the diagnosis is in doubt, skin biopsy may be useful. Functional testing of calf muscle pump function and venous valvular function using plethysmography is occasionally useful. Duplex Doppler ultrasonography can be useful to document valvular incompetence and to evaluate patients for possible sclerotherapy or surgery (see Chap. 250).

▲ **FIGURE 175-6** Atrophie blanche with irregular porcelain-white atrophic scars, small ulcerations, and crusting.

Differential Diagnosis (See Box 175-1)

Complications

Recurrent ulceration is frequent. Any open wound provides a portal of entry for bacteria, and cellulitis, though infrequent, may develop at any time. Given that venous dermatitis may be extremely pruritic, and that these patients are easily sensitized to the topical agents they apply, contact dermatitis, especially due to topical antibiotics, is common. The skin is easily excoriated and may become infected.[10] The advent of methicillin-resistant *Staphylococcus aureus* is a threat to this population. The dermatitis of venous disease may become generalized as an id reaction and may rarely produce an exfoliative erythroderma (see Chap. 17). Many of these individuals are predisposed to thrombi, and recurrent episodes of venous thrombosis are not uncommon.

▲ **FIGURE 175-7** Venous ulceration with stasis dermatitis, edema, and varicosities.

All patients with advanced venous disease have some degree of lymphatic impairment, though lymphatic impairment may also result from inherited defects in lymphatic development or destruction of lymphatics after cellulitis/lymphangiitis, surgical interruption, or radiation.[11] Loss of lymphatic drainage from the lower leg may lead to verrucous changes and cutaneous hypertrophy, elephantiasis nostras (see Acquired Lymphedema).

Prognosis and Clinical Course

The prognosis for healing areas of ulceration and inflammation is excellent in the absence of comorbid illness that interferes with healing. The vast majority of uncomplicated patients respond well to ambulatory outpatient therapy as outlined in the section Treatment. Permanent changes include hemosiderosis and fibrosis that develop before the initiation of therapy. Loss of valvular function is irreversible. In the absence of continual lifelong cutaneous support in the form of inelastic wraps or elastic stockings, skin and soft tissue injury continues.

Treatment

Treatment of chronic venous insufficiency is outlined in Box 175-2.

Box 175-1

Differential Diagnosis of Leg Ulcers

- Vascular diseases
  - Arterial (hypertensive atherosclerotic, vasospastic)
  - Venous (venous stasis ulcer)
  - Lymphedema
- Metabolic disorders
  - Diabetes mellitus
  - Necrobiosis lipoidica diabeticorum
  - Porphyria cutanea tarda
  - Gout
  - Pancreatitic (pancreatitis, carcinoma)
- Infections
  - Bacterial (especially *Staphylococcus aureus, Streptococcus*)
  - Spirochetal (syphilis)
  - Fungal (deep fungal, mycetoma)
  - Opportunistic in immunocompromised
  - Viral
- Vasculitis
  - Hypersensitivity vasculitis
  - Polyarteritis
  - Systemic lupus erythematosus
  - Rheumatoid vasculitis
  - Wegener granulomatosis
  - Lymphomatoid granulomatosis
- Lymphedema
  - Congenital
  - Post-infectious
  - Postsurgical
  - Postirradiation
- Drugs
  - Halogens (bromide, iodide)
  - Ergotism
  - Drug-induced vasculitis
  - Anticoagulant necrosis (Coumadin, heparin)
  - Hydrea
- Hematologic abnormalities
  - Hypercoagulable states (protein C, S, antithrombin III deficiency, activated protein C resistance, prothrombin gene polymorphism)
    - Lupus anticoagulant syndrome
    - Paroxysmal nocturnal hemoglobinuria
  - Sickle cell anemia
  - Thalassemia
  - Polycythemia vera
  - Leukemia
  - Dysproteinemia (cryoglobulinemia, macroglobulinemia)
- Tumors
  - Cutaneous (basal cell cancer, squamous cell cancer, sarcoma, malignant melanoma, Merkel cell)
  - Secondary (metastatic carcinoma, lymphoma)
  - Kaposi sarcoma
- Miscellaneous
  - Pyoderma gangrenosum
  - Trauma (including factitial)
  - Burns
  - Pressure ulcers, neuropathic ulcers
  - Insect bites (brown recluse spider)
  - Ulcerative lichen planus
  - Bullous diseases (epidermolysis bullosa)
  - Sweet syndrome
  - Idiopathic

Box 175-2

Treatment of Chronic Venous Insufficiency

- Mechanical
  - Leg elevation
  - Compression stockings
  - Compression bandages
  - Intermittent pneumatic compression pumps
- Drug therapy
  - Aspirin
  - Pentoxifylline
  - Topical steroids (for stasis dermatitis)
  - Horse chestnut seed extract
- Dressings
  - Wet and dry non-adherent dressings
  - Occlusive hydrocolloid or gel dressings
  - Zinc paste–impregnated bandages (Unna boot)
- Surgery
  - Sclerotherapy
  - Long saphenous vein stripping
  - Saphenofemoral/saphenopopliteal junction disconnection
  - Calf varicosity avulsions
  - Subfascial endoscopic perforator vein ligation
  - Endovenous laser therapy
  - Radiofrequency ablation

Given the limitations of bed rest as an effective therapy, the focus is now on an ambulatory outpatient approach to the management of venous ulceration. Most experts agree on the essential role of compression in treating chronic venous insufficiency.[12] Hence, unless there are contraindications (arterial occlusive disease or abnormal ankle-arm indexes), compression therapy should remain part of any treatment regimen for chronic venous disease.

Toward the end of the nineteenth century, Paul Gerson Unna recognized that by providing a compression bandage to the distal extremity he could heal venous ulcers in an ambulatory patient population using zinc impregnated gauze wrap, the "Unna boot." Though the literature over the years continued to document the success of this approach, it proved difficult to achieve graduated compression with this wrap, and compliance was poor. Eventually, the addition of a self-adherent second layer (Coban™, for example) over a zinc wrap was introduced as the "Duke boot" and has proven to be easy to apply with reproducible graduated inelastic compression (Fig. 175-8) bandaging to counter the outflow from perforator incompetence is the cornerstone of venous ulcer management.[13]

The dressings should be changed weekly, or more often for heavily exudating wounds. New tissue is vulnerable to the cytotoxic effects of most topical antiseptics, and these agents are to be avoided. One should not put anything in a wound that you would not be willing to put in your eye. A gentle rinse with tap water or saline is sufficient. It is preferable to have the patient supine during dressing changes if at all possible.

Mechanical therapy is the mainstay of treatment for all clinical manifestations of chronic venous insufficiency.

Each pharmaceutical therapy targets a specific clinical aspect of chronic venous insufficiency. Diuretics may be used in the short term for treating severe edema. Horse chestnut seed extract (often standardized to 50 mg escin twice daily) is an herbal remedy that appears to be safe and effective as a short-term treatment for leg pain and swelling.[17] Aspirin (300 to 325 mg/day)[18] and pentoxifylline[19] may improve healing of chronic venous ulcers. Finally, topical steroids and emollients aid resolution of stasis dermatitis.

Although all wounds harbor potential pathogens, there is no evidence that routine use of antibiotics is helpful in patients with venous ulcer. If cellulitis is suspected, empiric therapy with coverage for *S. aureus* and *Streptococci* is warranted. Topical antibiotics, especially mupirocin, are useful for folliculitis due to *S. aureus* and *Streptococci.* With the increasing incidence of community acquired methicillin-resistant *S. aureus* in this population, culture and sensitivity are suggested for suspected skin and soft tissue infections.

Venous disease is progressive and irreversible. Patients must be educated about the need for continual hemody-

▲ **FIGURE 175-8** Compression bandage using a zinc paste primary layer (Unna boot) followed by Coban™ at full stretch.

namic support after the wound has healed. Graduated stockings that provide a minimum of 30 to 40 mmHg at the ankle should be carefully fitted to all patients and worn for their lifetime. It is a mistake to place elastic stockings on edematous limbs, especially those that are tender. One should use compression bandaging until all edema, inflammation, and tenderness have resolved before fitting the patient with stockings.

In carefully selected cases, sclerotherapy or surgical techniques, especially endovenous ablation, may close incompetent perforators and correct the hemodynamic abnormalities that lead to venous ulcer (see Chap. 250).[20,21]

Prevention

Prevention of venous thrombosis prevents venous insufficiency. Because many thrombotic traits are genetic, it is likely those patients at extra risk for thrombosis may be identified and treated for this risk before an event, and efforts to prevent thrombosis during elective surgery and hospitalization should reduce the numbers of post-phlebitic limbs. Once a patient develops venous thrombosis, elastic compression stockings are the only proven method to reduce the risk of post-thrombotic syndrome.[22]

Valvular failure may develop during pregnancy. Therefore the use of supportive stockings throughout maternity, although not proven, can be recommended. If one's occupation or lifestyle involves long periods of immobility (long-distance flights appear to be especially risky), stockings are advisable.

OTHER VENOUS DISEASES

DVT is important for at least two reasons: The thrombosed veins are the sources of pulmonary embolisms, and the thrombosed leg may progress to chronic venous disease that has already been discussed. Superficial thrombophlebitis has associations with internal diseases as well.

Deep Vein Thrombosis

EPIDEMIOLOGY

ETIOLOGY AND PATHOGENESIS

CLINICAL FINDINGS Clinical diagnosis of DVT is unreliable. Swelling, pain, discoloration, warmth, and/or superficial venous dilation may be seen in the involved extremity; less than one-third of patients suspected of having a DVT on clinical grounds have the disease.[26]

LABORATORY TESTS

TREATMENT Details of anticoagulation management in these cases should be in conjunction with the appropriate consultants. Primary prevention follows the same procedures discussed above for peripheral vascular disease.

Superficial Venous Thrombosis and Phlebitis

EPIDEMIOLOGY

ETIOLOGY AND PATHOGENESIS

CLINICAL FINDINGS Superficial phlebitis is the clinical finding of pain, tenderness, induration, and/or erythema in a superficial vein often associated with a palpable cord. These signs may be due to inflammation, infection, and/or thrombosis. Various eponyms are used for phlebitis in certain locations. For example, *Mondor disease* (sclerosing lymphangitis) refers to superficial phlebitis of the breast or dorsal penile vein, and *superficial thrombophlebitis* usually refers to superficial phlebitis of a lower extremity vein. Clinically, a thrombus is suggested by superficial phlebitis with a palpable cord that persists after a limb is raised.

LABORATORY TESTS Due to the possibility of co-existing occult DVT in patients with superficial venous thrombosis, some experts recommend compression ultrasound for all patients with lower extremity superficial venous thrombosis. However, this recommendation has not been explicitly tested in any trial and clinical judgment should guide further testing.

TREATMENT

LYMPHEDEMA

Lymphedema is a consequence of prolonged edema; edema is an interference of the physiologic movement of fluid from capillaries through the interstitial spaces and back into lymphatics. In edema, the equilibrium is shifted and more fluid remains in the interstitial space—when this becomes chronic, inflammatory cells and their cytokines lead to an irreversible state.

Dysfunction of the lymphatic system because of genetic or congenital defects or related to infection, surgery, or external trauma leads to functional impairment of the tissue clearing ability and progression to clinical signs of lymphedema. The differential diagnosis of lymphedema is extensive but can be logically approached.

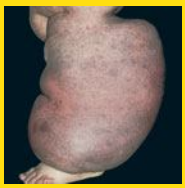
In all the clinical disorders discussed, edema may be transient and pitting with pressure but, with time, becomes fixed and accompanied by dermal sclerosis and epidermal hyperplasia.

Anatomy and Physiology of the Lymphatic System

Lymphedema-Related Genetic Diseases

Primary lymphedema (types I and II) is estimated at 1 in 6000. Other types are even rarer. A continuously updated

LYMPHEDEMA AT A GLANCE



- Lymphatics are essential for the clearing of extravascular fluids and debris and as transport of immunocompetent cells during the initiation of an immune response.
- Specific markers of lymphatic endothelia exist.
- Genetic defects causing lymphedema in childhood or early adult life are often caused by defects in a vascular growth factor receptor (*VEGFR3*) and *FoxC2*, a transcription factor.
- Lymphedema acquired in adult life is often related to chronic venous disease, after mastectomy with radiation and node removal, and, in certain geographic locations, filariasis.
- Cellulitis may complicate all forms of lymphedema and should be aggressively treated.

source on these diseases is Online Mendelian Inheritance in Man (OMIM; http://www.ncbi.nlm.nih.gov/omim/).

TYPE I LYMPHEDEMA (MILROY SYNDROME, OMIM #153100) ***Etiology and Pathogenesis.*** Type I lymphedema, an autosomal dominant disease characteristically has a mutation in *VEGFR3* (also called the *FLT4 gene*). Penetrance is relatively high (80 percent). There is a 2.3:1.0 female predominance in pedigrees; this sex ratio may be due to a more severe disease in males that leads to hydrops fetalis and fetal death.

CLINICAL AND RADIOLOGIC FINDINGS Lymphedema is almost always from birth and is confined to the legs with deep creases over the toes and small deformed ("ski jump") toenails and is characterized hypoproteinemia from intestinal loss of albumen, chylous ascites, and scrotal edema.[32]

Lymphangiography demonstrates dysplastic lymphatics in both clinically affected and clinically normal extremities, emphasizing the complexity of the pathophysiology, leading ultimately to disease. Prenatal ultrasound can show edematous legs in the fetus.

TYPE II LYMPHEDEMA (FORK-HEAD FAMILY TRANSCRIPTION FACTOR DEFECTS) ***Etiology and Pathogenesis.*** The fork-head family transcription factor defects have in common mutations in a transcription factor, the fork-head transcription factor, FoxC2 [MFH1 (mesenchyme forkhead-1); fork-head is the name of a *Drosophila* trait]. FoxC2 is inherited as an autosomal dominant trait. The concept of type II lymphedema can be enlarged to include four syndromes with similar molecular defects: Lymphedema-late onset (Meige syndrome), lymphedema-distichiasis syndrome, lymphedema and ptosis syndrome, and the hereditary forms of lymphedema with the yellow nail syndrome. Mutations have included nonsense and frameshift mutations inactivating FoxC2.

Clinical Findings. **MEIGE SYNDROME (OMIM #153200).** Edema develops around puberty, later than type I disease, and facial puffiness with deep creases and wrinkling may occur. Lymphedema *praecox* (Latin for *premature*) should not be used for this disease as it only leads to further nosologic confusion. Lymphangiosarcoma may be associated. Late onset-type II disease has decreased or absent axillary nodes and decreased lymphatics above the inguinal ligament on scintilymphangiography.

Other rare syndromes with lymphedema exist.

GENETIC DISORDERS AFFECTING BOTH LYMPHATICS AND VEINS

ACQUIRED LYMPHEDEMA ***Epidemiology.*** Chronic edema in a community sample in London had a prevalence of 1.33 per 1000 and was 5.4 per 1000 for those older than the age of 65 years.[36] Twenty-five percent of chronic edema was related to malignancy; and 29 percent of patients had at least one episode of cellulitis over the year before the survey; 70 percent to 80 percent of patients were female.

Worldwide lymphedema due to filariasis is estimated to affect between 90 and 100 million individuals (see Chap. 207). The microfilaria invade lymphatics, reproduce within the lymphatics, and damage local lymphatics and regional nodes, often resulting in hydroceles and scrotal swelling, classic components of filarial elephantiasis. In endemic areas, children may have subclinical disease that may be important to treat.[37]

Other infectious diseases with lymphedema are much less common and include lymphogranuloma venereum with elephantiasis of the penis and scrotum, granuloma inguinale (see Chaps. 203 and 204), and tuberculosis (see Chap. 184).

Etiology and Pathogenesis. There are two major etiologies to non-hereditary lymphedema on a worldwide basis—venous disease of the legs (discussed earlier in this chapter) and postcancer, especially carcinoma of the breast–related lymphedema.

Clinical Findings. Acquired lymphedema is often painless and leaves legs feeling heavy and the patient tired. Although the limb swells during the day, indentations from socks can be seen on the leg at nighttime, returning toward normal during the night, but the leg stays swollen, and initially concerns may be cosmetic in nature. The foot is often involved first and initially lesions pit with pressure. With time, lesions become woody or lardaceous and do not pit. The toe contours are lost (Fig. 175-9). Kaposi-Stemmer sign, a feature of chronic lymphedema, describes the skin over the proximal digit of the second toe that cannot be elevated; in edema the skin can be elevated.

Unilateral lymphedema suggests localized obstructing factors, but bilateral lymphedema can be due to obstruction in the pelvis or abdomen.

Inflammation with redness, pain, and swelling is not lymphedema but can be pyogenic infection, most commonly with *S. aureus* or *Streptococcus pyogenes*. Systemic antibiotics should be started before waiting for red lymphangitic streaking. A common complication is contact dermatitis from the use of topical antibiotics or multiple emollients and anti-inflammatory creams.

Special Tests.

Complications. Prolonged lymphedema leads to fibrosis and epidermal hyperplasia with verrucous hyperkeratosis (Fig. 175-10). Ulceration rarely occurs, although the edema and hyperkeratotic changes may be profound. Lymphangiosarcoma, the Stewart-Treaves syndrome when associated with postmastectomy lymphedema, is the common lesion in chronically lymphedematous locations (see Chap. 128).

Prognosis and Clinical Course. Careful, symmetric measurement at ankles, calves, and thighs should be made.

Treatment. Diuretics may worsen the condition and should not be used as a primary treatment for lymphedema. El-

▲ **FIGURE 175-9** Lymphedema of the left leg in a 47-year-old fireman. The extreme swelling began at birth and was painless. Note the lack of stasis pigmentation or ulceration. The patient functioned normally at work and wanted no treatment.

evation, massage, and sequential compression followed by elastic stockings can be used (see Treatment under Chronic Venous Disease). Various surgical approaches have been tried. In patients with primary and secondary lymphedema in the absence of venous or arterial disease, manual lymphatic drainage and sequential pneumatic pumps, in addition to compression wraps and garments, may be useful.

Cellulitis or recurrent lymphangitis is a significant problem in lymphedematous sites, and there is both a rationale and results that encourage long-term antibiotic use (e.g., 2.4 million units of benzathine-penicillin G intramuscularly every 2 weeks).[39]

▲ **FIGURE 175-10** Verrucous skin changes in chronic lymphedema.

Microsurgery of lymphatics to bypass obstructed nodes can be considered if nonsurgical treatments are not successful. This surgery consists of the formation of multiple end-to-end lymphatic-venous anastomoses.[40]

Excisional or suction-assisted lipectomy (liposuction) may be an option in selected patients.

Prevention. Any patient with lymphedema, whatever the cause, should keep their feet dry, nails trimmed, and prevent and aggressively treat pyogenic infection. Lymph moves faster during limb activity and exercise (e.g., walking should be encouraged).

LOCALIZED AREAS OF LYMPHEDEMA

Lymphedema is common in some locations, face and penis especially; low-grade infection is usually invoked as the cause.

In puffy hand syndrome, intravenous drug use with injections into hands or feet is associated with lymphedema. The condition is not drug specific.

SECTION 29

BACTERIAL DISEASE

CHAPTER 176

General Considerations of Bacterial Diseases

Timothy G. Berger

Bacterial infection of the skin may be thought of in four major categories: (1) primary skin infection, (2) secondary infection of a primary skin disease (e.g., infected atopic dermatitis), (3) the skin lesions as manifestations of primary infection in some other organ system, usually the blood, and (4) reactive skin conditions resulting from bacterial infection (e.g., erythema nodosum due to streptococcal pharyngitis). It is important to remember that the cutaneous changes associated with infection are not always suppurative but may present as a vasculitis or a hypersensitivity response (e.g., lesions in subacute bacterial endocarditis or erythema nodosum).

The importance of the skin as a mirror of systemic infection cannot be overemphasized, especially when classic clinical findings are distorted as in immunocompromised patients. The timely recognition of the cutaneous clues of bacteremia may provide the early warning to consider life-threatening infections due to organisms such as *Pseudomonas aeruginosa*, *Vibrio vulnificus*, *Salmonella typhi*, *Staphylococcus aureus*, and *Neisseria meningitidis*.

◀ Erysipelas. Painful, edematous erythema with sharp margination on both cheeks and the nose. There is tenderness, and the patient has fever and chills.

PATHOGENESIS OF BACTERIAL INFECTION OF THE SKIN

The development and evolution of bacterial infection involve three major factors: (1) the portal of entry, (2) the host defenses and inflammatory response to microbial invasion, and (3) the pathogenic properties of the organism.

Portal of Entry

The efficacy of the intact and functioning epidermis to resist direct bacterial invasion is illustrated by the high prevalence of septicemia in low-birthweight, premature infants who lack an effective epidermal barrier.[1] Because normal intact pediatric and adult skin is relatively resistant to infection, most infections occur when there is disruption of the skin barrier. Maceration, shaving, chronic wounds, excoriation of pruritic insect bites, and disruption of the epidermal barrier by other pathogens are the primary avenues by which bacteria can breach the skin barrier. For example, lower leg cellulitis in the otherwise healthy person without venous incompetence or a leg ulcer is a consequence, most commonly, of interdigital maceration or tinea pedis.[2]

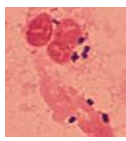
The character of the cutaneous inflammatory response to bacteria will be influenced by how the organisms reach the involved area. Local inflammation and suppuration commonly accompany direct bacterial infection of the skin. In septicemia, the vascular wall is often the primary site of skin involvement; hemorrhage or thrombosis with infarction is the initial manifestation. Certain bacteria can produce bacteremia or distant lesions without evoking an obvious inflammatory response at the portal of entry [e.g., *Yersinia pestis*, *Streptobacillus moniliformis* (rat-bite fever)], even in a nonimmunosuppressed host. Occasionally, a devastating *S. pyogenes* septicemia has followed closely on an innocuous pinprick or abrasion that has not induced a significant local lesion.

BACTERIAL SKIN DISEASES AT A GLANCE

- Bacteria cause disease by direct invasion of tissues, by secreting toxins, and by causing immunologic consequences that result in disease.
- The innate immune system is critical in the adequate handling of bacterial entry into the skin.
- The virulence and pathogenicity of bacteria is related to their ability to avoid activating the innate immune system or resisting killing within immune effector cells.
- Immunosuppression, especially neutropenia, puts the host at high risk for bacterial infections; some infections are rare except in the immunocompromised host.
- Treatment of bacterial infection needs to consider the nature of the host and that of the infecting bacterium to be successful.

Natural Resistance of the Skin

The normal skin of healthy individuals is highly resistant to invasion by the wide variety of bacteria to which it is constantly exposed. It is difficult to produce localized infections such as impetigo, furunculosis, or cellulitis if the integument is intact.[3] Pathogenic organisms such as *S. pyogenes* (group A streptococcus, GAS) and *S. aureus* produce characteristic lesions of cellulitis and furunculosis in hosts with normal defenses usually



Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

because there is a disruption of the normal skin barrier. The presence of a silk suture reduces by a factor of 10,000, in the case of *S. aureus*, the number of organisms needed to produce an abscess in the human skin.[4]

Bacteria are unable to penetrate the keratinized layers of normal skin and, when applied to the surface, rapidly decrease in number. Maceration and occlusion, which result in increased pH, higher carbon dioxide content, and higher epidermal water content, result in dramatic increases in bacterial flora.[5] Some bacteria, such as those that are Gram negative, can only be found in such sites, suggesting that normal skin conditions prevent them from colonizing the skin. The relative dryness of normal skin specifically contributes to the marked limitation of growth of bacteria, especially Gram-negative bacilli. Lipids found on the skin surface have antibacterial properties.[1] Reduction of skin surface lipids with topical solvents prolongs the survival time of *S. aureus* on the skin. The free fatty acids, linoleic and linolenic acids, are more inhibitory for *S. aureus* than for coagulase-negative staphylococci, a component of the normal skin flora. Sphingosine, glucosylceramides, and *cis*-6-hexadeconic acid have been demonstrated to have antimicrobial activity against *S. aureus*. Bacterial interference (the suppressive effect of one bacterial species on colonization by another) exerts a major influence on the overall composition of the skin flora.

The organisms that characteristically survive and multiply in various ecologic niches of the skin constitute the "normal cutaneous flora." As an example, the distribution of different species of coagulase-negative staphylococci varies among different anatomic areas, and their relative numbers can depend on age. In adults, *S. epidermidis* is the principal staphylococcal species isolated from the scalp, face, chest, and axilla. Gram-negative bacilli are relatively rare as components of the normal resident skin flora, with the exception of members of the *Acinetobacter calcoaceticus-baumannii* complex, found on approximately 25 percent of normal adults, primarily in axillae, groins, and toe webs.[6]

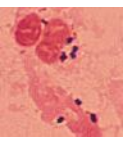
ANTIMICROBIAL PEPTIDES Human skin contains a wide range of proteins with inherent antimicrobial properties. These antimicrobial peptides (AMPs) are expressed on the skin surface as well as in eccrine sweat and saliva.[7] Activated keratinocytes produce AMPs. The AMPs produced in keratinocytes are delivered to the skin surface in the lamellar bodies, and their appearance on the skin surface is closely tied to the production of normal skin stratum corneum lipids (see Chap. 45). These small proteins have as a characteristic physical property the presence of an amphipathic organization, with one portion being cationic and capable of binding to microbial membranes, and another being hydrophobic allowing for insertion into the bacterial lipid membrane. The insertion into the membrane results in membrane disruption and microbial death. A second principle of AMPs is that they are processed after release by enzymes on the skin surface, resulting in multiple peptides each with different activities and different targets. The third principle of AMPs is that they not only kill microbes directly, but they are also potent activators of the host immune response. The two major AMPs studied to date on the skin are the cathelicidins (LL-37) and the defensins. The marked decrease of these molecules on the inflamed skin of patients with atopic dermatitis explains the susceptibility of atopic patients to infections with *S. aureus*, herpes simplex virus, and vaccinia virus.[8] T helper 2 cytokines specifically suppress the production of these AMPs, explaining why psoriatic skin has normal or elevated AMP content and is less susceptible to bacterial and viral infections.[9]

SPECIFIC FEATURES OF HOST INFLAMMATORY RESPONSE TO CUTANEOUS INFECTION

The adaptive immune system, which requires the development of targeted cells and antibodies, is highly effective in protecting humans from infection once the effector cells and antibodies have been produced. However, this takes days, and bacteria replicate and invade in hours. The discovery of the "innate" immune system explains the ability of organisms to mount an effective and targeted immune response to microbes before the adaptive immune system comes into play (see Chap. 10). The innate immune system is present in plants, invertebrates, and vertebrates. This system relies on a series of "pattern recognition receptors" that recognize "pathogen-associated molecular patterns" that are not present on "self."[10] Binding of the pattern recognition receptors to the pathogen-associated molecular patterns results in opsonization and activation of the complement system as well as induction of inflammatory signaling pathways. This process involves at least three pattern recognition receptors: (1) the AMPs discussed in Antimicrobial Peptides, (2) Toll-like receptors (TLRs), and (3) the complement system. These three systems all engage bacteria once they enter the skin and, by intercommunication and by signaling neutrophils and other immune cells, are vital in bringing to the site of infection the cells required to destroy the pathogen.

TLRs are a repertoire of pattern recognition receptors (see Chap. 10).[11] They occur on cell membranes and recognize certain exogenous ligands that are unique to invading microorganisms and not found in the host. They play a prominent role as primary sensors for invading pathogens. For instance, TLR5 recognizes flagellin, unique to flagellated bacteria, and TLR2 recognizes the peptidoglycan on the surface of Gram-positive bacteria. These structural elements of the invading organism are essential for its pathogenicity and therefore are hard to eliminate on an evolutionary basis. The TLRs not only engage the invader but they also orchestrate what type of immune response is generated for that specific pathogen. TLRs do this by instructing antigen-presenting cells that have engaged the organism to secrete appropriate cytokines to generate the desired immunologic milieu and eventual adaptive immune response (see Chap. 10). Alternative downstream signaling pathways can result in different immune responses from engagement of the identical TLRs.

Complement (see Chap. 36) is activated when mannin-binding lectin binds to carbohydrate patterns on bacteria and activates C2 and C4.[12] Activation of C3 liberates C3a and C3b. C3b on membranes leads to opsonization and enhanced phagocytosis. In addition, the cleavage of C5 leads to C5a, a potent activator of neutrophils and a stimulator of pro-inflammatory cytokines, including interleukin 1 (IL-1) and IL-8. The "membrane attack complex" is formed by completion of the complement cascade and kills invading microbes. Not surprisingly, complement components also modulate the immune system, and alter TLR stimulation of some activation pathways. Through an extensive repertoire of outcome options, the human host has the ability to develop an organism-specific response to a wide variety of infectious agents that the host has not previously encountered. In addition, the innate immune system through complement and TLR orchestrates the adaptive immune system to appropriately respond to the invading microbe. This elaborate innate immune response explains the variety of rather distinctive



clinical responses to various bacterial infections that have been described. The infectious agent, the anatomic site of the infection, and the attendant inflammatory response pattern create the clinical lesion.

Pathogenicity of the Microorganism

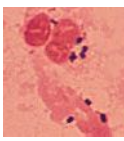
To effectively invade a host, the microbe must initially gain access. *S. aureus* uses teichoic acid and other surface proteins that promote adherence to the nasal mucosa. The bacteria are then available to contaminate any breaches in the skin, binding to fibronectin in wounds. The disease-producing capacity of bacteria is termed *virulence*. The genetic material encoding virulence factors and toxins are carried on mobile genetic elements called *pathogenicity islands*. Bacteriophages carry genetic elements from one bacterium to the next (Panton-Valentine leukocidin for example). Panton-Valentine leukocidin is a cytotoxin directed against human immune cells. It is associated with deep-seated and more inflammatory furunculosis. In addition, many bacterial species contain DNA elements within their own genome that specifically are designed to escape, inactivate, or suppress the host's innate immune response, especially by resisting killing by neutrophils and excreted products. These gene products that respond to the host's immune attack are usually composed of a two-protein interaction cascade involving a sensor and a response protein. This is called a *two-component gene regulatory system*. In the case of *S. aureus*, numerous specific substances target each element of the innate immune attack by the host. Staphylokinase (SAK) inactivates defensins. Aureolysin A cleaves LL-37. The *oatA* gene encodes a membrane protein that imparts lysozyme resistance. *S. aureus* is catalase positive, and the yellow pigment of *S. aureus* (carotenoids) protects it from oxidative killing by neutrophils. SAK also activates plasminogen to plasmin. Surface plasmin cleaves C3b and immunoglobulin G, removing important opsonic molecules from the bacterial surface. Chemotaxis inhibitory protein of *S. aureus* binds to C5a blocking neutrophil activation. Staphylococcal complement inhibitor binds to C3 convertase on the bacterial surface preventing it from cleaving C3 and activating the complement cascade. SAKS, chemotaxis inhibitory protein of *S. aureus*, and staphylococcal complement inhibitor are carried on the same pathogenicity islands.[13–16]

Although it is useful to distinguish between disease caused by toxins and those caused by direct invasion and virulence factors, most bacterial infections result from the combination of the invasive and toxigenic properties of the organism. Examples in which locally secreted toxins are instrumental in creating the characteristic lesions are infections with *S. aureus* (bullous impetigo), *Corynebacterium diphtheriae*, and *Bacillus anthracis* (see Chap. 178). Systemic manifestations of toxin secretion are seen in staphylococcal scalded skin syndrome and tetanus. In the case of *C. perfringens*, elaboration of a variety of extracellular toxins and enzymes (α-toxin or lecithinase, proteases, collagenases) appears to play an important role in the rapidly spreading skin lesions and the systemic manifestations of clostridial myonecrosis (see Chap. 179). *S. pyogenes*, specifically GAS, also contains numerous genes that help it evade the innate immune system. These include those within the genome, such as the M protein, which prevents phagocytosis by neutrophils, and those transmitted on prophages such as exotoxin A. The production of DNase SdaD2 protects GAS from extracellular killing by neutrophils in neutrophil extracellular traps and is important in skin infections. Tissue invasion and systemic spread are enhanced by streptokinase. GAS streptokinase is active only against human plasminogen, which may be critical in restricting GAS infection to humans. The proclivity of streptococcus to share the genetic material containing these virulence factors across strains has blurred the restrictions of streptococcal types to certain disease patterns. Now, for instance, in some regions, group G streptococcus is a major cause of pharyngitis and contains the same virulence genes that gave GAS the ability to cause this condition.[17,18]

Gram-negative bacteria (*Escherichia coli*, *S. typhi*, *N. meningitidis*, *N. gonorrhoeae*, *Brucella melitensis*, and others) contain endotoxin, complex phospholipid-polysaccharide macromolecules [lipopolysaccharides (LPS)] as an integral part of the bacterial cell envelope (see Chap. 180). Endotoxins, unlike exotoxins, are released only upon breakdown of the bacterial cell. Their toxicity appears to be linked principally to the lipid fraction, whereas their antigenic determinants reside with the polysaccharide component. Much is now known of the mechanisms by which LPS exerts its biologic effects in systemic infections due to Gram-negative bacteria or in major localized infections that may also be capable of producing the sepsis syndrome. The effects are both toxic and immunologic. The two cytokines most important in the toxic and pro-inflammatory effects of LPS are produced by LPS-activated macrophages: tumor necrosis factor (TNF) and IL-1. TNF initiates a pro-inflammatory cytokine cascade (see Chap. 11). TNF activates the coagulation system through its effects on vascular endothelium and decreases blood pressure and tissue perfusion by reducing myocardial contractility and by relaxing smooth muscle. High circulating levels of TNF are demonstrable in patients with meningococcemia and other forms of severe sepsis.[19] Infusion of high concentrations of purified TNF alone can produce shock and death. The ability of LPS, through TNF production, to induce leukocyte adherence to capillary endothelium and to induce fibrin deposition has been suggested as the basis for development of the hemorrhagic necrotic skin lesions (with or without direct bacterial invasion) that sometimes occur during the course of Gram-negative bacillary bacteremias and particularly in meningococcemia. Purpura fulminans develops in 10 percent to 20 percent of cases of marked meningococcal sepsis, and severe cases may develop thrombosis of large vessels with infarction of digits (see Chaps. 145 and 180).

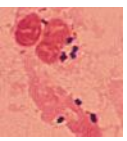
Changing Patterns of Bacterial Infections of the Skin

Three factors have resulted in an increase in the prevalence and virulence of bacterial infections. First, we have discovered new pathogens such as *Bartonella* sp., that were not previously known to cause human disease (see Chap. 182). Second, bacteria themselves have become more difficult to treat via the acquisition of virulence factors and antibiotic resistance. Third, there are an ever increasing number of immunocompromised patients due to increasing numbers of the elderly and debilitated, the human immunodeficiency virus-infected, and the iatrogenically immunosuppressed. In addition to the usual pathogens, a variety of "non-pathogenic" members of the cutaneous microflora are capable of producing disease in debilitated patients and in individuals with altered humoral or cellular defenses. For example, ecthyma gangrenosum due to local or systemic destructive invasion of the skin is seen virtually always in the setting of neutropenia (see



Chap. 180). In the immunocompetent host, a transient, self-healing folliculitis is caused by the same organism. *B. henselae* causes cat-scratch disease, a self-healing disorder in the immunocompetent host (see Chap. 182). In the acquired immunodeficiency syndrome patient with advanced immunosuppression (CD4 < 50) bacillary angiomatosis and systemic involvement, fatal without treatment, is seen (Chaps. 182 and 198).

Influence of Hypersensitivity to Bacterial Antigens on Inflammatory Reaction in Skin



The ability of bacteria to induce immunologic events on the part of the host explains certain syndromes. The flares of atopic dermatitis induced by *S. aureus* may be due to shifts in cytokine profile in the lesions induced by the bacterial infection. Similarly, streptococcal infection of the pharynx can induce an immunologic response that triggers psoriasis via activation of the immune system.

Neutrophilic Conditions as a Cutaneous Response to Systemic Infection

Inflammatory changes in and about small blood vessels in the skin may occur in a variety of bacteremic infections in the absence of obvious localization of bacteria at these sites. The papular and petechial lesions of chronic meningococcemia, and at times in disseminated gonococcal infection (see Chaps. 180 and 205) and the development of leukocytoclastic vasculitis following adequate treatment of endocarditis (probably induced by circulating immune complexes) are examples. The lesions of Sweet syndrome (see Chap. 31) and early erythema nodosum (see Chap. 68) can have prominent tissue neutrophilia, even though the initiating infection (e.g., streptococcal pharyngitis) is distant. The Osler nodes and petechiae of subacute bacterial endocarditis, caused by viridans streptococci, probably provide the best examples of this association of small-vessel vasculitis with bacteremia (see Chap. 181). Histologically, these lesions are more suggestive of vasculitis than of emboli. The occasional development of such lesions in profusion, localized to the lower extremities, supports the concept of cutaneous vascular inflammation rather than embolization.

CLASSIFICATION OF BACTERIAL INFECTIONS OF THE SKIN

The discovery of specific bacteria as the cause of skin infections has led in most cases to classification of skin diseases based on the pathogenic bacteria rather than by morphology. In many cases, however, the infectious agent will be identified by culture, and the results not known for at least 1 day. In addition, impetigo (see Chap. 177), cellulitis, and necrotizing fasciitis (see Chap. 179) are three examples where multiple pathogens are capable of causing the same clinical pattern and require treatment decision based on the most likely pathogens. Therefore, morphologic classification of skin lesions is still important and can guide initial diagnostic testing and empiric antibiotic treatment. To this end, the classification of skin findings caused by bacterial infections as (1) primary infections (pyodermas), (2) secondary infections, (3) cutaneous manifestations of systemic bacterial disease, and (4) reactive conditions resulting from distant infection, seems warranted. Primary bacterial infections are produced by the invasion of ostensibly normal skin by a single species of pathogenic bacteria. In such infections, there is usually no doubt as to the primary etiologic role of the specific agent in the pathogenesis of the lesion. Treatment aimed at the bacterial pathogen almost universally results in cure of the lesion. Impetigo, erysipelas, and furunculosis (see Chap. 177) are familiar examples of primary cutaneous infections. In contrast, secondary infections develop in areas of already damaged skin. Although the bacteria present did not produce the underlying skin disorder, their proliferation and subsequent invasion of surrounding areas may aggravate and prolong the disease. Such secondary infection may occur when the integrity of the skin has been broken, or the local immune milieu is altered by the primary skin condition, allowing for infection by bacteria. In contrast to the primary infections, the secondary infections at times show a mixture of organisms on culture, and not infrequently, it is impossible to determine which if any play the major role. It is important to know in which conditions recovery of a bacterial pathogen is important, and in which it is less predictable of response to antibiotic treatment. In flares of atopic dermatitis (see Chap. 14), the finding of numerous *S. aureus* on the skin surface is often associated with improvement of the dermatitis with antibiotic treatment. In contrast, even experts in the field disagree on the significance of culturing bacterial "pathogens" from chronic leg ulcers. In the case of secondary infections, the morphology of the primary skin disease may be minimally altered, and the presence of an exacerbating bacterial pathogen may only be suspected by poor response to treatment or an otherwise unexplained flare of the condition.

DIAGNOSTIC STRATEGIES

Direct Examination of Aspirates and Biopsies

Identification of bacteria from skin lesions may provide important information as to the cause of cutaneous infections. Examination of a Gram-stained smear of material from a suspected skin infection can guide decisions on early antibiotic therapy before a cultural diagnosis is made. For these reasons, bacteriologic investigation is an important part of the initial evaluation of patients with skin lesions and includes (1) appropriate sampling, (2) interpretation of Gram-stained smears, and (3) use of selective growth media for culturing.

Gram staining provides a very rapid method of examining a sample for number and type of bacteria, as well as for the character of the inflammatory exudate. Obtaining an appropriate specimen for microscopic study and culture requires care to avoid contamination. Results of needle aspiration of cellulitis and erysipelas are generally unrewarding. Aspirates from the advancing edge of cellulitis yielded positive cultures in only 10 percent of patients, and culture of skin punch biopsy specimens taken from the leading edge were positive in only 15 percent to 20 percent of patients,[20,21] perhaps higher in patients with diabetes mellitus and neoplastic disease. A higher yield (about 50 percent) for positive cultures has been reported in aspirates obtained from the point of maximal inflammation than that obtained from the leading edge of cellulitis (5 percent) in children.[22] Findings on needle aspiration, when positive, can provide an immediate useful guide to therapy. If sterile saline is injected into a lesion that initially yields no aspirate, bacteriostatic agent-free solutions should be employed. In circumstances in which no data are available from needle aspiration, a surgical biopsy may yield information that is lifesaving. In the bioterrorism-associated outbreak of anthrax infections in the United States, rapid specific diagnosis of cutaneous disease was accomplished by

punch biopsy of an erythematous, indurated plaque and tissue Gram stain demonstrated Gram-positive rods, confirmed as *B. anthracis* by immunohistochemical analysis (see Chap. 178).[23] Local lesions of the skin and subcutaneous tissues in immunocompromised patients should always be biopsied if aspiration fails to define a pathogen. Encouraging results have been reported in patients with suspected necrotizing fasciitis (see Chap. 179) who had biopsies done to confirm the diagnosis early in the course of this devastating infection.[24]

Other Diagnostic Procedures

FLUORESCENT ANTIBODY The practical use of this procedure in bacterial diseases of the skin is currently of limited applicability. Spirochetes can be demonstrated (by the direct or indirect techniques) in chancres, (see Chap. 200). *N. gonorrhoeae*, *Actinomyces israelii*, *Legionella* sp., *Francisella tularensis*, *B. anthracis*, and *Y. pestis* have been identified by this rapid direct fluorescent antibody staining method. Its greatest use is in the specific diagnosis of uncommon but serious infections.[25]

OTHER IMMUNOLOGIC METHODS A variety of serologic tests may be helpful in the diagnosis of bacterial infections of the skin, particularly in those where the cutaneous manifestations are secondary to systemic disease (e.g., "rose spots" of typhoid fever). Bartonella infections are routinely diagnosed in this manner. As with any serologic test, a fourfold or greater rise in titer during the course of the illness is considered significant.

POLYMERASE CHAIN REACTION Polymerase chain reaction technology can be applied to diagnosis of material obtained on skin punch biopsy of lesional tissue or aspirates from a vesiculo-bullous lesion just as it has been used in diagnosis of infection in body fluids (cerebrospinal fluid, pleural fluid, blood). Appropriate precautions to exclude contamination during the acquisition of the specimen must be taken. The use of this procedure is most helpful when one particular bacterial species is being considered, and appropriate primers are available. Such was the case in a patient with a cutaneous lesion during the bioterrorism-induced anthrax outbreak.[25]

ANTIBIOTIC THERAPY (See Chap. 231)

The selection of the appropriate antibiotic should be made initially on the basis of the appearance of the skin lesion, the characteristics of any systemic illness, and a Gram-stained smear of material from a lesion, if available. Culture results and susceptibility testing of the isolated pathogen(s) are usually available within 48 hours. Additional epidemiologic factors (current hospitalization or residence in a nursing home, recent antibiotic use, neutropenia, and immunocompromise) should be considered in the choice of initial antimicrobial therapy. Also, it is important to make the choice based on the latest data from the local area and from frequently updated sources in view of the rapidly changing patterns of antimicrobial resistance of various bacterial species.

Dosage: Methods of Administration—Excretion

Primary cutaneous infections of mild to moderate severity can be treated with local measures, topical drugs, oral antibiotics, or by a combination of these methods. Extensive infections of the skin, with or without systemic manifestations, should be vigorously treated with parenteral antibiotics in adequate dosages. In the immunocompromised host, parenteral treatment of cutaneous infections is virtually always recommended.

A number of factors must be considered in administering antibiotics: oral treatment may be limited by absorption and gastrointestinal disturbances; hypotension and extensive skin disease can prohibit the intramuscular route; and the proper drug selected may be suitable for administration only by a specific route. The excretory pattern of a given antibiotic should always be considered to avoid toxic accumulation in the face of specific organ malfunction (e.g., hepatic or renal impairment).

Toxicity

The toxicity of antibiotics should be considered on an individual basis but some problems are applicable to all antibiotics. Hypersensitivity reactions are relatively common and can include skin rashes, fever, or more severe manifestations such as acute anaphylaxis or exfoliative erythrodermas. The penicillins and sulfonamides are particularly likely to produce these problems. Questions regarding previous drug allergy should be asked whenever any antibiotic is to be administered. All antibiotics can alter the indigenous flora, especially broad-spectrum agents such as the cephalosporins. Gastrointestinal disturbances and oral mucous membrane lesions are the major problems encountered with alteration of the flora. There are numerous other potential untoward reactions (renal, hematologic, hepatic, nervous system) to antibiotics that may represent acceptable risks if the reasons for use of these drugs are compelling. It is the physician's responsibility to be aware of the usual and unusual manifestations of toxicity of any of the antibiotics used and to be alert to possible novel effects in individual patients.

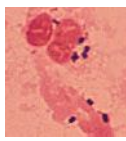
Antibiotic Resistance Because of "R" Factors (See Chap. 231)

Transferable resistance to multiple antibiotics has emerged as a widespread problem. Extrachromosomal genetic elements (R plasmids) in bacteria are the basis for much of such resistance.[26] Prolonged antibiotic therapy may select R-factor–carrying members of the indigenous flora (e.g., in the gastrointestinal tract), which may subsequently transfer this property to a potential pathogen. In this way, antibiotic resistance to chloramphenicol, tetracycline, and kanamycin conferred by a plasmid in *E. coli* can be transferred during mating to a *Klebsiella* or *Salmonella* strain.

Topical Antibacterial Agents (See Chap. 218)

Topical antibacterial agents are frequently used to prevent, as well as to suppress, bacterial growth in open lesions and surgical wounds. In the case of sutured dermatologic wounds, topical antibiotics have limited effect in reducing wound infections.[27] Topical neomycin and bacitracin not infrequently precipitate contact dermatitis. Contact dermatitis is especially common when these topical antibiotics are applied to venous insufficiency leg ulcers.

Among the most useful topical antibacterial agents are acetic acid (1 percent to 5 percent for *Pseudomonas* nail and toe web infections and bacitracin (500 units per milliliter or gram) for selected superficial *S. aureus* and streptococcal lesions. Neomycin (0.5 percent ointment) and gentamicin (0.17 percent cream) may be useful in selected patients when mixed Gram-negative bacteria require local suppression. Mupirocin (2 percent ointment) has antibacterial activity against various streptococci and *S. aureus*. A number of broad-spectrum antiseptics are also avail-



able for topical use. Povidone-iodine (Betadine) is effective against most Gram-positive and Gram-negative bacteria but does not persist in the skin to provide a residual action. Chlorhexidine gluconate (4 percent solution) combines broad antibacterial properties with prolonged action. An alcoholic preparation is especially effective, is not appreciably absorbed into the blood, and generally is not irritating to the skin. These broad-spectrum antiseptics can be used prophylactically or to treat local wounds and superficially infected dermatoses.

CHAPTER 177

Superficial Cutaneous Infections and Pyodermas

Noah Craft
Peter K. Lee
Matthew T. Zipoli
Arnold N. Weinberg
Morton N. Swartz
Richard Allen Johnson

Normal human skin is colonized soon after birth by a large number of bacteria that live as commensals on the epidermis and epidermal appendages. Coagulase-negative staphylococci (*Staphylococcus epidermidis*) are inoculated during vaginal passage and coryneform bacteria take up residence on neonatal skin shortly after birth. Within several weeks after birth, the flora of neonatal skin is similar to that of adults (see Chap. 176).

The majority of the primary and secondary pyodermas (cutaneous bacterial infections) are caused by either *S. aureus* or group A streptococcus. These bacteria cause a broad clinical spectrum of infection ranging from superficial pyodermas to invasive soft-tissue infections (STIs; see Chap. 179) depending on the organism, the anatomic location of infections, and on host factors.

STAPHYLOCOCCAL SKIN INFECTIONS

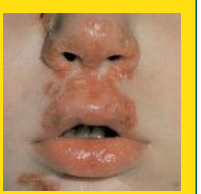
Epidemiology

Staphylococci are classified into two major groups: the coagulase-negative staphylococci and coagulase-positive (*S. aureus*) staphylococci. Individuals carry a minimum of 10 to 24 combined temporary and resident strains of *S. epidermidis*, the most common coagulase-negative strain. *S. epidermidis* is a common colonizer of the skin but is capable of causing superficial and invasive infections (particularly about implants and catheters).

S. aureus permanently colonizes the anterior nares in 20 percent of the population. Carriage is transient or intermittent in other individuals. Approximately 60 percent of healthy individuals have occasional carriage of *S. aureus* at some site.[1] Other sites of colonization include the axillae, perineum, pharynx, and hands. Conditions predisposing to *S. aureus* colonization include atopic dermatitis, diabetes mellitus (insulin-dependent), dialysis (hemo- and peritoneal), intravenous drug use, liver dysfunction, and human immunodeficiency virus (HIV) infection.

S. aureus is an aggressive pathogen and the most common cause of primary pyodermas and STIs, as well as of secondary infections on disease-altered skin. *S. aureus* in pyodermas or STIs can invade the bloodstream, producing bacteremia, metastatic infection such as osteomyelitis, and acute infective endocarditis. Some strains of *S. aureus* also produce exotoxins, which can cause constellations of cutaneous and systemic symptoms such as staphylococcal scalded-skin syndrome (SSSS) and staphylococcal toxic shock syndrome (TSS).

PYODERMAS AT A GLANCE



- Bacterial skin infections (pyodermas) are primarily caused by *Staphylococcus aureus* and *Streptococcus* sp.
- Twenty percent of individuals are continuously colonized with *S. aureus*, and occasional carriage is found in 60 percent of healthy people. This represents a common source of many infections.
- Contributing factors: Immunosuppression, atopic dermatitis, pre-existing tissue injury, and inflammation.
- Local manifestations include: Folliculitis, furunculosis, ecthyma, and impetigo.
- Systemic reactions include: Staphylococcal toxic shock syndrome and scarlatiniform eruption.
- Not particularly localized to one anatomic area.
- Pathology: Abundant neutrophilic infiltration admixed with lymphocytes.
- Treatment: Topical, oral, or parenteral antibiotics: Change predisposing conditions, if possible. When planning therapy, consider local and current antimicrobial resistance patterns.

Transfer of organisms to patients occurs predominantly via the hands of personnel rather than through the air. This appears to be particularly true in newborn nurseries. Any individuals with open staphylococcal infections are high-risk potential carriers and transmitters of infection. Nasal carriage of *S. aureus* appears to be a major risk factor for wound infection after cardiac surgery, resulting in higher mortality rates and longer postoperative stays.[2] The rate of *S. aureus* bacteremia is also higher in nasal carriers of *S. aureus*.[3] Good nursery technique, careful handling of patients, strict hand-washing procedures, and isolation of patients with open draining staphylococcal infections are important in the reduction of transmission of staphylococci. In older adults, *S. aureus* accounts for 9 percent of nosocomial infections and follows only *Escherichia coli, Pseudomonas aeruginosa*, and enterococci in prevalence.[4]

Etiology and Pathogenesis

Colonization by *S. aureus* may be transient or represent a prolonged carrier state. *S. aureus* produces many cellular components and extracellular products that may contribute to its pathogenicity. Host factors such as immunosuppression, glucocorticoid therapy, and atopy may play a major role in the pathogenesis of staphylococcal infections. Preexisting tissue injury or inflammation (surgical wound, burn, trauma, dermatitis, retained foreign body) is of major importance in the pathogenesis of staphylococcal disease.

Some strains produce one or more exoproteins, including the staphylococcal enterotoxins (SEA, SEB, SECn, SED, SEE, SEG, SEH, and SEI), the exfoliative toxins (ETA and ETB), TSS toxin-1 (TSST-1), and leukocidin. These toxins have unique potent effects on immune cells and other biologic effects as well, ultimately inhibiting host immune response.

TSST-1 and the staphylococcal enterotoxins are also known as *pyrogenic toxin superantigens*. These molecules act by binding directly to constitutively expressed HLA-DR molecules (major histocompatibility complex II) on antigen-presenting cells without antigen processing. Although conventional antigens require recognition by all five elements of the T-cell–receptor complex, superantigens require only the variable region of the β chain. As a result, 5 percent to 30 percent of resting T cells may be activated, whereas the "normal" antigenic response is only 0.0001 to 0.01 percent of T cells.[5] Non-specific T-cell activation leads to massive systemic release of cytokines, especially interleukin 2, interferon-γ, and tumor necrosis factor-β from T cells and interleukin 1 and tumor necrosis factor-α from macrophages.[6] Superantigen stimulation of T cells also results in activation and expansion of lymphocytes expressing specific T-cell–receptor variable region of the β chain. They may activate B cells, leading to high levels of immunoglobulin E (IgE) or autoantibodies.[7] Also, there is evidence that superantigens selectively induce cutaneous lymphocyte-associated antigen on T cells, thereby "homing" them to the skin.[8]

There are several other mechanisms by which *S. aureus* evades immune clearance. Approximately 60 percent of *S. aureus* strains secrete the chemotaxis inhibitory protein of staphylococci, which inhibits neutrophil chemotaxis. Additionally, protein A, staphylokinase, capsular polysaccharide, fibrinogen binding protein, and clumping factor A all act to aid in avoidance of being opsonized and phagocytosed. Staphylokinase and aureolysin bind and cleave antimicrobial peptides respectively, resulting in increased survival in vitro and probably in vivo.[1]

DRUG RESISTANCE A major problem in treating staphylococcal infections has been the emergence of antibiotic-resistant strains. With ever-increasing use of penicillins, methicillin-resistant *S. aureus* (MRSA) strains have become a major epidemiologic problem since the 1980s. Resistance to methicillin indicates pan-resistance to all β-lactam antibiotics. Recently, intermediate-level resistance of MRSA to vancomycin has emerged and constitutes a potential further problem in treatment. Although *S. aureus* infection prevalence has not changed much, in some countries the percentage of MRSA isolates of these infections has significantly increased. Those at higher risk for acquiring colonization or infection with MRSA are adults older than 65 years of age, the chronically ill, those with prolonged hospitalizations (especially surgical), exposure to others with MRSA, and prior antibiotic therapy. The main MRSA reservoirs are health care workers and hospitalized patients with subsequent transmission primarily through direct contact.[9]

Attempts to eradicate MRSA have generally been unsuccessful. Treatment of anterior nares and wounds with mupirocin ointment has been shown to decrease *S. aureus* colonization but in one study did not decrease the rate of transmission to a roommate in a long-term care facility.[10] Although there are many other reports of the use of topical mupirocin to reduce colonization of MRSA and methicillin-sensitive *S. aureus*, indiscriminate use of topical mupirocin must be avoided because significant mupirocin resistance has already emerged.

IMMUNITY The primary defense against *S. aureus* infections is the innate immunity provided by neutrophils. A major component of the innate response is antimicrobial peptides. These peptides can be found in various locales and include dermicidin, LL-37, protegrin, α-defensins and β-defensins, lactoferricin, and cascocidin. However, *S. aureus* also has the ability to thwart the immune system in several ways. One of the main virulence factors of *S. aureus* is the production of adhesins that facilitate binding to host epithelial cell surfaces. The almost universal presence in adults of circulating antibodies to one or more cell-wall antigens or extracellular toxins substantiates the high prevalence of staphylococcal infections. However, these antibodies are not the primary determinants of resistance to such infections. Recent evidence demonstrates that *S. aureus* can invade and survive in many types of host cells, suggesting that a cell-mediated immune response is required for killing intracellular organisms.

Clinical Findings

SUPERFICIAL STAPHYLOCOCCAL PYODERMAS Pyodermas are infections in the epidermis, just below the stratum corneum or in hair follicles. In industrialized nations, *S. aureus* is the most common cause of superficial pyodermas (Table 177-1), but group A streptococcus continues to be a common cause of pyoderma in developing countries. Untreated, pyodermas can extend to the dermis, resulting in ecthyma and furuncle formation.

Impetigo. Two clinical patterns of impetigo are recognized: bullous and non-bullous. Bullous impetigo is caused by *S. aureus*. Currently, in industrialized nations, non-bullous impetigo is most commonly caused by *S. aureus* and less often by group A streptococcus. Group A streptococcus remains a common cause of non-bullous impetigo in developing nations.

TABLE 177-1
Infections and Toxin Syndromes Involving the Skin and Soft Tissues Caused by *Staphylococcus aureus*

Sites of colonization (carrier state)
- Anterior nares
- Throat
- Axillae, perineum
- Hands
- Involved skin in individuals with atopic dermatitis

Sites of colonization in neonates (and sites of infection)
- Skin
- Umbilicus
- Circumcision site
- Conjunctivae

Superficial pyodermas
- Primary pyodermas
  - Skin
    - Impetigo
    - Bullous impetigo
    - Erythema
    - Botryomycosis
  - Hair follicles
    - Superficial folliculitis (follicular or Bockhart impetigo)
    - Folliculitis (sycosis barbae)
    - Furuncle (boil)
    - Carbuncle
  - Intertriginous sites
    - Perianal dermatitis
  - Digital infections
    - Paronychia
    - Blistering distal dactylitis
  - After skin disruption
    - Trauma (physical, thermal)
    - Foreign body (intravascular catheter, prosthetic device)
- Secondary pyodermas
  - Impetiginization of dermatoses such as atopic dermatitis, herpes simplex (superinfection)
  - Pyodermas associated with systemic disease
  - Job syndrome
  - Chédiak-Higashi syndrome
  - Chronic granulomatous disease

Invasive infections
- Lymphangitis, lymphadenitis
- Erysipelas
- Cellulitis
- Streptococcal gangrene
- Pyomyositis
- Bacteremia, septicemia

Metastatic skin infections associated with bacteremia (often *S. aureus* acute infections endocarditis)
- Abscesses (superficial and deep)
- Septic vasculitis (pustular purpura)

Purpura fulminans
- Disseminated intravascular coagulation associated with staphylococcal bacteremia
- Meningococcemia-like syndrome

Staphylococcal toxin–associated syndromes
- Staphylococcal scarlet fever
- Staphylococcal scalded-skin syndromes
- Staphylococcal toxic-shock syndrome

NON-BULLOUS IMPETIGO. The non-bullous type of impetigo accounts for more than 70 percent of cases of this form of pyoderma. It occurs in children of all ages as well as in adults. Intact skin is usually resistant to colonization or impetiginization, possibly due to absence of fibronectin receptors for teichoic acid moieties on *S. aureus* and group A streptococcus. Production of bacteriocins, produced by certain *S. aureus* strains (phage group 71) and highly bactericidal to group A streptococcus, may be responsible for the isolation of only *S. aureus* from some lesions initially caused by streptococci.

History. In a typical sequence, *S. aureus* spreads from nose to normal skin (approximately 11 days later) and then develop into skin lesions (after another 11 days). Lesions commonly arise on the skin of the face (especially around the nares) or extremities after trauma. Nasal carriers of *S. aureus* can present with a very localized type of impetigo confined to the anterior nares and the adjacent lip area (Fig. 177-1); pruritus or soreness of the area is a common complaint (Fig. 177-2). Conditions that disrupt the integrity of the epidermis, providing a portal of entry of impetiginization, include insect bites, epidermal dermatophytoses, herpes simplex, varicella, abrasions, lacerations, and thermal burns.

Differential Diagnosis. See Box 177-1 for differential diagnosis of non-bullous impetigo.

Cutaneous Lesions. The initial lesion is a transient vesicle or pustule (see Fig. 177-2) that quickly evolves into a honey-colored crusted plaque that can enlarge to greater than 2 cm in diameter (see Fig. 177-1). Surrounding erythema may be present. Constitutional symptoms are absent. Regional lymphadenopathy may be present in up to 90 percent of patients with prolonged, untreated infection. Untreated, the lesions may slowly enlarge and involve new sites over several weeks. In some individuals, lesions resolve spontaneously. In others, the lesions extend into the dermis, forming an ulcer (see Staphylococcal Ecthyma).

BULLOUS IMPETIGO. Three types of skin eruptions can be produced by phage group II *S. aureus*, particularly strains 77 and 55: (1) bullous impetigo, (2) exfoliative disease (SSSS), and (3) nonstreptococcal scarlatiniform eruption (staphylococcal scarlet fever). All three represent varying cutaneous responses to extracellular exfoliative toxins ("exfoliatin") types A and B produced by these staphylococci (see Chap. 178). Exfoliative toxin A acts as a serine protease of desmoglein 1, the desmosomal cadherin that is also the target of autoantibodies in pemphigus foliaceus.[11]

▲ **FIGURE 177-1** *Staphylococcus aureus:* Impetigo. Erythema and crusting on the nose and moustache area (**A**), which can spread to involve the entire centrofacial region (**B**).

In a study of bullous impetigo, 51 percent of patients had concurrent *S. aureus* cultured from the nose or throat, and 79 percent of cultures grew the same strain from both sites.

Cutaneous Lesions. Bullous impetigo occurs more commonly in the newborn and in older infants, and is characterized by the rapid progression of vesicles to flaccid bullae (Fig. 177-3). Decades ago, extensive bullous impetigo (archaic term: *pemphigus neonatorum* or *Ritter disease*) occurred in epidemics within neonatal nurseries.

Bullae usually arise on areas of grossly normal skin. The Nikolsky sign (sheet-like removal of epidermis by shearing pressure) is not present. Bullae initially contain clear yellow fluid that subsequently becomes dark yellow and turbid (see Fig. 177-3A), and their margins are sharply demarcated without an erythematous halo. The bullae are superficial, and within a day or two, they rupture and collapse, at times forming thin, light-brown to golden-yellow crusts (see Fig. 177-3B). So-called *bullous varicella* represents superinfection by *S. aureus* (phage group II) of varicella lesions (bullous impetiginization).

Laboratory Tests. Gram stain of exudates from bullous impetigo reveals Gram-positive cocci in clusters. *S. aureus* belonging to phage group II can be cultured from the contents of intact bullae.

Histologically, the lesions of bullous impetigo show vesicle formation in the sub-corneal or granular region, occasional acantholytic cells within the blister, spongiosis, edema of the papillary dermis, and a mixed infiltrate of lymphocytes and neutrophils around blood vessels of the superficial plexus.

Differential Diagnosis. See Box 177-2 for differential diagnosis of bullous impetigo.

▲ **FIGURE 177-2** *Staphylococcus aureus:* Nasal carriage with impetigo. Erythema with a small pustule on the tip of the nose and nares in individual whose nares are colonized by *S. aureus*.

Differential Diagnosis of Non-Bullous Impetigo

Consider

- Seborrheic dermatitis
- Atopic dermatitis
- Allergic contact dermatitis
- Epidermal dermatophyte infections
- Tinea capitis
- Herpes simplex
- Varicella
- Herpes zoster
- Scabies
- Pediculosis capitis

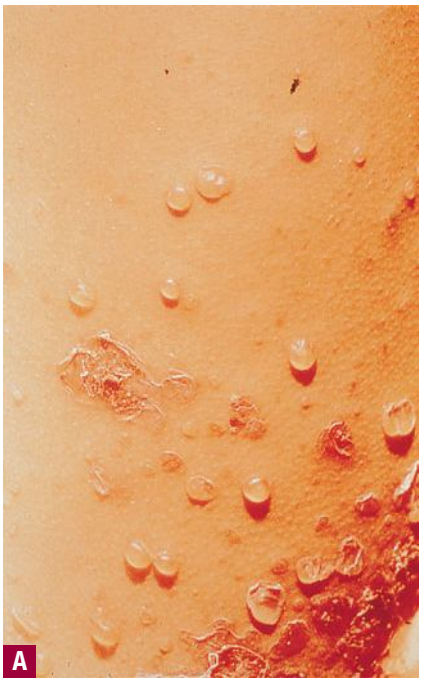
Always Rule Out

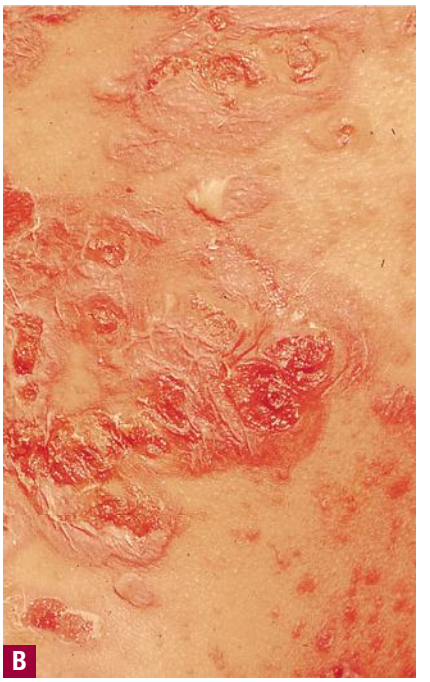
- Herpes simplex
- Herpes zoster
- Scabies

PROGNOSIS AND CLINICAL COURSE. Untreated, invasive infection can complicate *S. aureus* impetigo with cellulitis, lymphangitis, and bacteremia, resulting in osteomyelitis, septic arthritis, pneumonitis, and septicemia. Exfoliatin production can lead to SSSS in infants and in adults who are immunocompromised or have impaired renal function.

TREATMENT. Local treatment with mupirocin ointment or cream, removal of crusts, and good hygiene is sufficient to cure most mild to moderate cases (Box 177-3).[12] Systemic antibiotics may be required in extensive cases. The frequency of isolation of group A streptococcus makes such therapy a reasonable approach in most patients who have a significant degree of involvement. There is no role for general disinfectant treatments or bacitracin.[13]

Staphylococcal impetigo responds quite promptly to appropriate treatment. In an adult with extensive or bullous lesions, dicloxacillin (or similar penicillinase-resistant semi-synthetic penicillin), 250 to 500 mg orally (PO) four times daily (qid), or erythromycin (in the penicillin-allergic patient), 250 to 500 mg PO qid, should be given. Treatment should be continued for 5 to 7 days (10 days if streptococci are isolated). Also, a single course of oral azithromycin (in adults 500 mg on the first day, 250 mg daily on the next 4 days) has been shown to be equally as effective as dicloxacillin for skin infections in adults and children. For impetigo caused by erythromycin-resistant *S. aureus*, which is commonly isolated from impetigo lesions of children, amoxicillin plus clavulanic acid [25 mg/kg/day given three times a day (tid)],





▲ **FIGURE 177-3** *Staphylococcus aureus:* Bullous impetigo. **A.** Multiple vesicles with clear and turbid contents that (**B**) rapidly coalesce to form flaccid bullae.

cephalexin (40 to 50 mg/kg/day), cefaclor (20 mg/kg/day given tid), cefprozil (20 mg/kg once daily), or clindamycin (15 mg/kg/day tid or qid) given for 10 days are effective alternative therapies.

Staphylococcal Ecthyma. Ecthyma is a cutaneous pyoderma characterized by thickly crusted erosions or ulcerations. Ecthyma is usually a consequence of neglected impetigo and classically evolves in impetigo occluded by footwear and clothing. It thus is a lesion typically occurring in the homeless and soldiers in combat on maneuver in a humid and hot climate. *S. aureus* and/or group A streptococcus can be isolated on culture. Untreated staphylococcal or streptococcal impetigo can extend more deeply, penetrating the epidermis, producing a shallow crusted ulcer (Fig. 177-4). Ecthymatous lesions can evolve from a primary pyoderma or within a preexisting dermatosis or site of trauma. Ecthyma gangrenosum is a cutaneous ulcer caused by *P. aeruginosa* and resembles staphylococcal or streptococcal ecthyma (see Chap. 180).

Ecthyma occurs most commonly on the lower extremities of children, or neglected elderly patients, or individuals with diabetes. Poor hygiene and neglect are key elements in pathogenesis. Multiple ecthymatous ulcers on the ankle and dorsum of the foot were the most common pyodermas seen during wartime in tropical climates.[14]

The ulcer has a "punched out" appearance when the dirty grayish-yellow crust and purulent material are débrided. The margin of the ulcer is indurated, raised, and violaceous (see Fig. 177-4), and the granulating base extends deeply into the dermis. Untreated ecthymatous lesions enlarge over weeks to months to a diameter of 2 to 3 cm or more.

The lesions are slow to heal, requiring several weeks of antibiotic treatment for resolution. Problems of spread by autoinoculation or by insect vectors and of post-streptococcal sequela (glomerulonephritis) are the same as with impetigo.

Management of ecthyma is the same as for staphylococcal impetigo (see Box 177-3).

Folliculitis. Folliculitis is a pyoderma that begins within the hair follicle, and is classified according to the depth of invasion (superficial and deep), and microbial etiology (Table 177-2).

SUPERFICIAL FOLLICULITIS. Superficial folliculitis has also been termed *follicular* or *Bockhart impetigo*. A small, fragile, dome-shaped pustule occurs at the infundibulum (ostium or opening) of a hair follicle, often on the scalps of children and in the beard area (Fig. 177-5), axillae, extremities, and buttocks of adults. Isolated staphylococcal folliculitis is common on the buttock of adults. *Periporitis staphylogenes* refers to secondary infection of miliaria of the neonate by *S. aureus*. Staphylococcal blepharitis is an *S. aureus* infection of the eyelids, presenting with scaling or crusting of the eyelid margins, often with associated conjunctivitis; the differential diag-

Differential Diagnosis of Bullous Impetigo

Consider

- Contact dermatitis
- Bullous insect bites
- Bullous tinea
- Bullous fixed drug reaction
- Bullous drug eruption
- SSSS
- Thermal burns
- Pemphigus vulgaris
- Bullous pemphigoid
- Erythema multiforme
- Dermatitis herpetiformis

Always Rule Out

- Herpes simplex
- Varicella
- Bullous tinea
- Bullous fixed drug reaction
- Bullous drug eruption
- SSSS

SSSS = staphylococcal scalded-skin syndrome.
Note: Any of these disorders may occur primarily and become secondarily impetiginized with *Staphylococcus aureus* or group A streptococcus.

Box 177-3

Treatments for Impetigo[a]

	TOPICAL		SYSTEMIC	
First line	Mupirocin	bid	Dicloxacillin	250–500 mg PO qid for 5–7 days
	Fusidic acid (not available in United States)	bid	Amoxicillin plus clavulanic acid; cephalexin	25 mg/kg tid; 250–500 mg qid
Second line (penicillin allergy)			Azithromycin	500 mg × 1, then 250 mg daily for 4 days
			Clindamycin	15 mg/kg/day tid
			Erythromycin	250–500 mg PO qid for 5–7 days

[a]Washing and hygiene are important in all regimens.

▲ **FIGURE 177-4** *Staphylococcus aureus:* Ecthyma. Multiple thickly crusted ulcers on the leg of a patient with diabetes and renal failure. Ecthymatous lesions were also present on the other leg, the arms, and the hands.

nosis includes seborrheic dermatitis and rosacea of the eyelid.

S. aureus folliculitis must be differentiated from other folliculocentric infections. Also, three non-infectious, inflammatory, follicular disorders are more common in black men: pseudofolliculitis barbae, which occurs on the lower beard area (Fig. 177-6); folliculitis keloidalis or acne keloidalis nuchae, on the nape of the neck; and perifolliculitis capitis, on the scalp. *S. aureus* can cause secondary infection in these inflammatory disorders. Exposure to mineral oils, tar products, and cutting oils can cause an irritant folliculitis. Acne vulgaris, drug-induced acneform eruptions, rosacea, hidradenitis suppurativa, acne necrotica of the scalp, and eosinophilic folliculitis of HIV disease must be distinguished from infectious folliculitis as well. Also, "hot tub" folliculitis may be caused by *P. aeruginosa* (see Chap. 180).

DEEP FOLLICULITIS. Sycosis barbae is a deep folliculitis with perifollicular inflammation occurring in the bearded areas of the face and upper lip (Fig. 177-7). If untreated, the lesions may become more deeply seated and chronic. Local treatment with warm saline compresses and local antibiotics (mupirocin or topical clindamycin) may be sufficient to control infection. More extensive cases require systemic antibiotic therapy. Dermatophytic folliculitis must be differentiated from *S. aureus* folliculitis. In fungal infections, hairs are usually broken or loosened, and there are suppurative or granulomatous nodules rather than pustules. Also, in dermatophytic folliculitis plucking of hairs is usually painless (see Chap. 188).

Lupoid sycosis is a deep, chronic form of sycosis barbae associated with scarring, usually occurring as a circinate lesion. A central cicatrix surrounded by pustules and papules gives the appearance of lupus vulgaris (see Chap. 184).

TABLE 177-2
Classification of Infectious Folliculitis

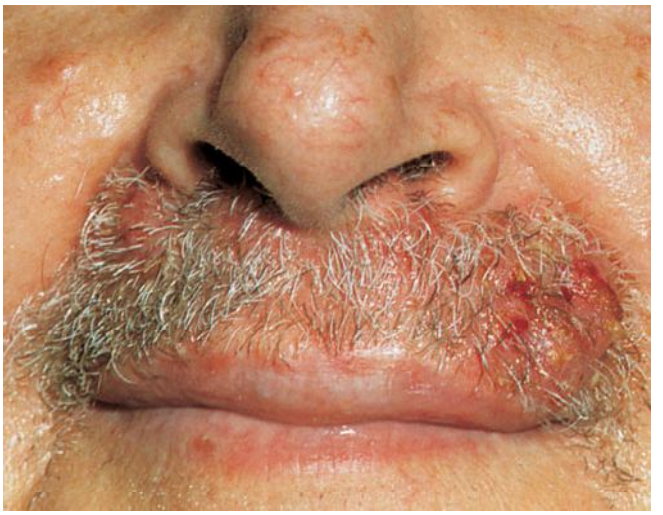
- Bacterial folliculitis
  - *Staphylococcus aureus* folliculitis
    - Periporitis staphylogenes
    - Superficial (follicular or Bockhart impetigo)
    - Deep (sycosis) [may progress to furuncle (boil) or carbuncle]
  - *Pseudomonas aeruginosa* folliculitis ("hot tub" folliculitis)
  - Gram-negative folliculitis (occurs at the site of acne vulgaris, usually the face, with long-term antibiotic therapy)
  - Syphilitic folliculitis (secondary; acneform)
- Fungal folliculitis
  - Dermatophytic folliculitis
    - Tinea capitis
    - Tinea barbae
    - Majocchi granuloma
  - *Pityrosporum* folliculitis
  - *Candida* folliculitis
- Viral folliculitis
  - Herpes simplex virus folliculitis
  - Follicular molluscum contagiosum
- Infestation
  - Demodicidosis

▲ **FIGURE 177-6** Pseudofolliculitis barbae. Multiple papules in the lower beard area caused by ingrowing of the curved hair shaft in a black man who shaves. If pustules are present, secondary *Staphylococcus aureus* infection must be ruled out.

Furuncles and Carbuncles. A furuncle or boil is a deep-seated inflammatory nodule that develops around a hair follicle, usually from a preceding, more superficial folliculitis and often evolving into an abscess. A carbuncle is a more extensive, deeper, communicating, infiltrated lesion that develops when suppuration occurs in thick inelastic skin when multiple, closely set furuncles coalesce.

FURUNCLES. Furuncles arise in hair-bearing sites, particularly in regions subject to friction, occlusion, and perspiration, such as the neck, face, axillae, and buttocks. They may complicate pre-existing lesions such as atopic dermatitis, excoriations, abrasions, scabies, or pediculosis, but occur more often in the absence of any local predisposing causes. In addition, a variety of systemic host factors is associated with furunculosis: obesity, blood dyscrasias, defects in neutrophil function (defects in chemotaxis associated with eczema and high levels of IgE, defects in intracellular killing of organisms as in

◀ **FIGURE 177-5** *Staphylococcus aureus:* Superficial folliculitis. Multiple pustules confined to the beard area.



▲ **FIGURE 177-7** Sycosis barbae. Deep staphylococcal folliculitis of the mustache region.

chronic granulomatous disease of childhood), treatment with glucocorticoids and cytotoxic agents, and immunoglobulin deficiency states. The process is often more extensive in patients with diabetes. The majority of patients with problems of furunculosis appear to be otherwise healthy.

Cutaneous Lesions. A furuncle starts as a hard, tender, red folliculocentric nodule in hair-bearing skin that enlarges and becomes painful and fluctuant after several days (i.e., undergoes abscess formation; Fig. 177-8A). Rupture occurs, with discharge of pus and often a core of necrotic material. The pain surrounding the lesion then subsides, and the redness and edema diminish over several days to several weeks. Furuncles may occur as solitary lesions or as multiple lesions in sites such as the buttocks (see Fig. 177-8B).

▲ **FIGURE 177-8** **A.** Furuncle of the upper lip. The lesion is nodular, and the central necrotic plug is covered by purulent crust. Several small pustules are seen lateral to the center of the lesion. **B.** Multiple furuncles. Multiple abscesses on the buttocks of long standing in a young man with inflammatory bowel disease. The lesions healed with scarring after a prolonged course of dicloxacillin.

Differential Diagnosis. See Box 177-4 for differential diagnosis of furunculosis.

CARBUNCLES. A carbuncle is a larger, more serious inflammatory lesion with a deeper base, characteristically occurring as an extremely painful lesion at the nape of the neck, the back, or thighs (Fig. 177-9). Fever and malaise are often present, and the patient may appear quite ill. The involved area is red and indurated, and multiple pustules soon appear on the surface, draining externally around multiple hair follicles. The lesion soon develops a yellow-gray irregular crater at the center, which may then heal slowly by granulating, although the area may remain deeply violaceous for a prolonged period. The resulting permanent scar is often dense and readily evident.

LABORATORY TESTS. Extensive furunculosis or a carbuncle may be associated with leukocytosis. *S. aureus* is almost always the cause. Histologic examination of a furuncle shows a dense polymorphonuclear inflammatory process in the dermis and subcutaneous fat. In carbuncles, multiple abscesses, separated by connective-tissue trabeculae, infiltrate the dermis and pass along the edges of the hair follicles, reaching the surface through openings in the undermined epidermis. The diagnosis is made on the basis of the clinical appearance. Gram stain of pus, clusters of Gram-positive cocci, or isolation of *S. aureus* on culture confirms the diagnosis.

PROGNOSIS AND CLINICAL COURSE. The major problems with furunculosis and carbuncles are bacteremic spread of infection and recurrence. Lesions about

- Apical dental abscess
- Osteomyelitis

▲ **FIGURE 177-9** Carbuncle. This lesion represents multiple confluent furuncles draining pus from multiple openings.

the lips and nose raise the specter of spread via the facial and angular emissary veins to the cavernous sinus. Invasion of the bloodstream may occur from furuncles or carbuncles at any time, in an unpredictable fashion, resulting in metastatic infection such as osteomyelitis, acute endocarditis, or brain abscess. Manipulation of such lesions is particularly dangerous and may facilitate spread of infection via the bloodstream. Fortunately, these complications are not common. Recurrent furunculosis is a troublesome process that may continue for many years.

Treatment. Simple furunculosis may be aided by local application of moist heat. A carbuncle or a furuncle with surrounding cellulitis, or one with associated fever, should be treated with a systemic antibiotic (as for impetigo; see Box 177-3). For severe infections or infections in a dangerous area, maximal antibiotic dosage should be employed by the parenteral route. If MRSA is implicated or suspected in serious infections, vancomycin (1.0 to 2.0 g intravenously daily in divided doses) is indicated. Antibiotic treatment should be continued for at least 1 week.

When the lesions are large, painful, and fluctuant, then incision and drainage is critical. If the infection is recurrent or complicated by co-morbidities, a culture can be sent. Antimicrobial therapy should be continued until all evidence of inflammation has regressed and altered appropriately as culture results become available. Draining lesions should be covered to prevent autoinoculation and diligent hand washing performed. Patients with recurrent furunculosis present a special and frequently exasperating problem (Table 177-3).

TABLE 177-3
Management of Recurrent Furunculosis

- Careful evaluation for underlying causes.
  - Systemic processes: Previously discussed.
  - Specific localized predisposing factors: Industrial exposure to chemicals, oils; poor hygiene; obesity; hyperhidrosis; ingrown hairs; pressure from tight clothing or belts.
  - Sources of staphylococcal contact: Pyogenic infections in the family, contact sports such as wrestling, autoinoculation.
  - Nasal carriage of *Staphylococcus aureus*: This is the site from which dissemination of the organism may occur to other body sites. The frequency of nasal carriage varies: 10%–15% in infants 1 yr of age, 38% in college students, 50% in hospital physicians and military trainees.
- General skin care: The aim of these measures is to reduce the numbers of *S. aureus* on the skin. General skin care of both hands and body with water and soap is important (an antimicrobial soap solution, such as 4% chlorhexidine solution, may be used to decrease staphylococcal skin colonization). The patient should avoid trauma to the skin as well as potential skin irritants such as strong soaps and deodorants. A separate washcloth (and towel) should be used and carefully washed in hot water before use.
- Care of clothing: Loose, lightweight, porous clothing should be worn as much as possible. Large numbers of staphylococci are frequently present on the sheets and underclothing of patients with furunculosis and may cause re-infection of the patient and infection of other members of the family. In problem cases, it is not unreasonable to recommend that these items be carefully and separately washed in boiling water and changed daily.
- Care of dressings: Dressings should be changed frequently if purulent drainage collects. They should be carefully discarded in a paper bag that can be sealed and disposed of immediately.
- General measures: Despite the above measures, some patients continue to have recurrent cycles of lesions. Sometimes, the problem can be ameliorated or abolished by removing the patient from the regular routine of work. This is particularly pertinent in individuals who are under considerable emotional stress and physical fatigue. A vacation for several weeks, ideally in a cool, dry climate, may help considerably by providing rest and also the time needed for carrying out the program of careful skin care.
- Measures aimed at elimination of nasal (and skin) carriage of *S. aureus* (methicillin-susceptible or methicillin-resistant):
  - Local use of ointment in the nasal vestibule reduces nasal carriage of *S. aureus* and secondarily reduces the "shedding" of organisms on the skin, a process that may contribute to recurrent furunculosis. Intranasal application of a 2% mupirocin calcium ointment in a white, soft, paraffin base for 5 days can eliminate *S. aureus* nasal carriage in 70% of healthy individuals for up to 3 mo. In immunocompetent staphylococcal carriers with recurrent skin infections, a 5-day course of nasal mupirocin ointment every month for 1 yr resulted in positive nasal cultures in only 22% of patients as compared with 83% in the placebo group. The nasal culture–negative patients also had significantly fewer skin infections during the treatment period. Staphylococcal resistance to mupirocin was observed in only 1 patient out of 17. Prophylaxis with fusidic acid ointment in the nares twice daily every fourth week for the patient and family members who are nasal carriers of the infecting strain (along with peroral anti-staphylococcal antibiotic for 10–14 days for the patient) has been used with some success.
  - Oral antibiotics (e.g., rifampin, 600 mg orally daily for 10 days) have been effective in eradicating *S. aureus* from most nasal carriers for periods of up to 12 weeks. Such a use of rifampin for a brief period to eradicate nasal carriage of *S. aureus* and interrupt a continuing cycle of recurrent furunculosis might be reasonable in a patient in whom other measures have failed. However, selection of rifampin-resistant strains can occur rapidly with such therapy. The addition of a second drug (dicloxacillin for methicillin-susceptible *S. aureus*; trimethoprim-sulfamethoxazole, ciprofloxacin, or minocycline for methicillin-resistant *S. aureus*) has been used to reduce the emergence of rifampin resistance and to treat recurrent furunculosis.

▲ **FIGURE 177-10** *Staphylococcus aureus* abscess. A large painful abscess on the heel of a patient with diabetes improved clinically; however, the severe pain persisted. X-ray films of the heel revealed a broken-off sewing needle. The patient had sensory neuropathy and was unaware of stepping on this foreign body.

Abscess. As discussed in Furuncles and Carbuncles, abscesses caused by *S. aureus* commonly occur in folliculocentric infections—that is, folliculitis, furuncles, and carbuncles. Abscesses can also occur at sites of trauma, foreign bodies, burns, or sites of insertion of intravenous catheters. The initial lesion is an erythematous nodule. If untreated, the lesion often enlarges, with the formation of a pus-filled cavity (Fig. 177-10).

The initial and most important treatment of an abscess is incision and drainage and antibiotic treatment as for furuncles.

Botryomycosis. (See Chap. 190) Botryomycosis is a rare pyogenic disease, possibly related to a balance between numbers of organisms and host defenses, presenting as a purulent chronic, subcutaneous infection. Predisposing factors include trauma, immunosuppression (HIV disease, hyper-IgE syndrome), chronic alcoholism, and diabetes mellitus. Lesions (usually solitary) can occur in skin, bone, and liver.

▲ **FIGURE 177-11** *Staphylococcus aureus* botryomycosis. A plaque on the chest had been present for several months in this human immunodeficiency virus–infected individual. The diagnosis was confirmed on lesional biopsy findings and culture.

Cutaneous botryomycosis usually presents as a solitary lesion or a few lesions, often occurring in the genital area. The lesion has the gross appearance of a ruptured epidermal inclusion cyst (an erythematous circumscribed tender nodule), or prurigo nodularis (Fig. 177-11). In the majority of reported cases, a foreign body (fish bone, broom straw, etc.) has played a role in initiating or perpetuating the lesion. For diagnosis and treatment, see Chap. 185.

Staphylococcal Paronychia. Individuals exposed to hand trauma or chronic moisture are predisposed to staphylococcal paronychia, as well as to other causes of paronychia (e.g., *Candida, Pseudomonas, Streptococcus,* dermatophytes). *S. aureus* is the major infectious cause of acute paronychia, usually around the fingernails, often originating from a break in the skin, such as a hangnail. Clinically, skin and soft tissue of the proximal and lateral nail fold are red, hot, and tender, and, if not treated, can progress to abscess formation (Fig. 177-12).

In contrast, chronic or recurrent paronychia caused by *C. albicans* is an infection of the space created by separation of the proximal dorsal nail plate and the undersurface of the proximal nail fold. Candidal paronychia is most common in individuals who have their hands in water for a great deal of time (see Chap. 189)

Management of paronychia caused by *S. aureus* includes oral and topical antibiotics, and incision and drainage of abscesses.

▲ **FIGURE 177-12** *Staphylococcus aureus* paronychia. An abscess is seen in the dorsum of the finger, beginning in a small break in the cuticle. In contrast, *Candida* paronychia is a space infection, occurring in the space created by the separation of the proximal dorsal nail plate and the overlying proximal nail fold.

Staphylococcal Whitlow (Felon). A whitlow is a purulent infection or abscess involving the bulbous distal end of the finger. The most common causes are *S. aureus* and herpes simplex virus. The portal of entry of *S. aureus* is a traumatic injury or possible extension of an acute paronychia. This infection is usually very painful. An obvious portal of entry is often apparent. The finger bulb is red, hot, tender, and edematous, with possible abscess formation (Fig. 177-13). In contrast, individuals with herpetic whitlows usually have a history of lesions occurring in the same site and present with grouped hemorrhagic vesicles, which may be-

▲ **FIGURE 177-13** *Staphylococcus aureus* whitlow (felon). A pyogenic granuloma arose 1 week after trauma to the bulb of the thumb. A week later, the bulb became swollen, erythematous, and very tender. Abscess formation is seen with loculation of pus. X-ray films showed early osteomyelitis complicating the whitlow.

come confluent and form a single bulla (see Chap. 193). Management of a staphylococcal whitlow requires surgical drainage of loculated abscess(es) within the tissue and intravenous antibiotic therapy. X-ray examination of the involved finger is indicated to determine the presence of osteomyelitis.

SYNDROMES CAUSED BY STAPHYLOCOCCAL EXOTOXINS SSSS, staphylococcal scarlatiniform eruption, TSS, recalcitrant erythematous, desquamating disorders (red disorders) and recurrent toxin-mediated perineal erythema are syndromes caused by staphylococcal exotoxins and are discussed in Chap. 178.

STREPTOCOCCAL SKIN INFECTIONS

General Features

EPIDEMIOLOGY Group A streptococci are usually spread by transfer of organisms from an infected person or carrier through close personal contact. The major source of such spread is from patients with infections in the upper respiratory tract. Approximately 10 percent of the normal population carry group A streptococcus asymptomatically—a higher percentage of adults than of children in the oropharynx and less commonly in the nares and anus. Although the carriage rate of group A streptococcus on normal skin is less than 1 percent, a variety of skin lesions and puerperal sepsis may also be the source of intrahospital spread of infection. Group A streptococci introduced into the operating room in the form of a minor skin infection, or even through perianal carriage by a surgeon or anesthetist, may be responsible for an epidemic of streptococcal wound infections.

The major factor in the spread from a carrier or an infected person is the proximity to the individual disseminating the organisms. Because many patients with group A streptococcal (GAS) skin infections harbor the same organism in their pharynxes, they are, for both reasons, potential sources for spread of infection in a hospital. Particular care must be taken to prevent spread of infection by isolating such patients until antibiotic therapy has rendered them noncontagious.

The overall incidence of streptococcal disease has surged since the mid-1980s.[15] Reports of invasive GAS infections often associated with shock and multiorgan failure have increased globally. Localized epidemics continue to appear and, during such outbreaks, the carrier and infection rates in the community increase. After recovery (without antibiotic treatment) from streptococcal pharyngitis, some individuals may carry the organism for prolonged periods. The carrier state may also occur in the absence of overt antecedent infection. Fifteen percent to twenty percent of schoolchildren carry group A streptococci in the throat.

ETIOLOGY AND PATHOGENESIS The Lancefield classification of streptococcal groups (A to T) is based on the C carbohydrate antigens of the cell wall. Although essentially all GAS strains are β-hemolytic streptococci, not all streptococci producing β-hemolysis belong to group A. Because serologic grouping of streptococci is not generally available, a reasonably accurate presumptive test for group A streptococci is necessary. Bacitracin disk ("Taxos S") sensitivity has been widely used; group A streptococci are, almost without exception, susceptible to the low concentration of bacitracin contained in the disk, whereas streptococci of other groups are often resistant. Subtyping of group A streptococci can be performed according to their M protein antigenicity (see below). Certain M protein serotypes appear to correlate with greater virulence of the organism. The M protein inhibits phagocytosis, promotes adherence to host cells and allows bacterial growth in human blood.[16] The M protein is highly polymorphic, with more than 150 variants coded for by the *emm* gene. Other virulence factors are cell surface molecules, including the hyaluronic acid capsule, C5a peptidase, opacity factor, and streptococcal inhibitor of complement. Secreted proteins playing a role in virulence include streptolysins O and S, cysteine proteinase, pyrogenic exotoxins, streptokinase, hyaluronidase, and other enzymes. It should be noted that horizontal gene transfer in GAS strains is a very common event. This transfer results in the rapid development of new and more virulent strains.[17]

The primary invasive streptococcal pyodermas are due almost exclusively to group A streptococcus, which is usually considerably more invasive than of other streptococci. Non-suppurative post-infectious complications have been limited mostly to those produced by group A streptococcus. Thus, GAS infections merit antibiotic treatment and eradication.

The hallmarks of invasive GAS infection are profuse edema, rapid spread through tissue planes, and a relatively thin exudative response. Infection may spread via the lymphatic or hematogenous routes and result in a fulminant clinical course.

The presence of streptococci of groups other than A in skin lesions may represent either surface colonization or actual secondary infection in pre-existing dermatoses. Group C and group G streptococci have occasionally been implicated in impetiginous lesions, secondarily infected dermatitis, wound infections with lymphangitis, and even in erysipelas and cellulitis (see Chap. 179). Streptococci of groups B and D have been isolated from infections of skin lesions secondary to ischemia or venous stasis and have particularly involved the perineal area and operative wound sites. As with most secondary infections, those due to group B and group D streptococci are frequently mixed infections with enteric bacteria or *S. aureus*. Group B streptococci may cause cellulitis and otitis in neonates and, sometimes, in adults. Group L streptococci (often carried by pigs, cattle, and poultry) have been responsible for impetigo, secondarily infected wounds, and paronychias in meat handlers.

The incidence of invasive complications (lymphangitis, suppurative lymphadenitis, bacteremia) of streptococcal infections of the skin has decreased in the antibiotic era. Other than these pyogenic complications, a variety of non-suppurative complications (acute rheumatic fever, acute glomerulonephritis, erythema nodosum) may follow GAS infections. Distinct differences exist between acute rheumatic fever and acute glomerulonephritis in the site of the antecedent infection, the length of the latent period, and the streptococcal serotypes involved. Acute rheumatic fever may be a complication of GAS pharyngitis or tonsillitis, but it does not occur after streptococcal skin infections. In contrast, acute nephritis may follow infection of either the skin or the upper respiratory tract. The latent period between streptococcal pharyngitis and the onset of rheumatic fever is 2 to 3 weeks; whereas the latent period for pharyngitis-associated nephritis is approximately 10 days. A longer latent period of approximately 3 weeks is characteristic of acute nephritis associated with streptococcal pyoderma.

Group A streptococci are classified into over 80 sub-types, based on the antigenicity of their M proteins (fibrillar structures extending out from the cell surface). Although there is as yet no strong evidence

of an association between infection with any specific group A serotypes and the subsequent development of rheumatic fever, several serotypes (particularly mucoid strains of types 1, 3, and 18) have been implicated in a few outbreaks of streptococcal sore throat complicated by this sequela.[18] However, there is a clear relationship between infection with certain serotypes and the subsequent occurrence of nephritis—the so-called *nephritogenic serotypes*. Type 12 is the classic serotype responsible for pharyngitis-associated acute nephritis, but other serotypes, such as 1, 4, 25, and 49, have been implicated. The pyoderma-associated nephritogenic strains generally belong to different serotypes: types 2, 49, 42, 55, 56, 57, and 60.[19,20] Unlike the pharyngitis strains, the pyoderma serotypes produce lipoproteinase or opacity factor, illustrating a fundamental difference between the two.[15] The skin rather than the pharynx is the principal site of antecedent streptococcal infection causing nephritis, and impetigo is now the most common form of such predisposing skin infections.

The frequency of acute glomerulonephritis after infection with a known nephritogenic strain is 10 percent to 15 percent; the frequency of rheumatic fever after an unrecognized or inadequately treated pharyngeal infection by any serotype of group A streptococcus is 2 percent to 3 percent or less. The distinction between nephritogenic and other strains of streptococci that might be associated with rheumatic fever can be seen in studies from Trinidad, a hyperendemic area for pyoderma-associated nephritis. There the streptococcal serotypes causing outbreaks of nephritis differed from the serotypes associated with sporadically occurring cases of acute rheumatic fever in the same population.[18]

It has been suggested that several biologic properties are associated with broad categories of group A streptococci. Most M proteins fall into one of two antigenic classes based on the presence (class I) or absence (class II) of a highly conserved antigenic domain. Almost all rheumatic fever outbreak–associated strains belong to serotypes of class I and require a precursor nasopharyngeal infection. However, because many class I serotypes are associated with impetigo as well, and because class II serotypes are responsible for both upper respiratory and skin infections, the class of M protein alone is not a determinant of tissue tropism. Current evidence indicates differences among class I organisms that may relate to their capacities to induce rheumatic fever: Class I nasopharyngeal isolates appear to lack human IgG-binding activity, whereas nearly all impetigo isolates of the same class bear human IgG receptors.[21]

As in *S. aureus*, there are several GAS superantigens that have been identified. These include streptococcal pyrogenic exotoxin (or erythrogenic exotoxin) A to C, F, and G to J, streptococcal superantigen, and streptococcal mitogenic exotoxin Z. These superantigens are associated with disease.[22]

ANTIBODY RESPONSE AND IMMUNITY The immune response to GAS infection depends to a large measure on the site of infection. *Streptococcal infection* is usually defined as a positive throat culture with a serologic response to group A streptococcus and the streptococcal carrier state by a positive throat culture and no serologic response. After streptococcal pharyngitis, specific antibodies develop to many of the extracellular enzymes of the streptococci. Eighty-five percent of patients with acute rheumatic fever and a proven preceding streptococcal infection have an elevated or increasing antistreptolysin O titer. The serologic demonstration of an antecedent streptococcal infection in this situation can be increased to virtually 100 percent by the simultaneous testing for several other antibodies (antihyaluronidase, anti-DNase B). Antibodies to extracellular products, with the exception of antibody to the erythrogenic toxin of scarlet fever, appear to have no effect on the manifestations of illness. Streptococcal immunity is type specific (but not group specific), long-lasting, and depends on the production of bactericidal antibodies to the specific M proteins of the over 80 different serotypes of group A organisms. Although recurrent pharyngeal infections caused by the same serotype are most unusual, repeated clinical infections caused by different types are not uncommon. Early treatment of streptococcal upper respiratory tract disease with antibiotics may suppress the appearance of type-specific antibody (and immunity), as well as the development of antibody to the extracellular products of the organism.

In contrast to pharyngeal infections, the antistreptolysin O response with streptococcal skin infections or pyoderma-associated nephritis is weak. To define the latter serologically, anti-DNase B titers are much more reliable. Although pyoderma strains of streptococci produce M proteins, and although type-specific antibody may develop in patients with pyoderma-associated nephritis, the frequency of production of such antibodies and their role in protection against re-infection are unclear. Although pharyngeal re-infection with the same streptococcal serotype is probably unusual, some evidence suggests that the same serotype can be associated with repeated episodes of pyoderma.

TABLE 177-4
Infections and Toxin Syndromes Caused by Group A Streptococci

- Superficial pyodermas
  - Nonintertriginous skin
    - Impetigo
    - Ecthyma
    - Blistering distal dactylitis
  - Intertriginous skin
    - Perianal streptococcal cellulites
    - Streptococcal vulvovaginitis
    - Streptococcal intertrigo
- Invasive infections
  - Acute lymphangitis
  - Erysipelas
  - Cellulitis
  - Streptococcal gangrene
  - Bacteremia, septicemia
- Toxin-associated syndrome
  - Scarlet fever
  - Streptococcal toxic-shock–like syndrome
  - Streptococcal gangrene
- Non-suppurative complications
  - Rheumatic fever
  - Glomerulonephritis
- Other associated cutaneous reaction patterns
  - Erythema nodosum
  - Erythema multiforme
  - Guttate-pattern psoriasis
  - Vasculitis

Specific diseases caused by group A (and other) streptococci are listed in Table 177-4. Streptococcal pyodermas include all types of superficial streptococcal skin infections except erysipelas—that is, impetigo, ecthyma, and secondary infections of pre-existing skin lesions (e.g., insect bites, abrasions, eczema). Streptococcal intertrigo such as streptococcal perianal "cellulitis" can occur primarily or secondarily in underlying conditions such as inverse psoriasis.

Impetigo

EPIDEMIOLOGY Impetigo caused by group A streptococcus is a highly communicable infection and occurs predominantly in preschool-aged children (usually before the age of 2 years except in highly endemic areas). It is more common in warmer, more humid climates than in

temperate zones. Its peak seasonal incidence is in the later summer and early fall. Non-group A (groups B, C, and G) streptococci may be responsible for rare cases of impetigo; group B streptococci are associated with impetigo in the newborn. Whereas many different serotypes of group A streptococci may cause pharyngitis, a limited number of newly described types predominate in impetigo (types 49, 52, 53, 55, 56, 57, 59, and 61).

ETIOLOGY AND PATHOGENESIS Group A streptococci appear on normal skin of children approximately 10 days before the development of impetigo, and they are not recovered from the nose and throat of the same patients until 14 to 20 days after skin acquisition of the organism. Streptococci are recovered from the respiratory tract of approximately 30 percent of children with skin lesions, but there is no clinical evidence of streptococcal pharyngitis. Thus, the sequence of spread in a given patient is from normal skin to lesions and eventually to the respiratory tract.[23] In contrast, the sequence of spread of *S. aureus* (in cases of impetigo in which it is the only organism isolated) is from nose, to normal skin, to skin lesions (see Impetigo).

When exposed to an infectious contact, pre-existing lesions, such as scabies, varicella, or eczema, predispose to the appearance of infected lesions. Crowding, poor hygiene, and neglected minor skin trauma contribute to the spread of streptococcal impetigo in families. Minor outbreaks have also occurred among athletes involved in contact sports. Although the majority of cases occur in children, particularly of preschool age, young adults are also affected. The inflammatory process of impetigo is superficial, with a unilocular vesicopustule located between the stratum corneum above and the stratum granulosum below. This is usually situated near the opening of a hair follicle. Organisms, as well as leukocytes and cell debris, fill the vesicle.

CLINICAL FINDINGS ***Cutaneous Lesions.*** Impetigo caused by group A streptococcus presents as a crusted superficial infection of the skin; an initial vesicular phase has been described but is rarely detected. Lesions are clinically indistinguishable from impetigo caused by *S. aureus*, with the exception of bullous impetigo (see Non-Bullous Impetigo and Figs. 177-1 to 177-3). Pruritus and burning may occur, but the lesions are usually painless. Systemic response is minimal unless complications occur.

Laboratory Tests. A slight leukocytosis may occur. A Gram-stained smear of early vesicle fluid reveals Gram-positive cocci in chains. Culture of the weeping area or of the area beneath an unroofed crust reveals group A streptococci or a mixture of streptococci and *S. aureus* (particularly from older crusted lesions).

PROGNOSIS AND CLINICAL COURSE Untreated, the process may persist and new lesions may develop over the course of several weeks; thereafter, the infection tends to resolve spontaneously unless there is some underlying cutaneous disorder such as eczema. Untreated, some lesions become chronic and deeper, such as ecthyma (see Staphylococcal Ecthyma). Complicating erysipelas, cellulitis, or bacteremia are unusual. The major serious sequela is acute post-streptococcal glomerulonephritis.

TREATMENT Topical treatment (removal of dirt, crusts, and debris by soaking with soap and water) is a valuable adjunct. Mupirocin ointment appears to be as effective as parenteral or oral penicillin for treatment of impetigo.[24]

In superficial pyodermas known to be caused by group A streptococcus, penicillin is the drug of choice, administered either as a single injection of long-acting benzathine penicillin (300,000 to 600,000 units for children; 1.2 million units for adults) or orally (25,000 to 100,000 units/kg/day in divided doses q6h for 10 days). Although penicillin treatment clears the lesions of GAS impetigo and prevents recurrence for a short time, streptococci can persist on or newly colonize unaffected skin in spite of this therapy. Erythromycin (30 to 50 mg/kg/day PO in divided doses q6h for children; 250 to 500 mg PO q6h for adults administered for 10 days) is a suitable alternative drug in patients allergic to penicillin. However, it should be noted that 20 percent or more of GAS strains became resistant to erythromycin in areas (Japan, Finland) where this antibiotic had been extensively used for a variety of indications.[25] There is still no evidence to suggest that treatment of GAS pyoderma can prevent subsequent nephritis in any individual. Although the latent period after impetigo is longer than that after pharyngeal infection, the mildness of the illness delays or negates the seeking of medical attention.

Practically, however, the majority of cases of non-bullous impetigo are caused by *S. aureus*, and topical or systemic antimicrobial treatment should be directed at that pathogen (see Box 177-3).

Streptococcal Ecthyma

See Staphylococcal Ecthyma.

Intertriginous Streptococcal Infections

Streptococcal pyodermas occur much less commonly in occluded sites such as the perineum/perianal region, vulva/vagina, axillae (Fig. 177-14), inframammary region, groin, preputial sac, and web spaces of the feet. Perianal (group A) streptococcal "cellulitis" occurs principally in children, presenting with intense perianal erythema (Fig. 177-15), pain on defecation, blood-streaked stools associated with anal fissures, and chronicity if untreated.[26] It is often confused with psoriasis, candidiasis, seborrheic dermatitis, inflammatory bowel disease, pinworm infection, or a behavioral problem. The infection can also involve the penis and vulva. Treatment options include oral antibiotics or topical mupirocin. Guttate psoriasis has also occurred in children, associated with perianal streptococcal infection.[27]

BLISTERING DISTAL DACTYLITIS Group A streptococcus is responsible for the majority of cases of blistering distal dactyli-

▲ **FIGURE 177-14** Group A streptococcus intertrigo. A sharply marginated erythematous and oozing plaque in the axilla, which was also present in the other axilla, inframammary area, and inguinal folds, was painful in this human immunodeficiency virus–infected woman.

▲ **FIGURE 177-15** Group A streptococcus intertrigo—perianal streptococcal cellulitis. Well-demarcated erosive erythema in the perianal region and perineum in an 8-year-old boy who complained of soreness.

tis, also called *bulla repens*, usually occurring in children and adolescents. However, group B streptococcus can also cause this infection. A large, tense blister develops, filled with seropurulent fluid, over the volar skin pad of distal fingers or toes (Fig. 177-16). The blisters are often surrounded by an erythematous base. The lesion may be more proximally located on the finger or extend to involve the nail folds. Group A streptococcus may be cultured from the vesicle fluid. Blistering distal dactylitis may be treated with oral penicillins or erythromycin and release of subungual pus is often required. Staphylococcal blistering distal dactylitis has been reported with an identical clinical picture.[28]

▲ **FIGURE 177-16** Group A streptococcus blistering dactylitis. A blister is seen on a toe adjacent to the nail fold; the patient also had group A streptococcal intertrigo of an abdominal skin fold.

ACUTE LYMPHANGITIS Acute lymphangitis is an inflammatory process involving the subcutaneous lymphatic channels. It is most often caused by group A streptococci, but occasionally may be caused by *S. aureus*; rarely, STIs with other organisms, such as *Pasteurella multocida* or herpes simplex virus may be associated with acute lymphangitis.

CLINICAL FINDINGS ***History.*** The portal of entry is commonly a wound on an extremity, an infected blister, or a paronychia. The systemic manifestations of infection may occur either before any evidence of infection is present at the site of inoculation or after the initial lesion has subsided. The patient may notice pain over an area of redness proximal to the original break in the skin. Systemic symptoms are often more prominent than expected from the degree of local pain and erythema.

An unusual spread of streptococcal infection of the thumb (paronychia) or of the interdigital webs between the thumb and index finger may occur occasionally. Lymphatic drainage from this area can bypass the lymph nodes at the elbow and drain into the axillary nodes, which, in turn, communicate with the subpectoral nodes and the pleural lymphatics. As a consequence, subpectoral abscesses and pleural effusion can develop. The subpectoral infection may dissect downward and appear over the lower chest and upper abdomen as an area of cellulitis. This is a very serious illness. The clinical clues to the development of this sequence of events are provided by the location of the original infection on the thumb or medial surface of the index finger and the early occurrence of axillary pain.

Cutaneous Lesions. Red linear streaks, which may be a few millimeters to several centimeters in width, extend from the local lesion toward the regional lymph nodes, which are usually enlarged and tender (Fig. 177-17).

DIFFERENTIAL DIAGNOSIS In the upper extremities, acute lymphangitis usually can be differentiated from subacute or chronic sporotrichoid syndrome caused by organisms such as *Sporothrix schenckii*. In the lower extremities, superficial thrombophlebitis may produce somewhat similar linear areas of tender erythema. The absence of a portal of entry and of tender regional adenopathy is helpful in distinguishing this process from lymphangitis.

▲ **FIGURE 177-17** Acute lymphangitis of forearm due to *Staphylococcus aureus*. There is a tender linear streak extending proximally from a small area of cellulitis on the volar wrist.

LABORATORY TESTS The peripheral white blood cell count is elevated, with a marked increase in polymorphonuclear cells. The offending organism cannot be cultured from the skin, as the infection is restricted to the lymphatic channels. However, the primary portal of entry or a suppurative lymph node, if overt infection is present, may reveal the etiologic agent.

PROGNOSIS AND CLINICAL COURSE The frequent development of bacteremia with metastatic infection in various organs makes this a potentially serious disease. The infection responds readily to penicillin therapy if instituted promptly.

Invasive Streptococcal Infections

Erysipelas, cellulitis, and streptococcal gangrene are invasive streptococcal infections and are discussed in Chap. 179.

Streptococcal Toxin Syndromes

Scarlet fever and toxic streptococcal syndromes are streptococcal toxin syndromes and are discussed in Chap. 178.

Cutaneous Manifestations of Subacute Bacterial Endocarditis (See Chap. 181)

Post-Streptococcal (Group A) Non-Suppurative Cutaneous Sequelae

ERYTHEMA NODOSUM (See Chap. 68)

ERYTHEMA MARGINATUM (CUTANEOUS LESIONS OF ACUTE RHEUMATIC FEVER) (See Chap. 161)

PURPURA FULMINANS (See Chaps. 145 and 181)

OTHER SKIN LESIONS ACCOMPANYING OR FOLLOWING GROUP A STREPTOCOCCAL INFECTIONS ***Erythema Multiforme–Like Lesions.*** Round erythematous macules, up to 1.5 cm in diameter, some developing bright borders and subsequently showing clearing in the center, may occur during bacteremia caused by group A streptococci (or *S. aureus*) in infants and young children (see Chap. 38).

Acute Guttate Psoriasis. Rarely, erythematous, papulosquamous, guttate psoriasiform lesions may develop during or after GAS pharyngitis or skin infections. Children appear to be most commonly affected. Clearing of the lesions may occur within weeks of antimicrobial therapy of the streptococcal infection. Although the temporal relation of the two processes is striking, a direct causal connection has not been established, but the role of superantigens in guttate psoriasis is the subject of current research (see Chap. 18).[29,30]

Management of Group A Streptococcal Skin Infections

GENERAL PRINCIPLES Penicillin G is the drug of choice in the treatment of known GAS skin infections. When the etiology is not known immediately (e.g., in cellulitis) and when *S. aureus* is also a distinct consideration, a semi-synthetic penicillin (nafcillin or oxacillin) should be employed initially. Penicillin treatment should be continued for at least 10 days to ensure eradication of the infection. Prophylactic penicillin therapy is indicated for close family contacts (particularly children) of patients with streptococcal pharyngitis.

Box 177-5

Treatment of Streptococcal Pyodermas[a]

	TOPICAL (for mild impetigo)	SYSTEMIC	
First line	Mupirocin bid	Penicillin V	250–500 mg PO qid for 5–7 days
		Dicloxacillin (if *S. aureus* is suspected)	250–500 mg qid for 5–7 days
Second line (penicillin allergy)		Azithromycin	500 mg × 1 then 250 mg daily for 4 days
		Clindamycin	15 mg/kg/day tid
		Erythromycin	250–500 mg PO qid for 5–7 days

[a]Washing and hygiene are important in all regimens.

ANTIMICROBIAL THERAPY Mild instances of infections, such as impetigo, scarlet fever, or certain cases of erysipelas and cellulitis, may be treated with oral penicillin V (250 to 500 mg qid). When staphylococcal infection is suspected, dicloxacillin (250 to 500 mg PO qid) should be substituted. In adults allergic to penicillin, erythromycin (250 to 500 mg PO qid) is a reasonable alternative. Other alternatives include azithromycin, clarithromycin, and clindamycin (Box 177-5).

PREVENTION OF SPREAD Patients hospitalized with GAS infections should be isolated until the organisms have been eradicated by antibiotic treatment. Individuals with recurrent episodes of GAS infections can be treated with dicloxacillin or erythromycin, 250 mg twice daily (penicillin-allergic individuals), as secondary prophylaxis.

Soft-Tissue Streptococcal Infections (See Chap. 179)

Cutaneous Infections Caused by Micrococcus: Pitted Keratolysis

Pitted keratolysis involves the stratum corneum of the web spaces and plantar surface. Originally named *keratoma plantare sulcatum* by Castellani in 1910, this disease has become more commonly called by its current name after Taplin and Zaias coined it in 1967. The disease was first seen in those who went barefooted during the rainy season.

ETIOLOGY AND PATHOGENESIS The likely causative organism is *Micrococcus sedentarius*, which is a Gram-positive staphylococcus-related bacterium that invades the stratum corneum softened by sweat and moisture. *Corynebacterium* sp. may also be involved. Pitted keratolysis tends to be much more severe in tropical climates than in temperate ones.

Pitted keratolysis occurs in adults and children of both sexes, but adult males with sweaty feet are most susceptible (96 percent of cases).[31] Sliminess of the skin, often manifest by the foot sticking to the socks, is also a common complaint (70 percent of cases). The feet are typically very malodorous (89 percent) and may be mildly pruritic (8 percent).

CLINICAL MANIFESTATIONS Pitted keratolysis presents as a superficial erosion of the stratum corneum, composed of numerous small crateriform pits coalescing to form a large discrete defect with serpiginous borders on the plantar surface of the foot. The pits are usually larger than 0.7 mm in diameter, but at times are smaller than 0.5 mm. The pits have elongated configurations along the plantar furrows and are located predominantly on the pressure-bearing areas, such as the ventral aspect of the toe, ball of the foot, and the heel, but they are also seen on non–pressure-bearing areas.[31] The web spaces between the toes are also commonly involved sites, and may be the only manifestation (Fig. 177-18). The diagnosis is made clinically.

DIFFERENTIAL DIAGNOSIS Interdigital tinea pedis can present with erosive lesions in the web spaces. Erythrasma in the web spaces is usually hyperkeratotic but can be erosive.

LABORATORY FINDINGS Gram-staining of scrapings may detect the microorganism more readily than potassium hydroxide examination. Histologically, the organisms are present in the walls and bases of the crateriform defects in the upper layer of the stratum corneum. The organisms appear as coccoid and filamentous forms with branches and septa.

▲ **FIGURE 177-18** Pitted keratolysis. The web spaces between the toes are sharply eroded. Interdigital tinea pedis and erythrasma may occur concurrently.

TREATMENT Prophylactic measures are aimed at keeping the feet as dry as possible. Inert antiseptic foot powders often help. Aluminum chloride 20 percent solution is an effective astringent. A benzoyl peroxide wash and 5 percent gel are effective therapy in most cases as well. Other commonly used topical adjunctive agents include clindamycin and erythromycin solutions.

Infections Caused by Corynebacterium

ERYTHRASMA Erythrasma is a common superficial bacterial infection of the skin characterized by well-defined but irregular reddish brown patches, occurring in the intertriginous areas, or by fissuring and white maceration in the toe clefts.

Etiology and Epidemiology. *C. minutissimum*, the etiologic agent of erythrasma, is a short, Gram-positive rod with subterminal granules. The infection is more common in tropical than in temperate climates. In a study in a temperate climate, 20 percent of randomly selected subjects were found to have erythrasma by Wood's lamp examination. The generalized disease is much more common in the tropics. Erythrasma is more common in men and may occur in asymptomatic form in the genitocrural area.

Clinical Findings. **HISTORY.** Symptoms vary from a completely asymptomatic form, through a genitocrural form with considerable pruritus, to a generalized form with scaly lamellated plaques on the trunk, inguinal area, and web spaces of the feet. When pruritic, irritation of lesions may cause secondary changes of excoriations and lichenification.

CUTANEOUS LESIONS. The most common site of involvement is the web spaces of the feet, where erythrasma presents as a hyperkeratotic white macerated plaque (Fig. 177-19), especially between the fourth and fifth toes. In the genitocrural, axillary, and inframammary regions, the lesions present as well-demarcated, reddish-brown, superficial, finely scaly, and finely wrinkled patches (Fig. 177-20). In these sites, the patches have a relatively uniform appearance as compared with tinea corporis or cruris, which often have central clearing.

Wood's lamp examination of erythrasma reveals a coral-red fluorescence caused by coproporphyrin III. The fluorescence may persist after eradication of the *Corynebacterium* as the pigment is within a thick stratum corneum.

DIFFERENTIAL DIAGNOSIS. Tinea versicolor is distinguished from erythrasma by the lesions on the trunk being most numerous at nonintertriginous sites. Tinea cruris tends to have an active scaling border with central clearing. Inverse psoriasis usually presents as sharply demarcated plaques with a shiny red color in the intergluteal cleft, inguinal folds, and axillae.

LABORATORY FINDINGS. Culture of the specific *Corynebacterium* in abundance from the lesion corroborates the diagnosis. Gram-stained imprints of the horny layer of the skin show rod-like, Gram-positive organisms in large numbers.

The diagnosis is strongly suggested by the location and superficial character of the process, but must be confirmed by demonstration of the characteristic "coral-red" fluorescence with Wood's lamp illumination.

PROGNOSIS AND CLINICAL COURSE. The disease may remain asymptomatic for years or may undergo periodic exacerbations. Relapses occasionally occur even after successful antibiotic treatment.

TREATMENT. For localized erythrasma, especially of the web spaces of the feet, benzoyl peroxide wash and 5 percent gel are effective in most cases. Clindamycin (2 percent solution) or azole creams are several of the many effective topical agents. For widespread involvement, oral erythromycin is effective. A 1 g single dose of clarithromycin has been used successfully.[32] For secondary prophylaxis, an antibacterial benzoyl peroxide bar when showering is effective.

▲ **FIGURE 177-19** Erythrasma. Hyperkeratosis with a yellowish hue in the web space of the foot. The three lateral web spaces of both feet were involved. The potassium hydroxide preparation was negative; the Wood's lamp examination showed a bright coral red fluorescence.

▲ **FIGURE 177-20** Erythrasma. Well-demarcated reddish-brown patches in the axilla (**A**) and groin (**B**). The potassium hydroxide preparations were negative; the Wood's lamp examination showed a bright coral red fluorescence.

TRICHOMYCOSIS AXILLARIS AND PUBIS

Trichomycosis axillaris, a bacterial infection of the hair shaft (not fungal as the name implies), is characterized by what appears to be nodular thickenings on the hair shaft, composed of colonies of aerobic *Corynebacterium*. The condition occurs both in the axillae and pubic areas, and not just in the axillae, as the name implies. The bacteria produce various pigments, giving the nodules a range of colors. In a study from the United Kingdom, axillary infection was noted in 27 percent of adult male students; in hospitalized mentally retarded patients, the finding was present in 42 percent of male patients and in 7 percent of female patients (many of the females had no axillary hair).[33]

▲ **FIGURE 177-21** Trichomycosis axillaris. Tan-yellow concretions on the hair shafts of the axilla.

Trichomycosis is asymptomatic except for the patient's concern regarding the lesions themselves and because they are malodorous. The concretions on the hair shaft are usually a tan color but may be reddish, yellow, or black (Fig. 177-21). Lesions are most dense in and may be present only in the central portion of the axillary hair. The same lesions may occur in the pubic hair as well.

The diagnosis is usually made on the basis of the physical findings. The concretions can be visualized using a potassium hydroxide preparation. Pediculosis pubis infestation with multiple eggs on the hair shaft should be ruled out.

The involved hair can be removed by shaving. Benzoyl peroxide wash and gel are effective as treatment and prevention against recurrence of trichomycosis.

CHAPTER 178

Gram-Positive Infections Associated with Toxin Production

Jeffrey B. Travers
Nico Mousdicas

Skin infections with the Gram-positive bacteria *Staphylococcus aureus* and group A streptococcus (*Streptococcus pyogenes*) are an important source of morbidity and even mortality. These bacteria produce toxins that can induce characteristic syndromes, including staphylococcal scalded-skin syndrome (SSSS) and toxic shock syndrome (TSS). Moreover, the production of these toxins is thought to underlie the ability of infection with these bacteria to initiate and/or propagate inflammatory skin diseases.

EPIDEMIOLOGY

All conditions discussed here are relatively rare but have high morbidity, and some have considerable mortality.

FACTORS IN TOXIN-MEDIATED DISEASE

Staphylococcal and streptococcal pathogenicity is due to the production of a range of immunomodulatory proteins including toxins, exoenzymes, and adhesins.[1] Among the best characterized are the toxins (Table 178-1).

Many risk factors play a role in the ability of a toxin-forming *Staphylococcus* or *Streptococcus* to produce disease. The development of disease is related to the resistance of the host to infection and to the virulence of the organism. Host resistance depends, among other factors, on intact skin and mucous membranes functioning as barriers to invasion and the host's ability to mount an immune response (e.g., neutralizing antibodies) against such toxins. Colonization by virulent *Staphylococcus* or *Streptococcus* toxin–producing organisms exposed to optimal, focal conditions for growth and toxin production (e.g., menstruation + tampon use or abscess) allows these bacteria to initiate and/or propagate infection.

Minor defects in these barriers such as those produced by superficial excoriations, toe web fungal infections or alternatively, major defects produced by surgery, trauma, burns, or foreign substances (packing, sutures, intravascular catheters, shunts) increase the risk of infection. The role of host response cannot be overstated. For example, if a patient has an underlying immunodeficiency and cannot produce adequate neutralizing antibodies or, as in chronic granulomatous disease where neutrophils lack the oxidative burst to destroy catalase-positive bacteria (e.g., *S. aureus*), the patient is at increased risk for colonization and infection by toxin-producing bacteria. Finally, the types of immune cells that are activated play an important role in the subsequent host response, especially as it relates to toxins that act as superantigens. The ability of a superantigen to activate numerous T cells is based upon the variable region of the T-cell receptor. This could result in various types of responses depending on the specificity of the individual T cell that happened to become activated. Table 178-2 provides an overview of Gram-positive coccal toxin related diseases.

DISEASES CAUSED BY EXFOLIATIVE TOXINS: STAPHYLOCOCCAL SCALDED-SKIN SYNDROME

S. aureus–mediated production of exfoliative toxin also results in a spectrum of blistering skin disorders ranging from localized bullous impetigo (see Chap. 177) to a severe generalized form, SSSS. The syndrome is a generalized exanthematous disease consisting of cutaneous tenderness and widespread superficial blistering and denudation.

Etiology and Pathogenesis

Exfoliative toxins (ETs) are made by certain strains of *S. aureus* (usually phage group 2). Exfoliatin A and B (ETA and

GRAM-POSITIVE INFECTIONS ASSOCIATED WITH TOXIN PRODUCTION AT A GLANCE

- Caused by *Staphylococcus aureus* and/or group A streptococcus toxin–producing bacteria
- Three characteristic syndromes (all with skin manifestations):
  - Predominantly cutaneous
    - Local: Bullous impetigo
    - Generalized: Staphylococcal scalded skin syndrome
  - Cutaneous and systemic
    - Local: Recurrent toxin mediated erythema—(recurrent perineal erythema)
    - Generalized: Recalcitrant erythematous desquamating disorder
    - Other abortive hybrids of predominantly systemic manifestations disorder
  - Predominantly systemic
    - Generalized: Toxic shock syndrome *Staphylococcus* (predominantly) or *Streptococcus*
    - Scarlet fever—*Streptococcus* (predominantly) or *Staphylococcus*

TABLE 178-1
Toxins and Diseases Due to *Staphylococcus aureus* and Group A Streptococcus

BACTERIA	TOXIN	TOXIN TYPE	CLINICAL DISEASE
Staphylococcus aureus	Exfoliatin type A	Epidermolytic	Bullous impetigo SSSS
	Exfoliatin type B	Epidermolytic	SSSS Bullous impetigo
	TSS toxin 1	Superantigen	TSS (menstrual > non-menstrual), food poisoning
	Staphylococcal enterotoxins A–C	Superantigen	TSS (non-menstrual > menstrual), food poisoning
Streptococcus pyogenes	Streptococcal pyrogenic exotoxins A, C	Superantigen	TSS (non-menstrual), scarlet fever

SSSS = staphylococcus scalded-skin syndrome; TSS = toxic shock syndrome.

TABLE 178-2
Gram-Positive Coccal Infections Associated with Toxin Production

Caused by *Staphylococcus aureus* and/or group A streptococcus toxin–producing bacteria

- Characteristic syndromes (all with skin manifestations): can be divided into three categories depending on the predominant clinical presentation
  - Predominantly cutaneous
    - Local: Bullous impetigo
    - Generalized: Staphylococcal scalded-skin syndrome
  - Intermediate cutaneous and systemic
    - Local: Recurrent toxin-mediated erythema (recurrent perineal erythema)
    - Generalized
      - ~ Recalcitrant erythematous desquamating disorder
      - ~ Other abortive hybrids of predominantly systemic manifestations
  - Predominantly systemic
    - Generalized
      - ~ Toxic shock syndrome—*Staphylococcus* (predominantly) or *Streptococcus*
      - ~ Scarlet fever—*Streptococcus* (predominantly) or *Staphylococcus*

Predominantly Cutaneous	Intermediate Cutaneous and Systemic	Predominantly Systemic
• Exfoliative toxins	• Unidentified toxins	• Superantigens
Clinical Features

		  • All arise from skin (e.g., furuncle/carbuncle)
		  • Special clinical features of staphylococcus, scarlet fever
		  • Absences of pharyngitis in a patient with generalized erythroderma with sandpaper texture

ETB) are two serologically distinct proteins produced by *S. aureus*.[2] ETs are serine proteases that bind to the cell adhesion molecule desmoglein 1 and cleave it, resulting in a loss of cell-cell adhesion.[3] Consistent with the expression pattern of desmoglein 1, which is expressed in the upper part of the epidermis, the epidermolysis takes place

usually between the stratum spinosum and granulosum. This results in a very thin-walled, flaccid blister that is easily disrupted, exhibiting a positive Nikolsky sign. The pathophysiology of ET resembles that of the autoimmune blistering disease pemphigus foliaceus, with desmoglein 1 targeted in both diseases. Presumably, staphylococcal bacteria have evolved this toxin to allow the bacteria to proliferate and spread beneath the barrier of the skin. There are two forms of ET-mediated disease: localized bullous impetigo and systemic SSSS. Recent studies suggest that the majority of cases of localized bullous impetigo are due to ETA, and systemic forms such as SSSS are due to ETB, possibly due to a lower titer of anti-ETB neutralizing antibodies in the general population.[4] Although some reports suggest that ET can also act as superantigens (see Diseases Caused by Superantigenic Toxins) in addition to their epidermolytic activities,[5] this has recently been called into question.[6]

Clinical Features

LOCALIZED FORM (BULLOUS IMPETIGO) Infection of the upper part of the skin (epidermis) by *S. aureus* or *S. pyogenes* results in impetigo contagiosa (Figs. 178-1 and 178-2). Impetigo, which may account for up to 10 percent of all pediatric skin disease consists of honey-colored crusts on an erythematous base. Approximately one-fourth of cases of impetigo are bullous with local ET-expressing staphylococcus without hematogenous dissemination. As is the case with SSSS, bullous impetigo is usually a disease of children (see Chap. 177), although adult cases can also occur. The early lesions of bullous impetigo are cloudy vesicles or bullae surrounded by an erythematous rim (see Fig. 178-2). These blisters often rupture leaving superficial erosions. Lesions at various stages can often be seen. The lesions tend to be found around exposed parts of the body and around orifices (see Fig. 178-1). Diagnosis is usually based upon clinical appearance. In contrast to SSSS, confirmation of diagnosis can be easily obtained by aspiration of blister fluid for Gram stain and cultures will reveal *S. aureus*.

▲ **FIGURE 178-1** Bullous impetigo in a child. Blisters are initially filled with cloudy fluid and later rupture, resulting in erosions and crusting.

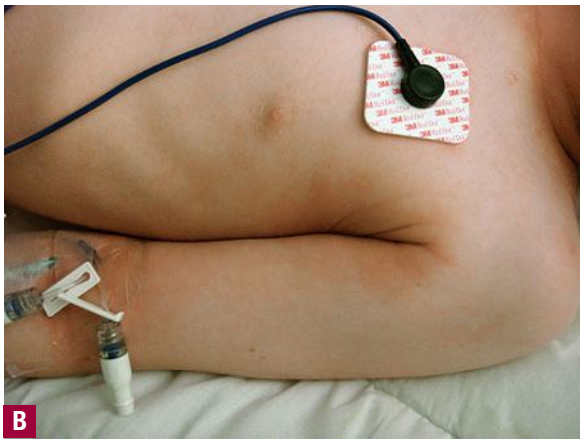
◀ **FIGURE 178-2** Bullous impetigo in a child. Note blisters filled with cloudy fluid and lesions that have ruptured, leading to erosions and crusting.

GENERALIZED FORM The clinical features of SSSS were first described in 1878 by the German physician Gotfried Ritter von Rittershain, who reported almost 300 cases of "dermatitis exfoliativa neonatorum" among young children.[7] Outbreaks of SSSS tend to occur in clusters as a consequence of cross-infection. Typically neonatal or maternity hospital staff colonized or infected with ET-producing staphylococci are the source of these outbreaks. Although more commonly seen in infants/children, SSSS can also be seen in adults. The risk factors for adults include a compromised immune response allowing for growth of the *S. aureus* and possibly impaired amounts of toxin-neutralizing antibodies or renal insufficiency, which decreases the clearance of the toxin. Affected individuals initially have a faint, orange-red macular exanthem or uniform erythema (Fig. 178-3) sparing mucosal surfaces in association with a purulent conjunctivitis, otitis media, nasopharyngeal infection, or, occasionally, pyogenic skin infection such as bullous impetigo or that which arises from an umbilical stump or boil (carbuncle). These are the staphylococcal foci from which the toxin is released. Periorificial (see Fig. 178-3A) and flexural (see Fig. 178-3B) accentuation of the exanthema is often noted.

Although the early rash is not distinctive in appearance, the concomitant cutaneous tenderness is usually present at this early stage. Tenderness can be often so severe that infants will refuse to lie down or allow anyone to hold them. Within 1 to 2 days the rash progresses from an exanthematous scarlatiniform to a blistering eruption (Fig. 178-4; see Fig. 178-3C and eFig. 178-4.1 in on-line edition). Very superficial tissue paper–like wrinkling of the epidermis, which is characteristic, progresses to large flaccid bullae in flexural and periorificial surfaces. A positive Nikolsky sign can be elicited by stroking the skin, which results in a superficial blister (see Fig. 178-4A and B and eFig. 178-4.1 in on-line edition). Large sheets of the epidermal surface are typically shed, revealing a moist underlying erythematous base. At this stage, the disease looks very worrisome, resembling a generalized scalding burn. Although fevers are often present and outwardly the signs of SSSS may look serious, the infants and children do not usually appear toxic unless they have developed complications such as septicemia or pneumonia. The cutaneous process usually resolves spontaneously or faster with antibiotics and superficial desquamation, with healing complete within 5 to 7 days (Fig. 178-5; see eFig. 178-5.1 in online edition). Cultures obtained from an intact blister are usually sterile consistent with the pathogenesis of a hematogenously disseminated toxin originating from a distant focus of infection.

Although most cases of SSSS occur in infants and children, the syndrome can also rarely be seen in adults, particularly when there is renal failure (see eFig. 178-5.2 in on-line edition). Histopathology shows acantholysis in the granular layer and sub-corneal cleft formation in early lesions (Fig. 178-6B) and an intact viable epidermis with shedding of the stratum corneum in the desquamative stage.

INTERMEDIATE (ABORTIVE) FORMS In addition to localized bullous impetigo and generalized SSSS, intermediate forms of



▲ **FIGURE 178-3** Staphylococcal scalded-skin syndrome. Pictures of early staphylococcal scalded-skin syndrome demonstrating the development of indistinct erythema (**A**, **B**) with positive Nikolsky sign (**C**) and superficial erosions.

staphylococcal-mediated eruptions, in which blistering can be apparent, can be encountered. One scenario is localized bullous impetigo that evolves to produce regionally limited bullae and denuded areas that may or may not actually harbor *S. aureus*. A possibly abortive form of SSSS has been described. It is known as the *scarlatiniform variant* and has features of the early erythrodermic and final desquamative stages yet very little blister formation is present (see Staphylococcal Scarlet Fever).[8] Again, because *S. aureus* bacterial strains can produce both exfoliative and other superantigenic toxins, and ETs could have superantigenic activity,[5] it is not surprising that overlap syndromes with features of toxic shock and scalded skin can infrequently be observed.

Diagnosis and Differential Diagnosis

All forms of SSSS are characterized by intraepidermal cleavage with splitting beneath and within the stratum granulosum. The cleavage space may contain either partially or totally unattached acantholytic cells. However, the remainder of the epidermis is usually unremarkable, and the dermis contains few inflammatory cells (see Fig. 178-6B). In localized bullous impetigo, more inflammatory cells, including neutrophils, can be often visualized (see Fig. 178-6A).

The principal diagnostic problem is distinguishing generalized SSSS from toxic epidermal necrolysis (TEN) (see Chap. 39). It should be noted that the cases that represented Lyell's first description of TEN actually included some that were probably SSSS.[9] The age distribution between SSSS (neonates, children) and TEN tends to be different, yet much overlap occurs. In contrast to TEN, SSSS never has mucosal erosions. Using a Tzanck smear that will show acantholytic cells in SSSS but not in TEN (see eFig. 178-6.1 in on-line edition) and the use of frozen sections that can rapidly differentiate the superficial subgranular acantholysis in SSSS versus the characteristic full-thickness epidermal necrosis and dermal-epidermal separation seen in TEN aid in the differential diagnosis.

Treatment and Prognosis

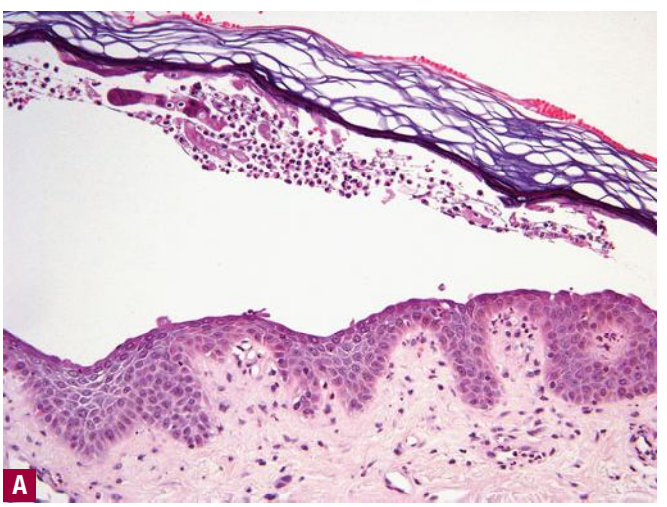
Therapy for bullous impetigo may include topical mupirocin ointment therapy alone and/or oral antibiotics. Prognosis for recovery is excellent. Therapy for SSSS should be directed toward eradication of *S. aureus*, which generally requires hospitalization and intravenous anti-staphylococcal antibiotics. For uncomplicated cases, oral antibiotics can usually be substituted after several days. The use of suitable antibiotics combined with supportive skin care and management of potential fluid and electrolyte abnormalities due to the widespread disruption of barrier function will usually be sufficient to ensure rapid recovery. Neonates benefit from incubators to maintain body temperature and humidity. The use of non-adherent dressings, including petrolatum-impregnated gauze, to the widespread areas of superficial blistering are helpful. Antibiotic mupirocin ointment applied several times per day to clearly impetiginized areas, including the original source, is often a helpful adjunct to systemic antibiotic therapy.

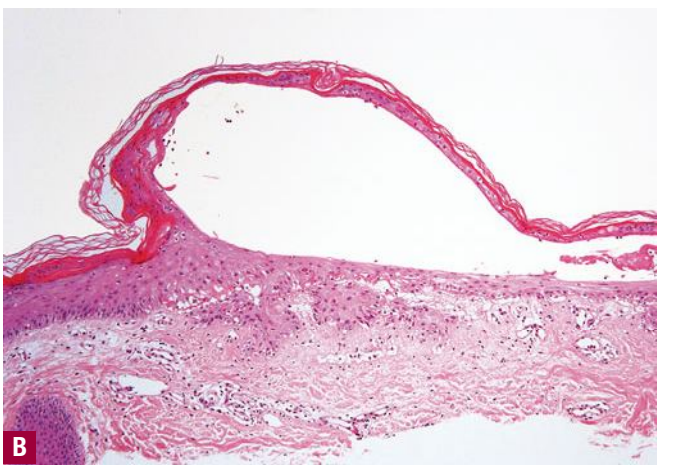
Major complications of SSSS are serious fluid and electrolyte disturbances. The mortality in uncomplicated pediatric SSSS is very low (2 percent) and is not usually associated with sepsis. Adult mortality is higher (approximately 10 percent) due to concomitant morbidity factors and increased likelihood of sepsis.

DISEASES CAUSED BY SUPERANTIGENIC TOXINS

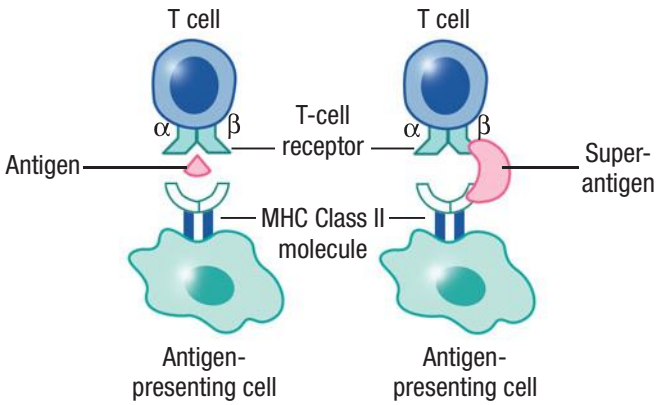
Etiology and Pathogenesis

Superantigens are a group of microbial and viral proteins that differ in several important respects from conventional peptide antigens (Fig. 178-7).[10,11] First,





▲ **FIGURE 178-6** Histology of **A.** Bullous impetigo (200×) versus (**B**) staphylococcal scalded-skin syndrome (100×). In both conditions, the intraepidermal cleavage induced by the epidermolytic toxin occurs within or just below the stratum granulosum. Note paucity of cells in generalized disease (staphylococcal scalded-skin syndrome) (**B**) in comparison to the large numbers of leukocytes found in the localized form (bullous impetigo) (**A**). In both, cleavage occurs in the granular layer and is due to acantholysis. Note free-floating acantholytic cells in **A** and compacted acantholytic cells in the blister roof of **B**.



▲ **FIGURE 178-7** T-cell activation in the presence of nominal peptide antigens (*left*) or superantigens (*right*). The peptide antigen binds in the groove of the major histocompatibility complex (MHC) class II molecule and activates only antigen-specific T cells through the T-cell receptor. In contrast, a superantigen is a large globular protein that binds to the MHC class II molecule outside the antigen-binding groove and directly cross-links the MHC class II molecule and the Vβ chain of the T-cell receptor, leading to polyclonal T-cell activation.

unlike conventional protein antigens, which are taken up and processed by antigen presenting cells, superantigens exert their effects as globular intact proteins. Similar to peptide antigens, they are presented by class II major histocompatibility complex (MHC) molecules; however, they do not interact with the MHC peptide β-antigen binding groove, but instead bind to conserved amino acid residues that are on the outer walls of the peptide antigen-binding groove. Thus, whereas recognition of conventional peptide antigens by the T-cell receptor is restricted by MHC alleles, recognition of superantigens is generally not MHC restricted. Second, superantigens primarily recognize and bind to the variable region of the T-cell receptor β chain (Vβ). This is in contrast to nominal peptide antigens, which require recognition by all five variable elements (i.e., Vβ, Dβ, Jβ, Vα, Jα) of the T-cell receptor. Therefore, the responding frequency of a superantigen for resting T cells is several orders of magnitude greater (up to 20 percent to 30 percent) than a conventional peptide antigen (0.01 percent to 0.1 percent) The unique ability of a superantigen to bind directly to (and signal through) MHC class II molecules, and cross-link (and thus activate) a large percentage of T cells expressing relevant T-cell receptor Vβ chains, provides an explanation for the potent immune stimulation seen with these molecules. Of note, in comparison to nominal antigens, superantigen-mediated T-cell activation tends to generate increased numbers of T cells expressing the skin homing receptor cutaneous lymphocyte antigen (CLA).[12] Given that CLA-positive T cells are the T-cell type that traffics readily to the skin, the increased numbers of CLA-positive T cells generated by these agents is thought to be responsible for the high propensity of cutaneous manifestations in these conditions. Superantigens lead to a massive release of cytokines, including tumor necrosis factor-α, interleukin 1, and interleukin 6. This cytokine "storm" is in great part responsible for a capillary leak syndrome and accounts for the majority of the clinical manifestations seen in superantigen-mediated diseases. The prototypical disease due to superantigens is TSS caused by staphylococcal or streptococcal toxins. Although specific syndromes such as TSS and scarlet fever have characteristic findings, overlap syndromes have been described. Because the individual clinical findings are the summation of amount and type(s) of toxins and the types of cells responding to activation, it should not be surprising that heterogeneity in clinical presentations occurs.

Unlike syndromes associated with ETs that usually do not have significant systemic symptoms, those due to superantigens are characterized by systemic manifestations. Superantigen-mediated toxin syndromes can be divided into intermediate cutaneous and systemic and predominantly systemic due to the relative amounts of systemic toxicity. Disorders which have predominantly systemic manifestations are scarlet fever and the most ominous toxin-mediated disease, TSS. The intermediate cutaneous and systemic category includes syndromes such as recalcitrant erythematous desquamating disorder (REDD) and toxin-mediated erythema, which are less systemic versions of TSS and scarlet fever, respectively. All of these superantigen-mediated disorders are diagnosed based upon clinical findings and can be due to toxins produced by either *S. aureus* or group A streptococcus (see Table 178-2).

Toxic Shock Syndrome (See Table 178-2)

TSS is an inflammatory response characterized by fever, rash, hypotension, and multiorgan involvement representing the severe end of the spectrum of superantigen-mediated diseases. Although first described in 1978 in a series of children with *S. aureus* infection,[13] TSS became more broadly recognized with reports of epidemics associated with use of highly absorbent tampons in menstruating women in the early 1980s.[14] Presumably, the tampon served as a nidus for infection: the blood added protein and neutralized the normally bacteriocidal acidic vaginal pH. Since the first descriptions of the disease, TSS has been shown to be associated with many types of staphylococcal and streptococcal infections.

CLINICAL FINDINGS ***Staphylococcal Toxic Shock Syndrome.*** The most common staphylococcal toxin associated with TSS is TSS toxin-1 (TSST-1), and it is the predominant toxin associated with menstrual-associated cases. TSST-1 appears unique among superantigens in its ability to cross mucosal surfaces. With the removal of highly absorbent tampons from the market along with patient education, the incidence of menstruation-associated TSS decreased steadily, and at present the incidence of non-menstrual TSS exceeds that of menstrual-associated cases. Non-menstrual TSS is associated with postsurgical wounds, sinusitis, osteomyelitis, influenza, intravenous drug use, burn wounds, and gynecologic infection (especially in the postpartum period). Other staphylococcal toxins, including staphylococcal enterotoxins B and C (SEB and SEC), can also be found, and the latter two superantigenic toxins comprise approximately 50 percent of non-menstrual TSS. The host response is an important factor in the development of TSS, as studies have shown an increased susceptibility in patients who do not have neutralizing antibodies against TSST-1.[15]

The symptoms of TSS begin with the acute onset of fever, sore throat, and my-

▲ **FIGURE 178-8** Toxic shock syndrome (TSS). Patient in intensive care unit with TSS due to *Staphylococcus aureus*. Note patient's eruption is non-specific erythema around intertriginous areas and face. The eruption associated with staphylococcal TSS varies and could be morbilliform, scarlatiniform, or even pustular.

algia. Diarrhea is common, and vomiting may also occur. The rash is most often a macular erythema but a scarlatiniform type can also sometimes be seen. The eruption usually begins on the trunk and spreads to extremities and can involve palms and soles (Fig. 178-8). If the patient is hypotensive, the eruption tends to be more prominent on the trunk than extremities. Symptoms of hypotension include orthostatic dizziness, fainting, or overt shock. Nonpurulent conjunctival hyperemia, pharyngeal inflammation, and strawberry tongue (see Scarlet Fever) are invariably present. Signs of decreased mentation can also occur. The rash will desquamate within 1 to 2 weeks after it appears. The Centers for Disease Control and Prevention criteria for TSS are listed in Table 178-3. Cases of lesser severity that do not meet the full definition probably do occur frequently, especially with earlier recognition and treatment. In nonmenstruation cases, especially those associated with postoperative infections, the classic signs of a localized infection such as erythema, pain, and purulence can be absent. This is often in contrast to streptococcal TSS.

Streptococcal Toxic Shock Syndrome. Streptococcal TSS was described in the late 1980s as a disease similar to staphylococcal TSS, but caused by invasive group A streptococcus. Recent reports have suggested streptococcal TSS is more commonly encountered than the staphylococcal form. The majority of cases of streptococcal TSS are due to streptococcal pyrogenic exotoxin A (SPEA), yet other superantigenic toxins including SPEB, SPEC, and involvement of other non–group A streptococcus have also been reported. Although not associated with tampon use, streptococcal TSS can result from nearly any type of group A streptococcal infection. The most common types of infections appear to be wounds, and streptococcal TSS has been well described as a complication of varicella and influenza A. However, in many cases the route of infection cannot be determined. In contrast to staphylococcal TSS, disease induced by group A streptococcus is from skin in 80 percent of cases. The initial presentation is skin pain that is localized to an extremity in many cases. The localized pain often progresses over several days to localized erythema (see Chap. 179) and edema. Cellulitis associated with necrotizing fasciitis and myositis with concomitant streptococcal invasion of the bloodstream then develop. It should be noted that blood cultures are positive in more than one-half of patients with streptococcal TSS, in contrast to only one-tenth of patients with staphylococcal TSS. Thus, a patient with signs of TSS and a localized cellulitis should suggest streptococcal TSS as soft-tissue infections are not usually seen with staphylococcal TSS. Although very young, elderly, diabetic, or immunocompromised patients would be more

TABLE 178-3
Centers for Disease Control and Prevention Case Definition of Staphylococcal Toxic Shock Syndrome

Major Criteria (all four must be met)	Multisystem Involvement (three or more must be met)	Normal Test Results (if performed)

• Fever
  • Temperature > 38.9°C (102°F)
• Rash
  • Diffuse macular erythroderma
• Desquamation
  • 1–2 wk after onset of illness, particularly on palms/soles
• Hypotension
  • Systolic blood pressure < 95 mm Hg for adults, or less than fifth percentile by age for children < 16 yr of age, or orthostatic syncope
	• Gastrointestinal
	  • Vomiting or diarrhea at onset of illness
	• Muscular
	  • Severe myalgia or creatine kinase level twice upper limit of normal
	• Mucous membrane
	  • Oropharyngeal, conjunctival, or vaginal hyperemia
	• Renal
	  • Blood urea nitrogen or creatinine level twice upper limit of normal, or > 5 white blood cells per high-power field in urine in absence of urinary tract infection
	• Hepatic
	  • Total bilirubin, aspartate aminotransferase, or alanine aminotransferase level at least twice upper limit of normal
	• Hematologic
	  • Platelets < 100,000/mm^3
	• Central nervous system
	  • Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent
		• Blood, throat, or cerebrospinal fluid cultures (blood cultures may be positive for *Staphylococcus aureus*)
		• No rise in titer in antibody tests for Rocky Mountain spotted fever, leptospirosis, or measles

susceptible to streptococcal TSS, the majority of cases have occurred in otherwise healthy adults.

DIFFERENTIAL DIAGNOSIS The differential diagnosis of staphylococcal TSS includes septic shock, staphylococcal exfoliative syndromes, Rocky Mountain spotted fever, viral hemorrhagic shock, measles, leptospirosis, and Stevens-Johnson syndrome. Although Kawasaki syndrome has many similar clinical findings, including swelling of extremities and desquamation of palms and soles during convalescence, Kawasaki syndrome differs in that the course of fever is prolonged, and there is absence of diarrhea and hypotension. Streptococcal-mediated syndromes including scarlet fever and especially streptococcal TSS can mimic staphylococcal TSS.

In a patient with fever, rash, and hypotension, a thorough search for possible sites of staphylococcal and streptococcal infection is critical. Surgical wounds should be carefully examined even if no clinical signs of infection are apparent. Vaginal examination and removal of tampon or other foreign body should be done, and vaginal irrigation with saline or povidone iodine has been recommended.

TREATMENT AND PROGNOSIS The treatment of TSS is supportive (and usually in the intensive care setting) and focused on eradicating the offending *S. aureus*. Large doses of a β-lactamase–resistant, antistaphylococcal antibiotics (e.g., nafcillin) have been used historically. Because these agents have been known to increase TSST-1 in vitro (probably as a result of cell lysis), concomitant clindamycin (which will inhibit bacterial protein toxin production) is often prescribed. Because of the increasing frequency of methicillin-resistant staphylococci in the community, vancomycin is often recommended. β-lactamase–resistant penicillins are of lesser value, not only because of emerging resistance, but also they are less effective with high levels of bacteria (in contrast to clindamycin or vancomycin). Todd has recommended a combination of vancomycin and clindamycin for suspected serious staphylococcal infections pending culture and sensitivity.[16] Recently intravenous immunoglobulin (IVIG; which presumably acts in part via neutralizing antibodies against toxins) has been used and appears to have significant promise.[17] At present, IVIG is used in severe or recalcitrant cases. Contraindications to IVIG include previous hypersensitivity to it or immunoglobulin A deficiency. Systemic corticosteroids are controversial and probably have less impact than considered as superantigen-mediated immune cell activation is associated with corticosteroid resistance.

Staphylococcal TSS is clearly a life-threatening disease but the mortality rate is only approximately 5 percent, most likely because the majority of cases occur in otherwise healthy young individuals. Unfortunately, recurrence can be seen in up to 20 percent. Women who have had TSS should avoid using tampons during menstruation as it will increase the likelihood of re-infection. Diaphragms and contraceptive sponges should also be avoided in this population.

The treatment of streptococcal TSS is similar to that for staphylococcal TSS. For cases associated with necrotizing fasciitis/myositis, rapid recognition and surgical débridement are imperative. IVIG is becoming increasingly recognized as an important part of treatment of streptococcal TSS, especially because the mortality rate in this disease can be greater than 30 percent.[18]

Recalcitrant Erythematous Desquamating Disorder (See Table 178-2)

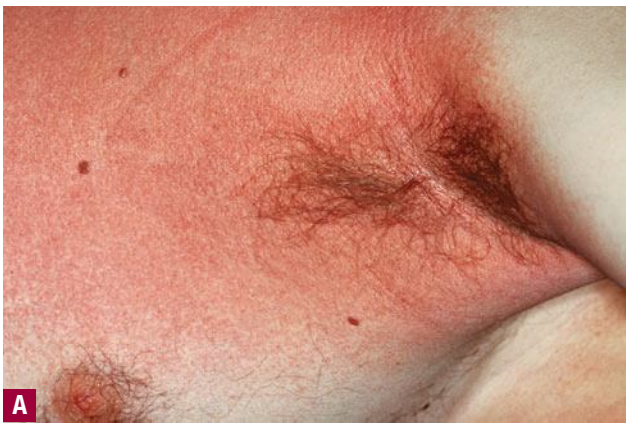
A new presentation of a toxin-mediated disorder, termed *recalcitrant erythematous desquamating disorder*, was first described in 1992.[19] The clinical findings include fever and hypotension. The rash of REDD consists of diffuse macular erythema with delayed desquamation. Other findings in common with TSS include ocular and oral mucosal injection and strawberry tongue. Staphylococci producing TSST-1, staphylococcal enterotoxin A or B (SEA, SEB), have been isolated from various places, including nasal sinuses, soft tissues, or blood. Although the majority of patients described to date have had acquired immunodeficiency syndrome, some REDD patients without acquired immunodeficiency syndrome have been reported. In contrast to TSS, this is a prolonged disease (measured in weeks to several months) in which only several of the TSS criteria are met. The diagnosis is often established by careful examination for occult colonization and/or infection in a susceptible individual.

Scarlet Fever (see Table 178-2)

Scarlet fever is a syndrome characterized by exudative pharyngitis, fever, and scarlatiniform rash. It is most commonly due to pyrogenic exotoxin-producing group A streptococcus, although staphylococcal infections can produce a similar-appearing disease. The exact mechanism by which toxins produce the symptom complex is unclear. Compelling studies by Schlievert demonstrated that the scarlatiniform eruption could only be induced in mice that were previously sensitized against toxins. This suggests that a combination of conventional delayed type and superantigen-mediated processes are occurring.[20] It should be noted that streptococcal toxins, especially SPEA, have areas of significant homology with collagen, which could provide a mechanism for rare autoimmune sequelae of streptococcal scarlet fever, including renal failure and rheumatic fever.[21] Scarlet fever is no longer the major public health threat it was in the past because of antibiotic treatment and because most streptococcal isolates causing scarlet fever express the less virulent SPEB and SPEC rather than SPEA.

CLINICAL FINDINGS ***Streptococcal Scarlet Fever.*** Streptococcal scarlet fever is a childhood disease that occurs most commonly in winter and early spring. It is estimated that up to 10 percent of childhood group A streptococcal pharyngitis patients develop scarlet fever. Approximately 12 hours to 5 days after exposure, an abrupt prodrome consisting of pharyngitis, headache, vomiting, abdominal pain, and fever develops. The rash appears 1 to 2 days after onset of the illness, first on the neck and then extending to the trunk and extremities, although it spares the palms and soles. The exanthem texture is usually coarse, like fine-grade sandpaper, and the erythema blanches with pressure (Fig. 178-9). The skin can be mildly pruritic but usually is not painful. A few days after generalization of the exanthem, the rash becomes more intense around skin folds and lines of confluent petechiae, due to increased capillary fragility (Pastia's sign), can be seen. The generalized exanthem begins to fade 3 to 4 days after onset and a desquamative phase begins, usually starting on the face. Peeling from the palms and fingers and, sometimes, soles occurs approximately 1 week later and can last for up to 1 month (see Fig. 178-9D).

Oral findings of streptococcal scarlet fever include edematous, erythematous tonsils sometimes covered with a yellow, gray, or white exudate. Tender anterior cervical lymphadenopathy is



▲ **FIGURE 178-9** Scarlet fever. **A.** Exanthematous rash with a sandpaper texture in the axilla. **B.** Exanthematous rash with a sandpaper feel on the chest. **C.** Perioral pallor and strawberry tongue. **D.** Post-streptococcal desquamation.

common. Petechiae and punctate red macules are seen on the soft palate and uvula (Forschheimer's spots). A flushed face with circumoral pallor is also commonly noted (see Fig. 178-9C). In scarlet fever, the tongue demonstrates characteristic changes. During the first 2 days of the disease, the tongue has a white coat through which the red and edematous papillae project (white strawberry tongue). After 2 days, desquamation occurs, resulting in a red tongue with prominent papillae (red strawberry tongue) (see Fig. 178-9C).

The diagnosis of scarlet fever is made by the characteristic clinical signs and confirmed by the rapid streptococcal test or throat culture. Scarlet fever usually follows a benign course, and any undue morbidity or mortality is likely due to suppurative complications, including peritonsillar abscess, sinusitis, pneumonia, and meningitis or nonsuppurative complications associated with immune-related rheumatic fever or glomerulonephritis. The risk of acute rheumatic fever following an untreated group A streptococcal infection has been estimated to be approximately 3 percent in epidemics and 0.3 percent in endemic circumstances. Glomerulonephritis can occur in up to 10 percent to 15 percent after infection with nephritogenic group A streptococcal strain. In addition to pharyngitis, group A streptococcus can cause scarlet-fever-like eruptions from skin (often surgical wounds) or uterine infections.

Scarlet fever is treated by antibiotics (penicillin or erythromycin for a 10-day course) and supportive care. Fever usually abates within 12 to 24 hours after initiation of antibiotic therapy. Recurrences are common.

Staphylococcal Scarlet Fever. Staphylococcal scarlet fever, also known as *scarlatiniform erythroderma or rash*, was first described almost 90 years ago and, until recently, was considered to be a milder or abortive form of SSSS. Patients usually develop a generalized erythroderma with a roughened, sandpaper-like texture very much like in streptococcal scarlet fever. However, the exanthem of staphylococcal scarlet fever tends to be more tender than corresponding streptococcal scarlet fever. Systemic signs including malaise and fever are invariably present. Within a few days of initiation of the rash, thick flakes develop, and the entire skin desquamates over the subsequent week. Unlike generalized SSSS, the scarlatiniform eruption is not associated with the formation of bullae or superficial exfoliation and can be very difficult to differentiate from other infectious erythrodermal causes such as TSS and streptococcal scarlet fever. Scarlet fever induced by staphylococci differs from streptococcal-mediated disease by the lack of pharyngitis. A recent study by Wang and colleagues examined the clinical characteristics and toxin detected in 20 children with staphylococcal scarlet fever.[22] They found that all of the patient's staphylococcal infections arose from the skin; 16 of 20 cases from furuncles/carbuncles; two each from abscesses or wound infections. All of the *S. aureus* strains expressed SEB. Of note, SEB shows significant protein sequence homology with SPEA, a known exotoxin associated with streptococcal scarlet fever. Yet other studies have implicated other staphylococcal enterotoxins.[23] One explanation for this heterogeneity of toxins associated with this disorder is that the diagnosis is made upon clinical grounds. It is indeed possible that staphylococcal scarlet fever represents an incomplete form of TSS, in which toxins spread from the skin, thus activating the skin-associated lymphoid

tissue rather than mucosal-associated lymphoid tissue. Because most cases of streptococcal scarlet fever arise from a pharyngitis, the lack of a pharyngitis in a patient with characteristic rash and other clinical signs of scarlet fever should alert the clinician to look for a localized nidus of infection (e.g., furuncle) that could be cultured to establish the diagnosis.

DIFFERENTIAL DIAGNOSIS The diagnosis of scarlet fever is made on clinical grounds with supporting positive bacterial cultures. The differential diagnosis should include other toxin-mediated disorders including SSSS. Although Kawasaki syndrome (see Chap. 168) has many similar clinical findings including mucosal involvement (e.g., strawberry tongue), swelling of extremities, and desquamation of palms and soles during convalescence, Kawasaki syndrome differs in that the course of fever is prolonged and cultures would be expected to be negative. Atypical drug hypersensitivity reactions can have some cutaneous features, but would lack the mucosal signs. There is usually a history of offending drug and peripheral eosinophilia. Scarlet fever from group A streptococcus can usually be differentiated from that induced by *S. aureus* as the usual nidus of infection in streptococcal scarlet fever is from a pharyngitis while the staphylococcal variant usually has its infectious nidus in the skin.

TREATMENT AND PROGNOSIS The treatment of scarlet fever includes antibiotics to eradicate the offending bacteria. If the localized nidus of infection is an abscess or furuncle/carbuncle, it should be drained. Acute rheumatic fever or glomerulonephritis is not associated with staphylococcal scarlet fever. For situations in which more systemic signs resemble TSS, the treatment should be that of TSS.

Toxin-Mediated Erythema (Recurrent Toxin-Mediated Perineal Erythema)

(See Table 178-2)

In 1996, Manders and colleagues recognized a previously unreported toxin-mediated disorder, they termed *recurrent toxin-mediated perineal erythema*.[24] Recurrent toxin-mediated perineal erythema is characterized by a striking diffuse macular perineal erythema that occurs within 24 to 48 hours after a pharyngitis with a toxin-producing group A streptococcus or *S. aureus*. Clinical findings seen in scarlet fever, including a strawberry tongue, as well as erythema, edema, and later, palmoplantar desquamation, are commonly found in recurrent perineal erythema. Fever, hypotension, and other systemic signs of scarlet fever or TSS are characteristically absent although diarrhea is a common feature. Recurrences are more frequently found in this localized form. It has been proposed by Manders that that the term *toxin-mediated erythema* be used to describe the following clinical settings in which a toxin-producing *Staphylococcus* or *Streptococcus* can be found: recurrent erythroderma associated with a preceding bacterial pharyngitis, isolated episodes of toxin-mediated erythema without recurrences, and patients with episodic mild hypotension, fever, and typical mucocutaneous findings in the absence of full criteria for TSS.[25]

Diseases Initiated and/or Exacerbated by Superantigens

In addition to the ability of superantigens to induce characteristic diseases including TSS, scarlet fever, and gastroenteritis, recent evidence is accumulating which indicates that these potent immunomodulatory agents can initiate or exacerbate other skin disorders.

PSORIASIS (See Chap. 18) Psoriasis is an autoimmune T-cell–driven keratinocyte hyperproliferative disease involving skin and rarely joints. Superantigens have been implicated in psoriasis in at least two settings: the guttate (acute eruptive) form and in situations where psoriasis flares in response to secondary infection.[11]

AUTOECZEMATIZATION (ID) RESPONSE (See Chap. 17)

ATOPIC DERMATITIS (See Chap. 14) Secondary infection with *S. aureus* or group A streptococcus is a well-known trigger of atopic dermatitis. It is estimated that *S. aureus* can be cultured from essentially all subjects with atopic dermatitis.[28] Recent studies have demonstrated that skin from subjects with active atopic dermatitis has decreased levels of antimicrobial proteins.[29] This lack of antimicrobial proteins may provide one explanation for the almost universal bacterial infection associated with flaring atopic dermatitis.

CHAPTER 179

Soft-Tissue Infections: Erysipelas, Cellulitis, Gangrenous Cellulitis, and Myonecrosis

Arturo Saavedra
Arnold N. Weinberg
Morton N. Swartz
Richard Allen Johnson

EPIDEMIOLOGY

Soft-tissue infections (STIs) account for roughly 10 percent of inpatient hospitalizations in North America, and their healthcare cost has been steadily increasing.[1] STIs are characterized by clinical findings that include an acute, diffuse, tender, spreading, edematous, suppurative inflammation of the dermis, subcutaneous or muscular tissues, often associated with systemic symptoms of malaise, fever, chills, and local pain. These infections are usually caused by β-hemolytic streptococci (primarily group A), *Staphylococcus aureus,* and, in deep fascia and muscle, by mixed anaerobic and facultative Gram-positive and Gram-negative organisms, including histotoxic *Clostridia*. There is less predictability in immunocompromised hosts where organisms may include a range of traditional and rare pathogens, usual commensals, yeast, fungi, and parasites. Because traditional patterns of symptoms and physical findings may be lacking or non-specific in immunocompromised patients, determining an etiologic diagnosis is especially important.[2] In both immunocompetent and compromised hosts, bullae, necrosis, or gas-forming bacterial infections signal urgency in establishing the location of infection and in defining the cause.

ETIOLOGY AND PATHOGENESIS (Table 179-1)

Intact skin plays a critical role in the defense against a wide range of pathogens. The details of the host–pathogen interaction are poorly understood but appear to involve barrier function, bacterial factors, and host factors. Importantly, diminished immune status [diabetes, cancer, renal failure, neutropenia, or (human immunodeficiency virus (HIV)] as well as circulatory compromise make the host susceptible to increased frequency of STIs (see Chap. 176).

Recently, the molecular interaction of strains, such as group A streptococcus (GAS) and *C. perfringens*, with the coagulation system have been elucidated. Injectable exotoxins from M-type 1 invasive streptococcus induce the aggregation of platelets and neutrophils, mostly secondary to streptolysin O and mediated by platelet P-selectin.[3] Via stabilization of glycoprotein IIb/IIIA, intravascular aggregates of platelets and neutrophils occlude vessels that may contribute to the rapid clinical progression and tissue destruction in myositis and necrotizing fasciitis. In *C. perfringens*, through the activity of α-toxin, phospholipase C-mediated upregulation in glycoprotein IIb/IIIA may lead to similar effects. The role of the coagulation and fibrinolytic system in causing ischemia during the course of these infections has been reviewed by Bryant.[4] In addition, the role of streptolysin S in mediating STIs caused by streptococcus G as well as the role of the Panton-Valentine leukocidin (PVL) determinant in soft-tissue and pulmonary infection by community-acquired, methicillin-resistant *S. aureus* (CA-MRSA), has recently been fortified.[5,6]

CLINICAL FINDINGS

History

STIs usually present at an antecedent lesion or site, including dermatitis, stasis ulcer, puncture wound, animal bites, percutaneous catheters, or trauma. In addition, surgical wounds after excision, electrodesiccation, and curettage or cosmetic procedures can serve as a nidus for infection. Less commonly, bacteremia, osteomyelitis, or visceral infections such as diverticular abscess may lead to seeding of the skin and soft tissues. With onset of infection, patients often experience local pain and tenderness along with variable degrees of erythema and systemic symptoms (fever, chills, and malaise). Erythema may rapidly intensify and spread. Local pain is often severe and, in the absence of erythema, should raise suspicions of early deep-seated infection. In some individuals, systemic symptoms may antedate localizing complaints and signs of STIs. In a study of 50 patients with cellulitis, only 26 percent had fever higher than 38°C (100.4°F). A potential portal of entry was identified in 66 percent of patients: 50 percent of those with upper extremity and 67 percent of those with lower extremity cellulites.[7] Patients with early gangrenous cellulitis may experience severe pain out of proportion to the appearance of the local area.

SOFT-TISSUE INFECTIONS AT A GLANCE

- Approximately 10 percent of hospitalizations in North America are due to soft-tissue infections.
- Routine organisms can be treated by empiric therapy but high index of suspicion for resistant organisms should be maintained for cases that do not improve or present in areas where resistant strains have been reported.
- Newer antibiotics are currently available or undergoing testing to treat resistant infections caused by methicillin-resistant strains or vancomycin-resistant strains.
- Though unnecessary in uncomplicated cases, aspiration, wound cultures, and blood cultures are required for identification of etiologic organisms.
- Nonnecrotizing soft-tissue infections are treated with antibiotics, drainage, and supportive measures.
- Necrotizing soft-tissue infections require surgical treatment.
- Radiographic imaging may be helpful in crepitant infections but should not delay surgical therapy in cases where necrotizing infections are suspected.

Skin Signs

ERYSIPELAS Erysipelas is a distinct type of superficial cutaneous cellulitis with marked dermal lymphatic vessel involvement caused by group A β-hemolytic streptococcus (very uncommonly group C or G streptococcus) and rarely caused by *S. aureus*. In the newborn, group B streptococci can cause erysipelas.[8,9] Lymphedema, venous stasis, web intertrigo, and obesity are risk factors in the adult patient.

In the absence of underlying edema or other skin abnormalities, erysipelas

TABLE 179-1
Etiology of Soft-Tissue Infections

Type of Infection	Most Common Cause(s)	Uncommon Causes
Erysipelas	Group A streptococcus	Group B, C, and G streptococcus, *Staphylococcus aureus*
Cellulitis	*S. aureus,* group A streptococcus	Group B, C, and G streptococcus*; Streptococcus iniae*; *Pneumococcus*; *Haemophilus influenzae* (children); *Escherichia coli; Proteus*, other Enterobacteriaceae; *Campylobacter jejuni*; *Moraxella; Cryptococcus neoformans; Legionella pneumophila, L. micdadei*; *Bacillus anthracis* (anthrax); *Aeromonas hydrophila; Erysipelothrix rhusiopathiae; Vibrio vulnificus, V. alginolyticus, V. cholerae* non-01
Cellulitis in children	*S. aureus,* group A streptococcus	Group B streptococcus (neonates)
Facial/periorbital cellulitis	*S. aureus,* group A streptococcus	*Neisseria meningitides, H. influenzae* (young children)
Perianal cellulitis	Group A streptococcus	*S. aureus*
Cellulitis second degree to bacteremia	*Pseudomonas aeruginosa*	*V. vulnificus; S. pneumoniae;* group A, B, C and G streptococcus
Crepitant cellulitis	Histotoxic *Clostridia* sp., (*C. perfringens, C. septicum)*	*Bacteroides* sp.; Peptostreptococci; *E. coli*, Enterobacteriaceae
Cellulitis associated with water exposure	*E. rhusiopathiae (erysipeloid)*	*V. vulnificus, Aeromonas hydrophila, Mycobacterium marinum* (nodular lymphangitis), *M. fortuitum* complex
Gangrenous cellulitis (infectious gangrene)		
NF		
Streptococcal gangrene	Group A streptococcus	Groups B, C, and G streptococcus
Nonstreptococcal NF	Mixed infection with one or more anaerobes (*Peptostreptococcus* or *Bacteroides)* plus at least one facultative species (non–group A streptococci; members of the Enterobacteriaceae such as *Enterobacter, Proteus,* etc.)	
Synergistic necrotizing cellulitis[a]	Polymicrobial with facultative and anaerobic organisms that originate in the intestine; one-third of patients have positive blood cultures, usually a coliform, *Bacteroides*, or *Peptostreptococcus*	
Facultative	Coliforms: *E. coli*, *Proteus*, *Klebsiella*	
Anaerobes	*Bacteroides, Peptostreptococcus, Clostridium, Fusobacterium*	
Fournier gangrene	Similar to nonstreptococcal NF (type I)	
Clostridial soft-tissue infections	*C. perfringens,* other histotoxic clostridial species	
Anaerobic cellulitis		
Anaerobic myonecrosis (gas gangrene)		
Spontaneous, nontraumatic anaerobic myonecrosis	*C. septicum* (bacteremic)	
Nonclostridial anaerobic cellulitis	Various *Bacteroides* sp., peptostreptococci, peptococci	
Progressive bacterial synergistic gangrene (Meleney gangrene)	Mixed bacterial infection	
Ulcer base	*S. aureus*	*Proteus* sp., other Gram-negative bacilli
Advancing margin	Microaerophilic or anaerobic streptococci	
Gangrenous cellulitis in the immunosuppressed individual	*P. aeruginosa* (ecthyma gangrenosum) *Mucor*, *Rhizopus*, *Aspergillus*	*Bacillus* sp., other bacterial and fungal sp.

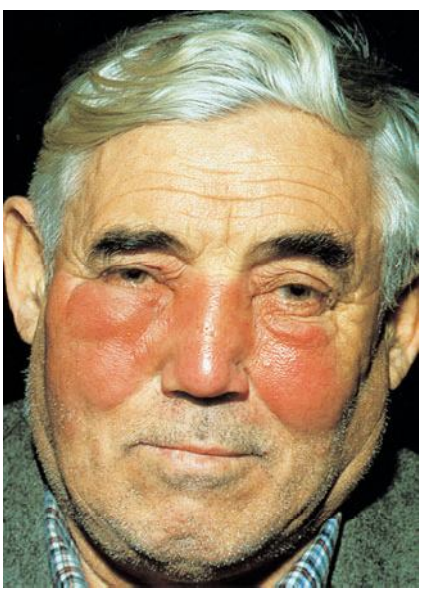
[a]Essentially the same as nonstreptococcal necrotizing fasciitis (NF) but with some involvement of adjacent skeletal muscle.

usually begins on the face or a lower extremity, heralded by pain, superficial erythema, and plaque-like edema with a sharply defined margin to normal tissue (Fig. 179-1). These findings are often described as *peau d'orange* appearance. In the presence of antecedent edema or other anatomic abnormalities, the margin between normal and diseased soft tissue may be obscure, much as in primary cellulitis. There may not be an obvious portal of entry, and skipped areas may confuse the nature of the process. Facial erysipelas is less frequent than lower extremity disease and begins unilaterally but may spread by contiguity over the nasal prominence to involve the face symmetrically (Fig. 179-2). The oropharynx may be a portal of entry, and throat culture may show GAS. Inflammatory edema may extend to the eyelids, but orbital complications are rare. Fever may precede local signs, and, occasionally, before distal extremity

▲ **FIGURE 179-1** Erysipelas. There is painful, warm erythema of the lower extremity with well-defined borders.

findings, patients complain of groin pain caused by swelling of a femoral node. Lymphangitis and abscess are very rare, but the process may spread rapidly from the initial lesion. Occasionally, in addition to rapid spread of the erythematous, edematous plaque, bullae may form in the involved area.[10]

Recurrent erysipelas is associated with saphenous vein harvest (occasionally in association with tinea pedis) and lymphedema complicating mastectomy with axillary node dissection. In these cases, erysipelas presents with edema and erythema along lines of venectomy or nodal dissection. In addition, resultant lymphedema from a previous episode of erysipelas is a risk factor for recurrence, particularly on the lower extremities. Congenital lymphedema (Milroy disease) may also lead to recurrent erysipelas.



▲ **FIGURE 179-2** Erysipelas. Painful, edematous erythema with sharp margination on both cheeks and the nose. There is tenderness, and the patient has fever and chills.

◀ **FIGURE 179-3** Cellulitis. The lower extremity is swollen, erythematous, and tender; there is blistering and crusting.

ACUTE CELLULITIS Cellulitis extends deeper into the dermis and subcutaneous tissue. *S. aureus* and GAS are by far the most common etiologic agents, but occasionally other bacteria are identified (e.g., group B streptococci in the newborn, pneumococci, Gram-negative bacilli, and in immunocompromised individuals, a variety of other microorganisms, including yeasts and molds). *Escherichia coli* and other Enterobacteriaceae and anaerobes are involved in cellulitis, especially in association with extremes of age, prolonged hospitalization, percutaneous intravascular lines, diabetes, immunocompromised states, and glucocorticoids.[11] Liposuction and "skin popping" are reported risk factors that may also lead to cellulitis from less common organisms.

Though cellulitis has many of the features of erysipelas (erythema, tenderness, pain), it can be differentiated from erysipelas by the lack of distinct margins between affected and normal skin, a deeper, firmer form of tender induration, fluctuance, and, occasionally, the presence of crepitus on palpation. In some cases of cellulites, the overlying epidermis undergoes bulla formation or necrosis, resulting in extensive areas of epidermal sloughing and superficial erosion (Figs. 179-3 and 179-4A,B). Alternatively, with or without antibiotic therapy, infection may localize in the soft tissue with dermal and subcutaneous abscess formation, necrosis, and fasciitis (Fig. 179-5). Regional lymphadenopathy may be associated with cellulitis on an extremity. In older individuals, thrombophlebitis may complicate lower leg cellulitis.

Similar to erysipelas, recurrent cellulitis has been reported after mastectomy. Cellulitis of the ipsilateral arm can be recurrent due to associated lymphedema caused by axillary lymph-node dissection and irradiation.[12] Cellulitis at the site of saphenous vein grafting for coronary artery bypass may also recur.

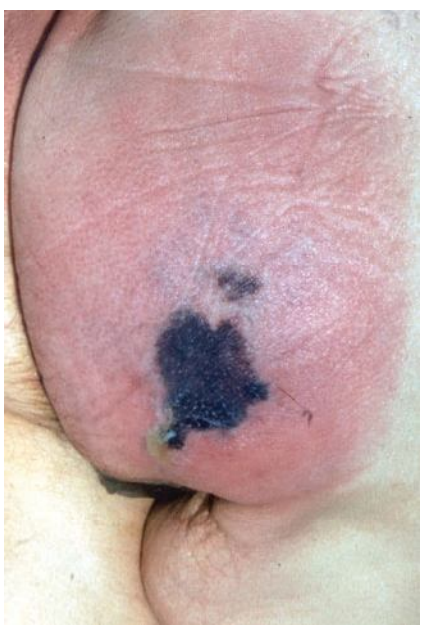
SURGICAL WOUND INFECTIONS Surgical wound infections are the most common adverse events in hospitalized patients undergoing surgery and are classified as incisional (superficial) or deep.[13] Incisional wound infections involve the skin, subcutaneous tissue, and/or muscle (see Fig. 179-4B). Deep infections involve structures adjacent to the surgical wound that were entered or exposed during the procedure, such as subfascial layers, viscera, and/or spaces within the peritoneum, thorax, or joints. Up to 80 percent of wound infections are incisional. A wound is considered to be infected if there is drainage of purulent material and evidence of inflammation. Incisional infections present with erythema, pain, tenderness, and local swelling and, often, with low-grade fever. Purulent drainage reveals neutrophils and cultures most often grow *S. aureus.* Separation of the margins of the wound is usual and this allows appropriate drainage. Deep-wound infections may be more subtle and delayed and often present as fever of uncertain cause. Progressive bacterial synergistic gangrene and other variants of gangrenous cellulitis can arise in surgical wounds or around sutures (see the section Gangrenous Cellulitis, Infection Gangrene, and Crepitant Soft-Tissue Wounds).

The complications of superficial and deep-wound infections include poor healing, bacteremia, the local and systemic effects of prolonged hospitalization, poor nutrition, residual compromised tissue integrity, and the consequence of prolonged antibiotic therapy in a hospital setting. Additionally, wounds infected with toxin-producing *S. aureus* or GAS may result

▲ **FIGURE 179-4** **A.** Cellulitis after puncture trauma. The forearm is swollen, erythematous, and tender; there is abscess formation, blistering, and crusting. **B.** Cellulitis arising at the site of a surgical excision: *Staphylococcus aureus.* Note discharge of pus.

in systemic complications such as toxic shock syndrome or scarlet fever (see Chap. 178).

CELLULITIS COMPLICATING A PRESSURE ULCER Pressure ulcers, particularly those located in the sacrum in elderly, frail, malnourished individuals, become contaminated by a variety of facultative and anaerobic microorganisms from the skin and the bowel, including *S. aureus,* enterococci, *Pseudomonas aeruginosa,* and *Bacteroides fragilis*. In addition to pain and cellulites, the ulcer can be undermined and may eventually be complicated by bacteremia, often polymicrobial, or the underlying bone can become infected. Similar to other open wounds, the identity of the active pathogen(s) may be difficult to determine.



▲ **FIGURE 179-5** Gangrenous cellulitis: Necrotizing fasciitis. Note the black necrotic plaque, resembling a third-degree burn, and an erythematous margin. There is severe systemic toxicity.

CELLULITIS ARISING AT SITES OF ANIMAL BITES Domestic dog and cat bites are frequent and can give rise to painful, necrotizing cellulitis caused by *Pasteurella multocida, Capnocytophaga canimorsus* (especially in asplenic individuals), and a host of other aerobes and anaerobes from the animal's mouth or the skin of the infected individual. Dog bites are often accompanied by a crush injury that devitalizes tissues. The bite of cats can inject organisms (via sharp incisors) deep into tissues, including joint spaces, tendon sheaths, or below the periosteum of bone (see Chaps. 183 and 209).

Human bites have a higher incidence of infection than do animal bites because of the mix of oral bacteria (aerobes and anaerobes), as well as the crush injury imparted along with the bite. Organisms include various streptococci, *S. aureus, Eikenella*, *Corynebacterium*, and the anaerobic peptostreptococci and peptococci.

GANGRENOUS CELLULITIS, INFECTIOUS GANGRENE, AND CREPITANT SOFT-TISSUE WOUNDS These STIs are characteristically rapidly developing, progressive, and accompanied by constitutional symptoms, severe pain, and tenderness, with changes in overlying skin that progress to bulla formation and frank necrosis. The process can be in the superficial or deep fascia with secondary changes in the overlying soft tissues. Palpation may reveal tenderness or gas in the area of involvement. This section focuses on the various types of necrotizing fasciitis and other necrotizing STIs, with and without gas formation, excluding myonecrosis (Table 179-2).

Streptococcal Gangrene, Including Type II Necrotizing Fasciitis. In streptococcal gangrene, a monomicrobial infection, the pathogen is almost always a GAS, although groups C and G isolates, as well as other microorganisms, are infrequently identified. Occasionally, in newborns but also in patients early postpartum, group B streptococci have been recovered. *Streptococcus pneumoniae* necrotizing fasciitis is rarely reported and behaves like GAS infections.[14] In addition, monomicrobial necrotizing fasciitis caused by both health care–acquired MRSA (HA-MRSA) and CA-MRSA, have been reported (see the section Methicillin-Resistant *Staphylococcus aureus*). Recently, 14 cases of CA-MRSA in patients with intraoperative findings consistent with necrotizing fasciitis, myonecrosis, or both, have been reported.[15]

Patients may be immunocompromised by age or illness such as diabetes, alcoholism, or cirrhosis, but are usually healthy individuals. The location of the necrotizing lesion is most often an extremity and rarely, the face. A small area of involvement may underestimate the deep extent of the infection. Pain, erythema, and edema with rapid formation of bullae, constitutional symptoms with high fever, and toxicity are characteristic of early progression. There is bacteremia in approximately two-thirds of patients and evolution of necrosis of the overlying skin can

TABLE 179-2
Findings in Gangrenous Cellulitis and Infectious Gangrene

Factor	Progressive Bacterial Synergistic	Synergistic Necrotizing Cellulitis	Streptococcal Gangrene	Clostridial Myonecrosis (Gas Gangrene)	Necrotizing Infections in Immunosuppression
Etiology	Streptococci, *Staphylococcus aureus*	Mixture of organisms: *Bacteroides*, peptosreptococci, or *Escherichia coli*	Group A streptococci or enteric bacteria	*Clostridium perfringens*	*Rhizopus, Mucor, Absidia, Pseudomonas aeruginosa*
Predisposing conditions	Surgery or draining sinus	Diabetes	Diabetes or abdominal surgery	Trauma	Diabetes, corticosteroid use, immunosuppression, burns
Fever	Minimal	Moderate	High	Moderate to high	Low in fungal, high in pseudomonal
Pain	Prominent	Prominent	Prominent	Prominent	Mild
Anesthesia	Absent	Absent	May occur	Absent	May occur
Crepitus	Absent	May occur	Absent	Present	Absent
Course	Slow	Rapid	Very rapid	Extremely rapid	Rapid

Modified with permission from Swartz MN, Pasternack MS: Cellulitis and subcutaneous tissue infections, in *Principles and Practice of Infectious Diseases*, edited by Mandell GL et al. Elsevier, Philadelphia, 2000, p 1183.

be rapid and dramatic, revealing deeper structures, including tendon sheaths and muscle. Though lymphangitis is rare, metastatic abscesses can occur. A streptococcal toxic shock–like syndrome often accompanies this infection, referred to in the lay press as a *flesh-eating bacterial process*. With bulla formation, the diagnosis is apparent from a Gram stain of an aspirate. As the process evolves, necrosis and eschar formation precede sloughing of tissues. Early symptoms of local pain eventually evolve to anesthetic areas and progressive toxicity is often accompanied by mental depression. Treatment with penicillin and clindamycin as well as surgical débridement and supportive therapy can be lifesaving, but the prognosis remains poor.[11,16] Chapter 178 provides a detailed discussion of the streptococcal toxic shock–like syndrome, its prognosis, and therapy.

Type I Necrotizing Fasciitis. Type I necrotizing fasciitis, a polymicrobial infection, is caused by a mix of facultative and anaerobic microbes, often delivered into the subcutaneous tissues after surgery, bowel perforation secondary to neoplasm or diverticulitis, trauma, or parenteral drug abuse via skin-popping. It often occurs in patients compromised by diabetes or malnutrition. Organisms include at least one anaerobic organism recovered in a mix of facultative microbes: nongroupable streptococci, enterococci, anaerobic streptococci and staphylococci, *Bacteroides* sp., and Enterobacteriaceae including *E. coli,* as well as various aquatic bacteria. Often, three to five species contribute to the infection, which may have a slower pace than GAS in evolving to a full-blown process with cutaneous manifestations.[17,18]

Type I necrotizing fasciitis most commonly occurs on an extremity, abdominal wall, perineum, or about operative wounds (see Fig. 179-5). Clinically, it is indistinguishable from streptococcal gangrene. Although the initial pace of the illness may be slower, it is important to recognize that when this infection presents in the thigh (dissection along the psoas muscle) or abdominal wall, it may be secondary to an intestinal source (occult diverticulitis, rectosigmoid neoplasm). The involved area may be painful at first and then evolve with objective findings: swelling, erythema, warmth, and tenderness. The process is often more extensive than the overlying skin changes would suggest. Within several days, the skin color becomes purple, bullae develop, and frank cutaneous gangrene ensues (Fig. 179-6). At this stage, the involved area is no longer tender but has become anesthetic as a result of occlusion of small blood vessels and destruction of superficial nerves in the subcutaneous tissues. Crepitus is often present, particularly in patients with diabetes mellitus or if gas-forming anaerobes, such as *Bacteroides* sp., are causative.[11,18] Though not universally used, the Laboratory Risk Indicator for Necrotizing Fasciitis has been devised from retrospective analysis of cases and tested in a secondary analysis of small clinical trials, with reported negative predictive value of 95 percent and high specificity.[19]

Fournier Gangrene. Fournier gangrene is a localized variant of necrotizing fasciitis involving the scrotum and perinis.[11,20,21] It is usually caused by the same mix of facultative and anaerobic organisms that are associated with type I necrotizing fasciitis. In rare cases, GAS as the single pathogen has been implicated, and this may be related to rectal ring carriage or to oral-genital sex. The average age at onset is 50 to 60 years of age. Most men have underlying diseases or history of procedures. These include diabetes mellitus, ischiorectal abscess, perineal fistula, bowel disease (rectal or colon carcinoma, diverticulitis), scrotal or penile trauma, prior hemorrhoidal or urogenital surgery, pressure ulcers of the scrotum and perineum (e.g., alcoholics

▲ **FIGURE 179-6** Type I necrotizing fasciitis with progressive gangrene of the pubic, perigenital, and perianal tissue.

▲ **FIGURE 179-7** Fournier gangrene. There is painful erythema with marked edema, superficial desquamation, and areas of necrosis in the inferior aspect of the scrotum.

sitting in a drunken stupor), paraphimosis and, rarely, obscure causes, such as dissection of pancreatic secretions through the retroperitoneum and into the scrotum in acute pancreatitis.

The onset of Fournier gangrene can be insidious, with a discrete area of edema, erythema, and necrosis on the scrotum, progressing to advancing skin necrosis rapidly over 1 to 2 days (Fig. 179-7). Pain, swelling, and crepitus in the scrotum, perineum, or suprapubic region may be marked. Foul-smelling drainage occurs, indicating a contribution from anaerobes. Purplish discoloration of the scrotum, an initial "red flag," progresses to frank gangrene. The infection tends to be superficial, limited to skin and subcutaneous tissue and extending to the base of the scrotum, but it may spread to the penis, perineum, and abdominal wall along fascial planes. The testes, glans penis, and spermatic cord are usually spared, as they have a separate blood supply. The infection may progress and invade the abdominal panniculus in obese patients, especially those with diabetes mellitus, leading to rapid and extensive destruction of tissue and requiring wide débridement and prolonged hospitalization.

Cervical Necrotizing Fasciitis and Craniofacial Necrotizing Fasciitis. Cervical necrotizing fasciitis is a type I infection (polymicrobial etiology), but GAS can be the single etiologic agent in rare cases, particularly in the setting of peritonsillar abscess formation. Most commonly, cervical necrotizing fasciitis originates from dental or pharyngeal sources. Crepitus may develop as the infection spreads to the face. This is in contradistinction to necrotizing fasciitis that starts in the face (craniofacial necrotizing fasciitis), which is most commonly caused by GAS after a traumatic episode. Cervical necrotizing fasciitis carries a much higher mortality rate than the craniofacial variant.

Synergistic Necrotizing Cellulitis (Necrotizing Cutaneous Myositis, Synergistic Non-Clostridial Anaerobic Myonecrosis). Synergistic necrotizing fasciitis is unique in that all soft-tissue structures, including muscle, can be involved in a painful, progressive, polymicrobial infection that is highly lethal. The poor prognosis relates to the demography of the usual patient: frail, elderly, diabetic, wasted, or obese, and almost always with compromising cardiovascular and renal disease. The process may begin slowly, evolving over 7 to 10 days with mild symptoms, primarily pain. Individuals are often afebrile or have only low-grade fever, lacking systemic toxicity in the early stages. The initial skin lesion is a small area of necrosis or reddish-brown blister with extreme local tenderness; the superficial appearance belies the widespread destruction of the deeper tissues. Skin sinuses (with surrounding areas of blue-gray gangrene) form, draining a foul-smelling thin pale "dishwater" exudate containing fragments of necrotic fat. Gram stain of the drainage reveals both Gram-positive and Gram-negative organisms and rare or absent neutrophils. Extensive gangrene of the superficial tissues and fat can be visualized by direct inspection through open skin areas or with skin incisions. Gas can be palpated in the tissues in approximately one-fourth of patients. Organisms frequently isolated included anaerobes (streptococci and/or bacteroides) and facultative bacteria, especially Enterobacteriaceae (*E. coli, Proteus, Klebsiella)*. Coagulase-negative staphylococci have also been reported.[22,23]

The most common site of involvement in approximately one-half of the cases is the perineum. The major predisposing causes are peri-rectal and ischiorectal abscesses. These localized infections track to the deeper structures of the pelvis, leading to a severe infection. A more superficial form involves the buttocks without extension to deeper muscles; 40 percent of individuals have involvement of the thigh and leg. Some infections arise in the adductor compartment of the thigh, often extending from an infected amputation stump or diabetic gangrene. The remaining 10 percent of cases are often associated with severe vascular disease and diabetes and are found on the lower abdomen, distal leg, and, rarely, on the neck.

Even with rapid surgical and medical interventions, the mortality rate remains in the 40 to 50 percent range, in part because of accompanying diseases. Incision, drainage, extensive débridement, and amputation are the aggressive actions that must be taken in concert with antibiotics (including one directed at bacteroides) guided initially by the Gram stain.[11]

Progressive Bacterial Synergistic Gangrene (Meleney Gangrene). Progressive bacterial synergistic gangrene typically occurs in association with wire stay sutures in a drain site after an abdominal operation (ileostomy, colostomy), in an incision in the chest wall after abdominal or thoracic infection (empyema), at the exit site of a fistulous tract, or in a chronic ulcer. The infection usually is recognized as one or more shaggy, painful ulcers developing within a week or two of the procedure, especially in proximity to wires or other foreign bodies.[11,24,25] *S. aureus* and the anaerobic streptococci are most commonly implicated. Though controversial, a role for *Entamoeba histolytica* has been proposed.

Gangrenous Cellulitis in the Immunocompromised Individual. The microorganisms associated with necrotizing cutaneous infections in the normal host are joined by a variety of other traditionally pathogenic and non-pathogenic bacteria, as well as fungi in compromised patients. In the presence of thermal burns, bacteremic *P. aeruginosa* may colonize normal skin, producing ecthyma gangrenosum (see Chap. 180), or may be attracted to burn areas, leading to extensive bacteremic *Pseudomonas* gangrenous cellulitis. Mucormycotic gangrenous cellulitis can engraft onto thermal burns or complicate percutaneous catheter areas in immunosuppressed individuals.[26] In the immunocompromised host, it becomes mandatory to biopsy any necrotic cellulitic lesions and to be alert to the possibility of a wide range of bacterial, viral, fungal, and even parasitic pathogens.

Nonclostridial Crepitant Cellulitis. The patient with nonclostridial crepitant cellulitis may have experienced a traumatic or surgical injury that was inadequately

débrided or had an underlying local infection, a poorly performed needle stick, or skin popping for delivery of illicit drugs.[27] Underlying diabetes, glucocorticoid or nonsteroidal anti-inflammatory drug (NSAID) use, and granulopenia may be present. The clinical presentation is often insidious, with low-grade fever, mild pain, and tenderness, but with early palpable gas and edema. Anaerobic non-spore–forming isolates may include *Bacteroides* sp. or peptostreptococci, often with facultative Gram-negative bacilli. In uncontrolled diabetes, the presence of gas may result from metabolism of glucose by *E. coli, Klebsiella, Aeromonas,* and other microorganisms (see Chap. 180).

CLOSTRIDIAL SOFT-TISSUE INFECTIONS The histotoxic clostridia are responsible for a variety of infections that involve the subcutaneous and muscular tissues, with changes in the overlying skin that can be abrupt and dramatic. Clostridial anaerobic cellulitis is an infection of the more superficial subcutaneous zone, usually in tissues that are already devitalized, and, rarely, involving the deep fascia or muscle. Clostridial myositis, or gas gangrene, is a process that is anatomically in the muscle layer but with significant changes in the skin and subcutaneous tissues via interference with vascular and lymphatic structures. The histotoxic clostridia primarily involved in these infections include the human gut commensal *C. perfringens* and the environmentally resident *C. septicum*. *C. perfringens* is present in approximately 90 percent of normal colons but *C. septicum* is rarely found, perhaps only in 5 percent of asymptomatic individuals. Newer and traditional bacteriologic techniques allow for easy identification of these obligate anaerobes.[28]

ANAEROBIC CELLULITIS Anaerobic cellulitis is an infection of devitalized tissue usually caused by *C. perfringens* with or without other bacteria, occurring in a dirty or inadequately débrided wound several days after injury or after a needle stick or surgery. The onset is more gradual than in anaerobic myonecrosis (gas gangrene). The clostridia are able to grow in the wound and extend rapidly through tissue planes with attendant formation of large quantities of gas that is readily palpable. A thin, dark-gray to brown, foul, serous discharge is produced. Gram stain of the drainage reveals short, plump, blunt-ended, Gram-positive rods with a variable number of polymorphonuclear leukocytes and, occasionally, other bacterial forms. Unlike gas gangrene, there is relatively little local pain or edema, change in overlying skin, or toxemia. At surgery, the muscles appear normal, but gas may be readily evident throughout the exudate. Anaerobic cellulitis can be distinguished from anaerobic myonecrosis by inspection of muscle to avoid needless mutilating surgery and amputations. Treatment consists of opening the wound, removing necrotic debris, and administering antibiotics (penicillin and either clindamycin or metronidazole). Occasionally, bacteremic *C. septicum* can spread to subcutaneous tissues. These patients are toxic, unstable, and, usually, the suspicion of *C. septicum* is raised on finding subterminal spores in large Gram-positive bacilli.[29]

Recently, infection by *C. sordellii* and *C. novyi* has been reported in intravenous drug users. Patients develop toxic shock and necrotizing fasciitis, though fever is not universally seen. The organism can usually be cultured from wounds, but blood cultures may remain negative. Before these reports, most of these cases were associated with childbirth or medical abortion.[30]

ANAEROBIC MYONECROSIS (GAS GANGRENE) Anaerobic myonecrosis is a rapidly progressing, toxemic, potentially lethal infection involving muscle but with secondary changes in the overlying skin. Gas gangrene may also occur in the uterus, intraperitoneal viscera, as well as the brain and eye in the absence of bacteremia. The infection may develop as a complication of muscle injury, a traumatic dirty wound with extensive muscle and soft-tissue damage, including injectable drugs,[31] or after surgery on the bowel or gallbladder. *C. perfringens* is the most common pathogen and also part of the normal flora but rarely associated with spontaneous gas gangrene. Two toxins appear most important in pathogenesis. α-Toxin (phospholipase C/lecithinase) hydrolyzes cell membrane and increases capillary permeability and platelet aggregation. θ-Toxin (perfringolysin O), though non-essential for disease, appears to inhibit recruitment of polymorphonuclear leukocytes, explaining their paucity in biopsies of infected muscle tissue.[4] Group A and anaerobic streptococcus, as well as bacteroides, *E. coli* and *Klebsiella*, have also been reported.

The incubation period of anaerobic myonecrosis is often short (12 to 24 hours) but may be delayed, rarely developing after anaerobic cellulitis. The first symptom is usually severe local pain followed by fever, tachycardia, and hypotension. Gas formation is present but not prominent in subcutaneous tissues, and may be completely obscured by edema of the superficial tissues. The skin often takes on a dark yellow or bronze discoloration with tense blebs or bullae containing dark brown fluid. A serosanguineous exudate can be expressed from the wound or aspirated from a bullous lesion. Gram stain of the exudate reveals plump Gram-positive rods and rare or absent white blood cells even with a systemic leukocytosis. The overlying skin may develop patchy necrosis and desquamation. At surgery, the process in the muscle is evident, with gray pallor, absence of bleeding, presence of gas and failure of muscle to respond to direct stimuli. Removal of devitalized tissue, antibiotics, and supportive therapy must be quickly undertaken, and amputation can be lifesaving in limb involvement. Antitoxin is no longer available and hyperbaric oxygen is reserved for involvement of areas not amenable to débridement but is not recommended as monotherapy.[28]

SPONTANEOUS, NONTRAUMATIC ANAEROBIC MYONECROSIS In the absence of an external wound, septicemic gas gangrene may occur spontaneously, usually caused by *C. septicum* and often associated with hematologic malignancies or occult colon cancer, especially in the cecal area. Spontaneous *C. septicum* gas gangrene is a fulminant disease, with a mortality approaching 100 percent and marked by a precipitous onset and progression, often with subcutaneous gas, myonecrosis, and high-grade septicemia. In addition, the organism may be aerotolerant and thus lacks susceptibility to hyperbaric oxygen. Progression is more rapid than in other forms of anaerobic myonecrosis, and no controlled treatment trials exist for this disease. Overlying skin of an involved area becomes red-brown and the epidermis sloughs early in the illness.[29]

Recently, spontaneous gas gangrene from *E. coli* has been reported. All three patients were cirrhotic, and no obvious source of bacteremia, such as gastrointestinal perforation, was noted.[32] In addition, sterile, spontaneous diabetic myonecrosis is important to consider in the differential diagnosis, though patients are usually not febrile and do not appear toxic. This entity is most common in women with late-stage diabetes complicated by nephropa-

thy and retinopathy and usually affects the quadriceps and thigh muscles, occasionally with little, if any rise, in muscle enzymes.

LABORATORY STUDIES

Smears of Pus, Exudate, and Aspirates

The typical appearance of an STI coupled with epidemiologic and clinical data may guide antimicrobial therapy but is not completely reliable, particularly in patients who are immunocompromised by diseases or their therapies. Immediate and more substantial clues can come from aspiration of complicated, fluctuant lesions or bullae and from swabs of open lesions using the Gram stain, fungal stains, and other direct methods, including immunofluorescence (see Chap. 176).

Though not indicated in routine or uncomplicated cases, nonbacteriostatic saline can be injected into the advanced border of the infected site, followed by aspiration of tissue fluid that is then subjected to staining. Successful identity of pathogens is accomplished between 7 percent and 33 percent of the time, but cultures of the material in addition to blood cultures is a vital part of the search for the etiologic agent in all STIs.[1,33] Sampling the most inflamed area of the lesion, rather than the advancing edge, may increase the yield of cultures.[12] Open lesions such as postsurgical, traumatic, and pressure ulcers, may contain multiple organisms, some of which may be significant whereas others are contaminants.[34] The Gram stain may help initially to identify the most significant morphologic and staining bacteria but often a biopsy as well as the inflammatory cell type of the lesion, followed by cultures, special stains, and pathologic investigation, proves most helpful compared to study of surface material. Biopsy for tissue culture may have a much higher yield in establishing a pathogen than needle aspiration. Pathogens are more likely to be seen microscopically and cultured from abscesses, surgical wounds, bullae, and deeper tissue exudates from necrotizing fasciitis and myonecrosis.

Bacteremia is uncommon in cellulitis and positive blood cultures are only noted 4 percent of the time. Therefore, routine blood cultures do not appear to be cost effective in routine care of the immunocompetent host. If cellulitis is complicated by lymphedema, the diagnostic yield of blood cultures rises to 30 percent. In addition, high fever, chills, buccal and periorbital cellulitis, or exposure to salt- or freshwater sources, are indications for ordering blood cultures.[12] Identification of the responsible pathogen is the gold standard in effective antimicrobial therapy of STI (see Chap. 176 for a discussion of other methods, many noncultural, currently used or developed to identify a responsible pathogen).[35]

Imaging

Routine imaging is generally not necessary in uncomplicated cases. Infections with anaerobic organisms, especially *Clostridia* and bacteroides, may lead to gas formation, which can then be visualized radiographically. Conventional x-ray of anaerobic cellulitis may reveal pockets of gas confined to superficial tissues and is usually readily palpable. True gas gangrene (clostridial myositis) can be distinguished from anaerobic cellulitis by the linear feathery appearance of gas infiltrating through groups of muscle fibers, although palpation may not reveal crepitus.[11,28] Lack of gas pattern on x-ray does not rule out necrotizing fasciitis or myonecrosis caused by non-gas–producing organisms such as *S. pyogenes*, however. In addition, if underlying osteomyelitis or source of bacterial seeding to the skin is suspected plain films or computed tomography are indicated.

Magnetic resonance imaging has gained favor as a technique in diagnosing STIs. In a recent study, 23 patients with acute STIs underwent magnetic resonance imaging evaluation. T2-weighted images best highlighted the cutaneous disease process. In patients with pyomyositis or subcutaneous abscesses, a spindle-shaped or round, well-defined area of high signal intensity was observed in the muscle or fat, respectively. Patients with necrotizing fasciitis had deep dermal, well-defined, dome-shaped areas of increased signal. Patients with nonnecrotizing cellulitis had smaller, heterogeneous areas of increased signal.[36] However, it is important to note that radiographic testing should never delay open surgical examinations in cases with high-index of suspicion where definite diagnosis and curative therapy can be obtained.

HISTOPATHOLOGY

In addition to direct stains and cultures pathologic investigation with special staining can be very useful. Direct immunofluorescent techniques have been reported to identify streptococcal pathogens in 19 of 27 cases of erysipelas and in 10 of 15 cases of cellulites.[37] Lesional skin punch biopsy is often helpful in ruling out a cellulitis-simulating non-infectious inflammatory lesion or a co-existing diagnosis such as erythema nodosum, vasculitis, or eosinophilic cellulitis. For instance, in ecthyma gangrenosum (caused by *P. aeruginosa*), a septic vasculitis is seen with epidermal necrosis and Gram-negative bacilli occasionally seen in vessel walls.

Histologically, erysipelas is characterized by intense edema, marked lymphatic and vascular dilatation of the superficial dermis, and a profuse infiltration of tissue spaces and lymphatic channels with streptococci and neutrophils. The streptococci are not found in the blood vessels themselves, but their presence in the lymphatics produces an inflammatory reaction about these vessels. The dermis is markedly edematous and there is infiltration with neutrophils, and mononuclear cells, mostly centered around vessels. Histiocytes and granulation tissue may be seen in chronic lesions. The epidermis is only secondarily involved, primarily with edema.

Deep incisional biopsy and histopathologic examination on frozen section has been shown to improve diagnosis and decrease mortality in necrotizing fasciitis by rapidly establishing the diagnosis and thus defining the need for surgical débridement.[38] Indications for an open exploration and a biopsy include confusion, pain and tenderness, tachycardia, tachypnea, ketoacidosis/hyperglycemia, bullous or gangrenous skin changes, bronzing of the skin, spreading areas of anesthesia, thin reddish discharge with undermining of wound edges, crepitus, and an abscess with multiple tracts.

In streptococcal gangrene, the prominent angiitis and focal dermal necrosis with spread along fascial planes suggest that the disease is fundamentally gangrene of the subcutaneous tissues followed by necrosis of the overlying skin. Microscopically, fibrinoid necrosis is present in the media of many arteries and veins passing through the edematous and damaged fascia.[39] Fibrin thrombi are present. The epidermis, dermis, skin appendages, and even fascial planes in the area of gangrene undergo coagulation necrosis. Numerous polymorphonuclear leukocytes and mononuclear cells infiltrate the lesion, and the up-

per layers of the dermis contain large numbers of Gram-positive cocci.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of erysipelas, cellulitis, necrotizing cellulitis, and myonecrosis includes other infections, as well as non-infectious inflammatory disorders that have features that may be confused with STI (Box 179-1). Most notably, these include Sweet syndrome, lymphoma, carcinoma erysipeloids, and spontaneous, sterile diabetic myonecrosis.[40–42]

Specific Bacterial Species Associated with Soft-Tissue Infection

PERSON-TO-PERSON SPREAD **Staphylococcus aureus *and Groups A, B, C, and G β-Hemolytic Streptococcus.*** (See Chap. 177)

***Enterobacteriaceae,* Haemophilus influenzae, Neisseria meningiditis, *and* Pseudomonas aeruginosa.** (See Chap. 180)

Streptococcus pneumonia. *S. pneumoniae* is a rare cause of cellulitis and necrotizing fasciitis, perhaps occurring more frequently in recent years and behaving similar to GAS STI.[43,44] Predisposing or associated conditions include chronic alcoholism, drug abuse, HIV, connective-tissue disorders, glucocorticosteroids, and the use of NSAIDs.[14] Bacteremia is an underlying mechanism in approximately one-half of the cases described, but relative or absolute penicillin resistance in STIs does not appear to be a factor.

Specific Bacterial Species Associated with Aqueous Environments. *Aeromonas* sp. and *Vibrio* sp. (see Chap. 183).

Specific Bacterial Species Associated with Soil Exposure. *Clostridium* sp. (primarily, excluding endogenous *C. perfringens,* the most frequently isolated pathogen) were discussed earlier in this chapter.

Specific Bacterial Species Associated with Animal Exposure. (See Chap. 183) *S. iniae, Erysipelothrix rhusiopathiae, Bacillus anthracis,* and *P. multocida* are associated with animal exposure.

Specific Bacterial Species Associated with Bioterrorism. (See Chap. 213) *B. anthracis*, *C. botulinum*, *Yersinia pestis*, and *Francisella tularensis* comprise category A disease agents. These agents can easily disseminate from person to person and result in high mortality rates. Category B agents, which include *Brucella* sp., *C. perfringens,* as well as several other bacteria considered to be food and water safety threats, are defined as those with moderate ability to disseminate but lead to lower mortality rates compared with category A agents (see Chap. 213).

Box 179-1

Differential Diagnosis of Erysipelas, Acute Cellulitis, and Necrotizing Soft-Tissue Infections

	NON-INFECTIOUS	INFECTIOUS
Erysipelas and cellulitis	Dissecting cellulitis of the scalp Acne conglobata Hydradenitis suppurativa Acute allergic contact dermatitis Erythema nodosum Eosinophilic cellulitis Giant urticaria and angioedema Fixed drug eruption Deep venous thrombosis Lipodermatosclerosis Vasculitis such as polyarteritis Kawasaki disease Familial Mediterranean fever Gout Deep venous thrombosis Sweet syndrome Pyoderma gangrenosum Inflammatory breast carcinoma (carcinoma erysipeloids) Lymphoma	Osteomyelitis of the maxillary or frontal bones secondary to paranasal sinusitis Extension of subperiosteal infection from long bone osteomyelitis Erythema migrans Erythema infectiosum (human parvovirus B19) Early herpes zoster
Necrotizing soft tissue	Factitial ulcers Pyoderma gangrenosum Calciphylaxis Ischemic necrosis (atherosclerosis obliterans or thromboembolism) Fixed drug eruption warfarin necrosis, heparin necrosis Pressure ulcer Brown recluse spider bite Spontaneous sterile diabetic myonecrosis	Purpura fulminans Amebic (*Entamoeba histolytica*) gangrene after bowel surgery

***Methicillin-Resistant* Staphylococcus aureus.** Antibiotic resistance is of increasing concern particularly in the case of MRSA, which accounts for a large number of STIs that are not responsive to empiric therapy. Most of these resistant strains were initially thought to be acquired from health care settings such as hemodialysis centers, after prolonged hospitalizations, or after use of indwelling catheters. HA-MRSA was initially treated with vancomycin, and most infected patients were hospitalized because oral formulations are poorly absorbed and do not achieve sufficient concentrations in soft tissue. With the advent of linezolid (see the section Treatment), which is available orally, more of these infections are now treated in the outpatient setting.

Though still a controversial issue, CA-MRSA strains are thought to be "escaped" nosocomial isolates. Up to 18 percent of people with CA-MRSA had a history of hospitalizations 12 months before infection and up to 85 percent of patients with CA-MRSA have at least one risk factor for acquiring HA-MRSA.[47] Novel multi-resistant strains also include *S. sciuri* and *S. haemolyticus*, which have also been reported in STIs.[52]

Vancomycin-Resistant Enterococcus. Vancomycin-resistant enterococcus is usually acquired as a nosocomial pathogen and less frequently causes STIs when compared with its ability to colonize skin and wounds. In a recent study, only 5 percent of enterococcal infections involved the skin or soft tissue.[53]

Mycobacterium *Species.* *Mycobacterium fortuitum* complex species are rapid growers

and include *M. fortuitum, M. chelonae,* and *M. abscessus* (see Chap. 184). These organisms are widely distributed in soil, dust, and water. Inoculation can occur via puncture wounds (injection or traumatic) or surgical procedures (augmentation mammoplasty, median sternotomy, percutaneous catheterization); rarely, primary cellulitis occurs without recognizable skin trauma.[54,55] Contaminated gentian violet used for skin marking has been the source in some outbreaks. *M. fortuitum*–complex STIs characteristically occur several weeks after the inciting injury and appear as indolent wound infections (nodules, ulcers, granulomatous papules, or verrucous plaques). In immunocompromised individuals, *M. fortuitum* can disseminate hematogenously to skin (multiple recurring abscesses on the extremities) and joints. Treatment regimens are complex, require careful susceptibility testing, and may include excisional biopsies.

Box 179-2

Antimicrobial Treatment of Necrotizing Infection of Skin, Fascia, and Muscle

ORGANISM	DRUG OF FIRST CHOICE	ALTERNATIVE DRUGS
Mixed infection	Ampicillin/sulbactam Imipenem/cilastatin, meropenem Ticarcillin/clavulanate	Cefoxitin, clindamycin, or metronidazole + an aminoglycoside
Streptococcus (A, C, G, B)	Penicillin G + clindamycin for toxic shock syndrome or necrotizing fasciitis	Ceftriaxone + clindamycin Vancomycin, linezolid, daptomycin
Enterococcus (systemic infection)	Penicillin G or ampicillin + Gentamicin or streptomycin	Vancomycin + gentamicin or streptomycin, linezolid Quinupristin/dalfopristin, or daptomycin
Staphylococcus aureus	Nafcillin (or oxacillin) Vancomycin (for methicillin-resistant strains) Linezolid, daptomycin	Cefazolin or amoxicillin/clavulanic acid, clindamycin, quinupristin/dalfopristin,
Clostridium perfringens	Penicillin G + clindamycin	Metronidazole and imipenem or meropenem, Ceftriaxone Chloramphenicol

PROGNOSIS AND CLINICAL COURSE

Uncomplicated erysipelas remains confined primarily to the lymphatics and subcutaneous tissues, occasionally complicated by bleb formation and, rarely, by the presence of an abscess. Even in the days before antibiotic therapy, it was often a self-limited process, subsiding over 7 to 10 days. Occasionally, untreated erysipelas or cellulitis may be complicated by bacteremia with metastatic infection in various organs. Prompt treatment prevents both suppurative and non-suppurative complications. However, in young infants and elderly debilitated patients and in individuals receiving glucocorticoids, the disease may progress with devastating rapidity to a fatal outcome.

Erysipelas has a tendency to recur in the same area, probably a result of the predisposing effects of chronic lymphatic obstruction, persistent edema, and even elephantiasis-like swelling caused by earlier infections. Such recurrent infections may produce persistent swelling of the lips (macrocheilia), cheeks (particularly the lax tissues beneath the eyes), lower extremities, or even abdomen. Chronic lymphedema of the lower extremities secondary to recurrent erysipelas may result in elephantiasis nostra verrucosa (see Chap. 175). Early therapy and prolonged elevation of the affected area can help to preserve better tissue resistance to reinfection. Some patients with frequent recurrences in the same area benefit from prophylactic antibiotics, usually monthly benzathine penicillin injections.[56]

Acute cellulitis, with or without abscess formation, has a tendency to spread through the lymphatics and bloodstream and may be a serious disease if not treated early. In older patients, involvement of a lower extremity may be complicated by thrombophlebitis. In patients with chronic edema, the process may spread extremely rapidly and recovery may be slow, despite drainage and sterilization of the lesions by antibiotics.

The mortality rate for necrotizing fasciitis is high (reported to be approximately 40 percent greater when complicated by streptococcal toxic shock–like syndrome; see Chap. 178). Early diagnosis and aggressive treatment of necrotizing fasciitis is the most important factor in determining outcome.[57] Overall, clostridial infections have a mortality of 20 percent to 70 percent, depending on the location of the process, with myonecrosis associated with the more lethal prognosis. Spontaneously occurring gas gangrene tends to have an even more ominous mortality, approaching 100 percent, because of its rapid onset, without an obvious predisposing traumatic or surgical wound and the association with an underlying malignancy. The mortality for synergistic necrotizing cellulitis is at least 50 percent, the patient usually succumbing to septic shock and circulatory collapse.

In assessing prognosis, the wide ranges described for these infections depends on the underlying health and immune status of the patients. Early recognition and definition of etiologic agents guides appropriate antibiotic usage, as well as surgical decisions. Many of these infections are life threatening, and, therefore, urgent evaluation and therapy can improve prognosis.

TREATMENT

Antibiotics

See Box 179-2 for therapeutic guidelines for necrotizing infections.

Mild cases of early erysipelas can be treated on an outpatient basis with either intramuscular procaine penicillin (600,000 units twice daily) or with oral penicillin V, 500 mg every 6 h. Dicloxacillin (500 mg four times a day) as well as the oral cephalosporins are also effective, particularly if clinical findings make exclusion of acute cellulitis difficult. Macrolides and clindamycin can be used in penicillin-allergic individuals, but increasing resistance of *S. pyogenes* to erythromycin has been reported.[58,59]

Individuals with more extensive streptococcal infections and with underlying medical problems such as diabetes mellitus should be hospitalized and treated with intravenous aqueous penicillin G (1 to 2 million units every 4 to 6 hours). In severe streptococcal skin infections (e.g., extensive erysipelas, cellulitis, or streptococcal gangrene), parenteral aqueous penicillin G should be administered in higher doses. In the ill patient in whom a staphylococcal etiology is identified, a penicillinase-resistant

semi-synthetic penicillin (e.g., nafcillin) should be used and/or vancomycin substituted in the penicillin-allergic individual. In the patient with a questionable penicillin allergy, cefazolin 1 g intravenously every 8 hours) may be chosen. Vancomycin (1 g intravenously twice a day) is the drug of choice in patients who have a methicillin-resistant organism or a prior history of an immediate type reaction (immunoglobulin E mediated) to a penicillin or a cephalosporin.

With the advent of resistant organisms, particularly MRSA, newer agents have been approved by the U.S. Food and Drug Administration for the treatment of STIs and include linezolid (an oxazolidinone), quinupristin-dalfopristin (a streptogramin combination antibiotic), and daptomycin. Though some resistant strains have already been reported after use of linezolid (600 mg twice a day), it has been shown to reduce hospital stay when compared with vancomycin in the treatment of MRSA skin and STIs.[60,61] It is also useful in treating infections caused by vancomycin-resistant enterococcus, though resistance to *Enterococcus faecium* has been reported. In addition, its oral formulation of equal bioavailability makes it useful in outpatient treatment of documented resistant infections. Use of quinupristin-dalfopristin is limited to required intravenous infusions of large volume. Daptomycin (4 mg/kg/day) is bactericidal and has been shown to be equivalent to vancomycin in the treatment of skin and STIs. In addition, given its novel mechanism of action, which is poorly understood but includes disruption of bacterial membrane electric potential, less chance for bacterial resistance is postulated.[62] Tigecycline, a minocycline derivative, has been approved and is in use. In addition, oritavancin and dalbavancin, new glycopeptides with long half-lives that belong to the same class as vancomycin, as well as ramoplanin, a glycolipodepsipeptide, are in development and testing and have shown activity against resistant Gram-positive organisms, particularly *S. aureus*.[63]

The quinolones moxifloxacin and gatifloxacin have been approved by the U.S. Food and Drug Administration for treatment of uncomplicated STIs.[63] On the other hand, meropenem used as monotherapy has been shown to be equally effective to imipenem-cilastatin in the treatment of complicated skin and STIs.[64] Of note, in complicated cases, fluctuant lesions or any fluid collections should be drained in addition to treating with antibiotics.

Treatment decisions for patients with crepitant or gangrenous STI, including necrotizing fasciitis, anaerobic cellulitis, and myonecrosis, must be based on a rapid or presumptive identification of the etiologic agent(s) (see Box 179-2).

Local Measures

Care of the local lesions of erysipelas and cellulitis includes bed rest and elevation of the involved area to reduce local edema. Cool, sterile saline dressings decrease the local pain and are particularly indicated in the presence of bullous lesions. The application of moist heat may aid in the localization of an abscess in association with cellulitis, but it should not be used in a patient with arterial insufficiency of the involved extremity.

Surgical Intervention

Treatment of necrotizing STIs requires early and complete surgical débridement of necrotic tissue in combination with appropriate drainage and high-dose antibiotics. Inspection of the deep fascia can confirm the presence of fat necrosis and preservation of the deep aponeurosis overlying muscle and provide material for bacterial and pathologic study.[41] Re-exploration and débridement should be performed as necessary to ensure that all necrotic tissue has been removed and pockets of pus are drained.

When synergistic necrotizing cellulitis is considered a more likely diagnosis than an abscess, it becomes essential to explore the involved area, including careful assessment of the area of necrosis in the deep subcutaneous tissues as well as inspection of the underlying muscle.

Anaerobic clostridial cellulitis is treated with surgical débridement of all devitalized tissue. The use of hyperbaric oxygen drenching, particularly in patients with far-advanced disease involving the trunk in whom surgical excision would be mutilating, appears to have a place in current therapy.

The surgical approach to clostridial or streptococcal myonecrosis requires rapid evaluation, appropriate antibiotics with penicillin and metronidazole or clindamycin and exploration and débridement of affected muscle. Amputation of a limb can be rapidly accomplished and may be lifesaving in selected patients. Spontaneous myonecrosis and anaerobic cellulitis caused by *C. septicum* or other histotoxic clostridia may benefit from exposure to hyperbaric oxygen because bacteremia is frequently present, toxin production may be halted, and tissues still viable may be protected by an oxygen barrier.[66]

Other Therapies

Other adjunctive considerations in treatment of STI include the use of intravenous γ globulin for type II necrotizing fasciitis caused by GAS, particularly in the setting of toxic shock syndrome. However, evidence for its benefit in the absence of toxic shock syndrome is lacking. Tefibazumab, a humanized monoclonal antibody raised against microbial surface compounds, is currently in trials for staphylococcal infection in newborns. A vaccine against *S. aureus* has also been developed for use in hemodialysis patients but has only shown a temporary effect.[47] Recombinant human activated protein C has been used in severe sepsis related to these STIs.[67,68] Patients with poor granulocyte production may benefit from granulocyte colony-stimulating factor administration. There is some evidence from the recent literature and from speculative observation that NSAIDs should be avoided in patients suspected of incubating or expressing early bacterial infections, as they may interfere with leukocyte chemotaxis (inhibition of lipoxygenase), decrease the inflammatory response (through decreased leukotriene production), and blur cardinal symptoms of infection (fever and pain) by inhibition of prostaglandin action.[14] Though these observations and speculations argue for more thoughtful and cautious use of NSAIDs in fragile patients, further study is needed in this controversial area. A recent case control study including 21 children with necrotizing fasciitis and 19 children with STI without necrosis, did not find an increased risk of infection in those taking ibuprofen for short-term use.[69]

Given the newly described role of the coagulation system in causing platelet and neutrophil aggregation that leads to hypoperfusion, a role for calcium channel blockers and inhibitors of glucoprotein IIb/IIIa in STIs has been suggested.[4] In addition, the role of photodynamic therapy in halting quick spread and in treating STI has been postulated.[70]

PREVENTION

Prevention, education of health care providers, adherence to infection-control measures, and judicious use of antimi-

crobials are paramount, particularly in preventing bacterial resistance. Decolonization strategies to prevent outbreaks have been attempted with oral and topical antibiotics, but their effectiveness in some resistant strains remains to be proven, and development of further resistance from these protocols is a feared complication.[51]

CHAPTER 180

Gram-Negative Coccal and Bacillary Infections

Morton N. Swartz

Many of the characteristic cutaneous manifestations of infection with Gram-negative organisms are due to direct microbial invasion of the skin or subcutaneous tissues. In addition, responses of host cytokines, chemokines, receptor molecules, and other effector cells and factors may contribute to fever, hypotension, and a variety of cutaneous manifestations.[1–4]

INFECTIONS DUE TO *NEISSERIA MENINGITIDIS* (MENINGOCOCCUS)

Three clinical syndromes associated with cutaneous involvement occur in meningococcal disease: meningitis, acute meningococcemia, and chronic meningococcemia. Skin lesions are frequently the most dramatic manifestations of these infections. The presence of areas of purpura or gross hemorrhage is associated with higher numbers of organisms in the bloodstream and indicates a poorer prognosis than for a petechial eruption. The epidemiology, pathogenesis, and clinical presentations of these processes have been reviewed.[1,3,4]

Bacteriology and Pathogenesis

Neisseria are aerobic, encapsulated, Gram-negative, bean-shaped cocci. *N. meningitidis* grows well on blood-enriched media in 5 percent to 10 percent CO_2. With potentially mixed bacterial exudates, these organisms should be grown on a selective medium (e.g., modified Thayer-Martin). They can be distinguished from *N. gonorrhoeae* by their fermentation of both glucose and maltose rather than of glucose alone. Meningococci are separable on the basis of capsular antigens, of which A, B, C, Y, and W-135 are the major human pathogenic groups. Outer membrane proteins that can identify serotypes are helpful in epidemiologic studies.[3] In an epidemic of meningococcal disease a shift of capsular group can occur (e.g., from group B to group C and vice versa), which facilitates evasion of host antibodies.[5]

Skin lesions associated with meningococcemia result from damage to small dermal blood vessels. Light and electron microscopy reveal bacteria within endothelial and polymorphonuclear cells in needle aspirate or punch biopsy specimens.[9,10] Endothelial damage, thrombosis, and necrosis of the vessel walls occur. Immunoglobulins and complement are present, even in early lesions.[3,9] Edema, infarction of overlying skin, and extravasation of red blood cells are responsible for the characteristic macular, papular, pustular, petechial, hemorrhagic, and bullous lesions. Many of the cutaneous hemorrhagic lesions may be caused directly by the effects of lipopolysaccharide (LPS) endotoxin or indirectly by stimulation of lease of outer membrane vesicles (blebs) has been observed on electron microscopy of meningococci in the plasma of patients with very high levels of circulating endotoxin in fatal meningococcal septicemia.[11] Another contribution to the dermal inflammatory vascular injury, independent of immune complexes and cytokine activity, may be the interaction be-

MENINGOCOCCUS INFECTIONS AND THE SKIN AT A GLANCE

- In the United States up to 2800 cases of meningococcal disease occur annually.
- Skin lesions associated with meningococcemia result from damage to small dermal blood vessels.
- Three clinical syndromes are associated with meningococcal disease: meningitis, meningococcemia, and chronic meningococcemia.
- Purpura and gross hemorrhage correlate with higher numbers of organisms in the bloodstream and indicate a poorer prognosis.

tween vascular endothelium (intercellular adhesion molecule 1) and an adhesion glycoprotein (CD18) on leukocytes, the so-called *dermal (localized) Shwartzman reaction* (LSR).[12] Mouse neutrophils express a surface protein, gp 49 B1, that prevents neutrophil-dependent vascular injury in response to LPS; humans have a leukocyte analog. The LSR requires a priming dose of LPS followed by a systemic challenge 18 to 24 hours later. A single intradermal injection of LPS into gp 49 B1–null mice produces an exaggerated microangiopathy in the LSR not seen in wild-type gp 49 B1 mice.[13] LSR and the generalized Shwartzman reaction (in which both doses of LPS are administered systemically) serve as models for the thrombohemorrhagic vasculopathy, purpura fulminans, of meningococcal sepsis. The profound effects on small blood vessels, caused directly by bacterial invasion or indirectly by LPS, host cytokines, or LSR, may lead to diminished blood volume, lowered cardiac output, anoxia, myocardial failure, hypotension, acidosis, and diffuse intravascular coagulation (DIC).[4] Purpura fulminans, the cutaneous manifestation of DIC (see Chap. 145), occurs in 10 percent to 20 percent of children with meningococcal septic shock and is associated with functional impairment of protein C activation. The latter is thought to result from (1) downregulation of thrombomodulin and endothelial protein C receptor on endothelial surfaces to which protein C binds for its activation, (2) shedding of thrombomodulin from the endothelial surface, and (3) enzymatic cleavage of the thrombin-coupled protein C activation complex.[14]

Meningococci can be isolated from blood in chronic meningococcemia, usually during periodic fevers and rash, and joint manifestations. This form of meningococcal infection has been linked to absence of terminal complement components in several patients and to an isolated immunoglobulin A (IgA) deficiency in one patient, associations that may provide insights into pathogenic mechanisms.[15,16] Absence of bacteria, bacterial antigenic material, and granulocytic inflammation distinguishes chronic from acute infection. Skin biopsy findings in an infant revealed leukocytoclastic vasculitis, an exception to the usual absence of vascular damage seen in chronic meningococcemia.[16] The chronic course of the disease, the lack of endotoxin-like manifestations, and the potential for eventual complications such as meningitis or endocarditis suggest that an unusual host-parasite relationship is central to this rare infection.

Epidemiology

Humans are the only known natural hosts of *N. meningitidis*. Nasopharyngeal carrier rates vary with age: 1 percent in young children, 5 percent in those 14 to 17 years of age, and 20 percent to 40 percent in adults. In the United States there are 1400 to 2800 cases of meningococcal disease annually. In schools and military camps, or when a carrier of a new strain develops disease in a day care or family setting, carrier rates can increase dramatically.[17,18]

Globally, group A strains have been responsible for epidemics of meningitis, especially in sub-Saharan Africa. In Europe and the Americas, groups B and C have predominated, and in the United States, a recent surge in group Y disease has been reported.

In most industrialized countries a few clonal serogroup B electrophoretic types (e.g., ET-5 strains) have predominated during recent decades. Similarly, clonal complex ET-37 strains, usually expressing the serogroup C capsule but sometimes expressing serogroup B, W-135, or Y, are found around the world.[3] Adult family members probably introduce the organism into the household, but secondary cases are most frequently spread from ill children to other family members in the same age group, especially under crowded conditions.[19] Household spread is 500 to 800 times more frequent than the occurrence of secondary cases in the community, and there is an increased incidence of secondary cases in day care centers where large numbers of susceptible children congregate.[4,20] Absence of the spleen has been associated with fulminant meningococcal disease.

Immunity to meningococci increases with age, and protective bactericidal antibodies, both IgG and IgM, are found in 70 percent to 95 percent of young adults. Newborns are often resistant to meningococcal disease until they are 3 to 6 months of age.[21]

The quadrivalent vaccine containing polysaccharides of groups A, C, Y, and W-135 had been the only licensed vaccine against meningococcal disease until 2005. Its inadequate protective efficacy in infants led to the development of protein polysaccharide conjugate vaccines that appear to have the same protective efficacy as the currently available *Haemophilus influenzae* type b conjugate.[3,4] The group B capsular polysaccharide, a polysialic acid polymer similar to fetal neural tissue, does not induce protective immunity. Efforts continue to develop a vaccine using outer membrane proteins of group B organisms.[22]

Acute Meningococcemia and Meningitis

CLINICAL MANIFESTATIONS ***History.*** The disease often follows a mild upper respiratory tract infection associated with headache, grippe-like complaints, nausea, and muscle soreness. These symptoms can be so short-lived that fever, obtundation, and other manifestations of meningitis are the initial findings. In fulminant meningococcemia, vomiting, stupor, precipitous development of a hemorrhagic rash, and hypotension may be evident within a few hours of the onset of symptoms. Milder cases develop at a slower pace.

Cutaneous Lesions. Skin findings in acute meningococcal infections are characteristically petechial, but transient macular or papular lesions (Fig. 180-1A), which can resemble those seen in viral exanthems, may be evident.[23] The petechiae are small and irregular with a "smudged" appearance. Although most often located on the extremities and trunk, lesions can also be found on the head (see Fig. 180-1B), palms, soles, and mucous membranes. Extensive hemorrhagic lesions with central necrosis (suggillations) and bullae can develop. Gangrenous hemorrhagic areas (indistinguishable from purpura fulminans; see Chap. 145) can appear in severe meningococcemia, often with DIC (see Fig. 180-1C). Skin lesions and bacteremia are rarely seen with meningococcal pneumonia.[24] Cellulitis has been noted occasionally, especially in children with meningococcal conjunctivitis (see Primary Meningococcal Conjunctivitis).

Other Physical Findings. Patients with meningitis display signs of meningeal irritation and altered consciousness. Cranial nerve palsies, long-tract signs, seizures, and alterations in vital signs associated with changes in intracranial pressure may be present.

Obtundation and hypotension without meningeal signs, associated with the syndrome of DIC, are characteristic features of fulminant meningococcemia. Rarely, meningococcemia may result in septic foci in other areas: (1) septic arthritis, (2) purulent pericarditis with enlarging cardiac silhouette and findings of tamponade, and (3) bacterial endocardi-

▲ **FIGURE 180-1** *Neisseria meningitidis* infection. Acute meningococcemia. **A.** Transient macular and papular lesions on the upper chest. **B.** Discrete pink-to-purple macules and papules, as well as purpura, on the face of a young child. These lesions represent early diffuse intravascular coagulation (DIC). **C.** Map-like gray-to-black areas of cutaneous infarction are seen in this child with DIC.

tis. More commonly, a delayed immune complex–mediated syndrome results in a sterile arthritis, pericarditis, or episcleritis.[3] The acute arthritis-dermatitis syndrome, characterized by petechiae and nontraumatic arthritis, has traditionally been identified with disseminated *N. gonorrhoeae* infection (see Chap. 205). There has been a decline of gonococcal cases and an increase in cases of this syndrome caused by *N. meningitidis*.[25]

LABORATORY FINDINGS A polymorphonuclear leukocytosis is present in peripheral blood and cerebrospinal fluid (CSF) in meningitis. The CSF glucose value is commonly reduced. Characteristic organisms may be seen on Gram-stained smears of fluid, and meningococci are usually isolated from the CSF. *N. meningitidis* may be isolated from the blood of approximately one-third of patients with meningitis and from almost 100 percent of patients with acute meningococcemia. Demonstration of organisms in cutaneous lesions has been variable, and the presence of Gram-negative commensal organisms on the skin requires cautious interpretation. Reports describe positive results for 50 percent to 80 percent of aspirates, skin film samples, and punch biopsy specimens of petechial lesions.[9,26]

In patients already exposed to antimicrobial agents, the development of rapid, accurate, and inexpensive procedures for detection of soluble antigens in the CSF has been a major advance. The latex agglutination method and enzyme-linked immunosorbent assay methods are sensitive and very specific, but their clinical usefulness in most situations has been questioned.[27] Rapid diagnosis using polymerase chain reaction (PCR) testing is available in research settings.[28]

HISTOPATHOLOGY Endothelial swelling is seen, a perivascular infiltrate of polymorphonuclear leukocytes is present, thrombi occlude capillaries and postcapillary venules, and the walls of capillaries and venules are destroyed, as in leukocytoclastic vasculitis (see Chap. 164).

DIFFERENTIAL DIAGNOSIS Meningococcal infection warrants consideration in a patient with fever and a petechial or purpuric eruption, even in the absence of clinical meningitis (Box 180-1). Occasionally, the characteristic rash is absent, which delays consideration of meningococcal disease.

COURSE AND PROGNOSIS Untreated, acute meningococcal disease usually ends fatally. With treatment, recovery occurs in 90 percent of patients with meningitis.

In severe meningococcemia, especially with the rapid emergence of cutaneous hemorrhages, hypotension, and

Box 180-1

Differential Diagnosis of Acute Meningococcemia

- Acute bacteremias and endocarditis: In endocarditis, mucous membrane and conjunctival lesions, as well as subungual "splinter" hemorrhages, occur. Very infrequently, numerous petechial and purpuric lesions occur in patients with acute *Staphylococcus aureus* endocarditis. Usually, a few skin lesions in a patient with acute *S. aureus* endocarditis are purulent purpura. In acute gonococcemia, the skin lesions are usually acral, nodular, hemorrhagic, and few in number (see Chap. 205). Occasional patients with *Haemophilus influenzae* or *Streptococcus pneumoniae* bacteremia develop petechial eruptions.
- Cutaneous necrotizing vasculitis (see Chap. 164): Here, lesions are usually palpable. Renal involvement and hypertension may be present.
- Enteroviral infections: Fever, petechial eruptions, and aseptic meningitis are frequent features.
- Rocky Mountain spotted fever: The history of exposure to ticks in an endemic area, absence of an antecedent respiratory infection, and delay in appearance of the rash are clues (see Chap. 199).
- Toxic shock syndrome (see Chap. 178).
- Purpura fulminans (see Chaps. 145 and 181).
- Weil disease (leptospirosis) (see Chap. 183).

DIC, the entire course from onset to death can be measured in hours. In patients with sepsis-associated DIC, cutaneous thrombotic hemorrhages on the distal extremities may lead to skin and digital necroses that necessitate amputation.[29] Rarely, young children with meningococcal sepsis, shock, and DIC suffer thrombotic injury that causes growth plate arrest.[30] Myocardial dysfunction often occurs in meningococcal septic shock and is associated with high circulating levels of interleukin 6.[31] These cases are often associated with massive adrenal hemorrhage (*Waterhouse-Friderichsen syndrome*). Children who die from meningococcal septic shock have relatively low cortisol levels (but not in the range expected in adrenal insufficiency).[32] The mortality rate for meningococcal septic shock approaches 100 percent. Gradations in the severity of meningococcal disease make it difficult to assign an accurate prognosis, although a bedside predictive model has been proposed.[4,33]

Chronic Meningococcemia

CLINICAL MANIFESTATIONS ***History.*** The manifestations of chronic meningococcemia are vague at onset but tend to establish a pattern over a period of weeks or months.[15,34] Initially, there may be an acute febrile illness, but it wanes and leaves the patient with intermittent muscle aches, joint soreness, mild headache, and anorexia with weight loss. The simultaneous emergence of a localized rash with several days of fever and joint soreness are characteristic. As fever recedes, the rash fades, and the patient may be totally free of skin manifestations for days or weeks. This pattern of recurring fever and rash may last from a few weeks to 6 or 8 months. Untreated cases may eventually evolve into acute meningococcemia, meningitis, or endocarditis. Rare case reports relate this syndrome to the absence of a terminal component of complement, a finding also observed in some sporadic and recurrent acute meningococcal infections.[15]

Cutaneous Lesions. Skin lesions are usually distributed about one or more painful joints or on pressure areas in contrast to the acral distribution in gonococcemia. They may vary in appearance and size (1 to 20 mm) from one crop of lesions to the next and include (1) pale to rose-colored macular and papular lesions (the most common type), (2) slightly indurated and tender erythema nodosum–like nodules, (3) petechiae of variable size, (4) petechiae with vesicular or pustular centers, (5) hemorrhage (minute) with an areola of paler erythema, and (6) grossly hemorrhagic areas with pale blue-gray centers.

Other Physical Findings. Aside from the rash, the physical findings of chronic meningococcemia are minimal except for occasional joint swelling and tenderness.

HISTOPATHOLOGY The skin lesions differ pathologically from those in acute meningococcemia in that bacteria are absent, and fluorescent antibody techniques do not detect meningococcal antigens. Also, thrombi do not occlude capillaries and venules, endothelial cell swelling is absent, and the perivascular infiltrate consists of mixed polymorphonuclear and mononuclear cells.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS During febrile periods, blood cultures frequently reveal meningococci and provide the specific diagnosis. No data are available on the use of antigen detection procedures.

A number of diseases with periodic fever, skin lesions, and joint involvement resemble chronic meningococcemia:

- Subacute bacterial endocarditis: A prolonged febrile course with a pleomorphic petechial rash, joint symptoms, and no overt focus make subacute bacterial endocarditis an important consideration. A prominent heart murmur, evidence of renal impairment, and blood cultures help establish the diagnosis.
- Acute rheumatic fever: When fever is prolonged, joint findings are prominent, and macular and papular rashes appear, the diagnosis may be acute rheumatic fever (see Chap. 161).
- Henoch-Schönlein purpura: The petechial hemorrhagic rash in Henoch-Schönlein purpura is more often symmetric, usually only on the lower extremities, and does not have the periodicity of the rash of chronic meningococcemia (see Chap. 164).
- Rat-bite fever, also referred to as *Haverhill fever*, may be acute (mimicking acute meningococcemia) or chronic (resembling chronic meningococcemia). Intermittent fever, rash, and joint manifestations are hallmarks of an illness that follows a rodent bite or ingestion of contaminated milk (see Chap. 183).
- Erythema multiforme: The iris-type configuration of lesions suggests erythema multiforme (see Chap. 38).
- Gonococcemia (chronic): The cutaneous and joint manifestations of chronic gonococcemia may continue for many days or weeks (see Chap. 205), and tenosynovitis in gonococcemia can be an important clue.

COURSE AND PROGNOSIS Some patients with chronic meningococcemia recover spontaneously without specific therapy, whereas others develop serious systemic complications, such as endocarditis or meningitis. The prognosis for treated infection is excellent.

Primary Meningococcal Conjunctivitis

N. meningitidis is responsible for up to 2 percent of cases of bacterial conjunctivitis. The source of infection is either direct inoculation of airborne organisms from close contact with carriers or manual contact with secretions from the patient's own nasopharynx.[35]

Treatment and Prophylaxis

CHEMOTHERAPY Widespread emergence of sulfonamide-resistant strains approximately 40 years ago has complicated therapy for meningococcal infections. Initially, these strains belonged predominantly to serogroup B, but in recent years, they have been from serogroups A to C. Penicillin G, or ampicillin, has supplanted the sulfonamides as the treatment of choice for acute meningococcal infections.

The usual adult dosage of penicillin G for meningococcal meningitis is 4 million units given intravenously (IV) every 4 hours for 7 days. Penicillin, 6 to 12 million units divided into four to six daily doses, given IV for 7 to 10 days, should be effective therapy for chronic meningococcemia. In highly penicillin-allergic adults, administration of chloramphenicol (1 g IV every 6 hours) is preferable to risking cross-reactions with a third-generation cephalosporin. In Europe and the United States, where meningococci relatively resistant to penicillin have been isolated (30 percent or more), a third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) should be considered for initial therapy.[37] All meningococcal isolates from blood, CSF, or other normally sterile body cavities should be tested for penicillin susceptibility.[4] Immune complex–associated complications (fever, sterile arthritis, vasculitis, pericarditis, episcleritis) can occur in

15 percent of patients 4 to 10 days after initiation of antimicrobial therapy for severe meningococcal disease.[38]

SUPPORTIVE THERAPY Although it has been postulated that hypotension in acute meningococcemia may be due to adrenal failure associated with Waterhouse-Friderichsen syndrome (adrenal hemorrhage), blood cortisol levels and corticosteroid secretion rates have been found to be elevated or in the low normal range (not in the range associated with adrenal insufficiency).

The modern treatment of shock in sepsis begins with a number of well-accepted measures, including antibiotic selection, drainage procedures for abscesses, appropriate use of volume expanders, administration of β-adrenergic–stimulating drugs such as dopamine or isoproterenol, correction of severe acidosis, and, in selected patients, use of peripheral vasodilators. Therapies still considered experimental include those that neutralize host cell–mediated cytokines (e.g., interleukin 1, tumor necrosis factor)[1] and protein C.[39] Although numerous studies of glucocorticoid therapy have been completed, results have been variable, and on balance glucocorticoids do not appear to be indicated for septic shock.

Because of the impaired conversion of protein C to its activated form through the downregulation of thrombomodulin by inflammatory cytokines during sepsis, intravenous recombinant human activated protein C (drotrecogin alfa activated) has been used as ancillary treatment in a large randomized trial involving patients with severe sepsis (but none with meningococcal sepsis) accompanied by dysfunction of at least one organ.[39] The mortality rate was reduced from 30.8 percent in the placebo group to 24.7 percent in those receiving drotrecogin alfa. The incidence of serious bleeding was 3.5 percent in the drotrecogin alfa group compared with 2.0 percent in the placebo group. Any patients with meningococcal infection with DIC should be closely monitored for increased bleeding.[40] Severe meningococcal infections can be complicated by the syndrome of DIC. The basis for the diagnosis is usually a composite of associated hematologic abnormalities, including thrombopenia and hypofibrinogenemia, prolongation of the prothrombin time and partial thromboplastin time, and the presence of fibrin split products. If bleeding occurs, it may be necessary to administer fresh frozen plasma. Treatment for each case must be individualized, because therapy may be harmful and produce more problems than the DIC syndrome. Data on the use of heparin in treating DIC remain unconvincing, and because of potential adverse effects, this drug is no longer recommended. Investigators continue to study antibodies to various cytokines whose levels are elevated in meningococcal septicemia and immunomodulatory therapies.[41]

CHEMOPROPHYLAXIS There is a critical need for reliable chemoprophylaxis to rapidly protect children exposed in a day care nursery, contacts in crowded household, and institutional groups, because secondary cases can emerge, often within 24 to 48 hours of an index case.[17,42]

Currently recommended prophylactic drug regimens for children and adults favor rifampin, 600 mg orally twice daily for 2 days (age adjusted for children).[20] Rifampin resistance occurs, however, and reports have documented the development of invasive meningococcal disease.[37] Fortunately, ciprofloxacin and ofloxacin are effective single-dose substitutes, and ceftriaxone is available for parenteral single-dose use in children as well as adults.[43]

IMMUNIZATION Polysaccharide vaccines (groups A, C, Y, and W-135 *N. meningitidis*) are safe and effective in preventing meningococcal disease in adults and in children older than 2 years of age.[20]

Protein-conjugated meningococcal vaccine, MCV-4 (groups A, C, Y and W-135), is available in the United States.[4] The Centers for Disease Control and Prevention recommends routine vaccination of young adolescents (11 to 12 years old) with MCV-4. Elucidation of the complete genome of *N. meningitidis* has identified several conserved proteins that, in an experimental mouse model, have been protective against challenge with all pathogenic *N. meningitidis* organisms.

INFECTIONS DUE TO *PSEUDOMONAS AERUGINOSA*

Bacteriology and Pathogenesis

Pseudomonas aeruginosa is a nonfermentative, obligately aerobic, Gram-negative bacillus. Some strains produce a blue pigment (pyocyanin), a water-soluble yellow-green substance (fluorescein), or black pyomelanin. With Wood's lamp, the presence of organisms in lesions of skin or nails can be detected if the infecting strain produces fluorescein. The pigments impart a characteristic greenish color to the surrounding growth media or the tissue substrate involved in clinical disease (e.g., "green nail" syndrome, Fig. 180-2). In addition, an odor of grapes, characteristic of trimethylamine, often accompanies the growth of these microorganisms.

Organisms gain entry at sites of maceration, dermatophytic foci, trauma, or foreign bodies (e.g., indwelling venous catheters), or via aspiration into the respiratory tract. Infections in otherwise healthy individuals are unusual; when they occur, the involved regions are often areas with increased moisture (e.g., toe webs, the external auditory canal). Infection may begin in the base of the nail in persons who frequently have their hands or feet in water. This can progress to paronychia, followed by development of a green-blue discoloration of the nail due to local pigment production. The ability of this organism to infect healthy, but moistened, skin is evidenced by the occurrence of disseminated papules and pustules on areas

PSEUDOMONAS AERUGINOSA INFECTIONS AND THE SKIN AT A GLANCE

- The ubiquitous Gram-negative bacillus *Pseudomonas aeruginosa* can cause serious infections, usually in individuals who have altered defenses, who are receiving intense antibiotic therapy, or who are in the hospital.
- Cutaneous manifestations of *Pseudomonas* infections are common and characteristic.
- These cutaneous manifestations may represent the overt finding in septicemia (ecthyma gangrenosum) or may be the localized focus of serious infections of the ear.
- *Pseudomonas* infection can produce trivial cutaneous lesions involving the nails, toe webs, other skin areas, and external auditory canal.

▲ **FIGURE 180-2** *Pseudomonas aeruginosa* infection. "Green nails." This 36-year-old bartender noted a greenish yellow discoloration of 8 of 10 fingernails during the preceding year. Several of the fingers show chronic candidal paronychia as well.

of skin of people immersed in hot tubs ("hot tub folliculitis," Fig. 180-3), wading pools, and swimming pools.[44] These ubiquitous organisms can sometimes be aggressive secondary invaders in open wounds, in decubitus and other skin ulcerations, or in association with thermal burns. Rarely, a superficial pyoderma due solely to *Pseudomonas* is engrafted on a generalized or localized dermatitis, such as tinea pedis or eczema, producing irregular pustular areas with macerated borders.[44,45] Serious invasive infections occur in debilitated patients; malnourished infants; individuals whose normal bacterial flora has been suppressed by antibiotics; patients with neoplastic diseases, granulocytopenias, or impaired circulating or cellular immunity, including that associated with acquired immunodeficiency syndrome (AIDS)[46]; and individuals requiring mechanical respiratory assistance. These organisms frequently colonize body surfaces and survive exposure to antibiotics. *P. aeruginosa* can spread widely via the bloodstream, producing a disseminated infective vasculitis in which organisms can appear in the adventitia and media of vessels without luminal clots. Occasionally, features of the generalized Shwartzman reaction are found, but less frequently than in infections due to *N. meningitidis* or Enterobacteriaceae.

Epidemiology

Because *P. aeruginosa* is widely distributed in nature, it is not surprising that it may contaminate plants, vegetables, hot tubs, and swimming and wading pools. Moist regions of skinfolds and the external auditory canal are the most common sites of colonization (3 percent to 5 percent of cases). *P. aeruginosa* is found in small numbers in the feces of 10 percent to 20 percent of the population.

▲ **FIGURE 180-3** *Pseudomonas aeruginosa* infection. "Hot tub folliculitis." This 22-year-old woman noted the appearance of erythematous, pruritic papules and pustules on the trunk, buttocks, and upper thighs several days after bathing in a hot tub. The eruption resolved without antibiotic therapy.

Any activity that leads to excessive local moisture—laundry work, dishwashing, or hiking for long periods in wet terrain—will enhance the growth of these organisms. Moist or weeping cutaneous lesions (e.g., thermal burns) encourage the growth of *Pseudomonas* as well as of other Gram-negative bacteria. Increased environmental humidity is frequently associated with overgrowth of these organisms. Synthetic sponges easily become contaminated with Gram-negative bacteria and have served as vehicles of transmission.

Systemic infection with *P. aeruginosa* depends primarily on altered susceptibility of the host rather than on spread from individual to individual or on increased pathogenicity. However, exceptions may be seen in newborn nurseries, respiratory care units, and occasionally urology wards, where dissemination from a primary source may occur. Neutropenic or immunocompromised hospitalized patients are more likely to become colonized and develop invasive disease.

Local and Secondarily Infected Lesions

Pseudomonas produces a number of characteristic lesions. In addition, colonization by these organisms complicates other skin diseases and open wounds.[51]

CLINICAL MANIFESTATIONS ***History.*** Painful paronychial lesions, with or without characteristic green discoloration of the nails, occur most often in women with a history of continual immersion of the hands in water with soaps and detergents. People with toe web infection characteristically work in an atmosphere of high humidity, often have wet feet, and experience soreness and scaling of web tissues. There are numerous reports of the appearance of skin rashes in healthy individuals within 1 to 5 days after the use of public bathing facilities such as therapeutic or recreational whirlpools, hot tubs, or swimming pools (see Fig. 180-3). *P. aeruginosa* organisms have been isolated in large numbers from pool water. The rash usually clears without therapy within 1 week but is often accompanied by malaise, low-grade fever, external otitis, and mastitis.[44] *P. aeruginosa* folliculitis has also occurred after shower or bath exposure or exposure to contaminated bath articles.[45] Hot-foot syndrome caused by *P. aeruginosa* contamination of a wet surface exemplifies the organism's opportunism in infecting the ventral surfaces of feet abraded by a roughened floor.[52]

Cutaneous Lesions. In addition to a tender paronychial lesion, patients with green nail syndrome may have a nail that is partly or entirely green. The color may be in horizontal bands, representing intermittent activity of the infection at the nail base (see Fig. 180-2). Individuals with toe web *Pseudomonas* infections have thick, macerated, scaling, foul-smelling discolored areas between the toes. Hot-foot syndrome is characterized by tender, painful, red plantar nodules that develop within 1 to 2 days of exposure to an abrasive wet surface, such as a wading pool.[52]

In external otitis the lesion has a swollen, macerated appearance in the local area without involving the eardrum. Often referred to as *swimmer's ear*, the condition produces intense swelling and discoloration with excruciating pain on movement of the pinna. If the skin is traumatized, local infection can spread to the pinna, producing perichondritis and chondritis with intense tender swelling. Cartilaginous necrosis may result unless immediate drainage with through-and-through incisions and appropriate antibiotic therapy are instituted. Organisms other than *P. aeruginosa*, including *Staphylococcus aureus* and streptococci, may be causal.[53] The most severe form of *Pseudomonas* infection, malignant external

otitis, has a high mortality rate if therapy is delayed or inadequate. It usually occurs in elderly people with diabetes but may also be seen in healthy elderly people after surgery or minor trauma, such as water irrigation of the external canal, and in patients with AIDS.[54] The onset and early progression are insidious, with swelling, erythema, moderate discharge, and pain without fever or constitutional symptoms. As the surface breaks down, *Pseudomonas* invades the soft tissues at the junction of cartilage and bone; the process then advances to involve cartilage, mastoid, and temporal bone. Inflammation at the stylomastoid and jugular foramina can lead to seventh nerve palsy followed by palsy of the ninth to eleventh nerves. Diagnosis is made clinically if granulation tissue can be seen erupting at the cartilage-bone interface in the posterior inferior canal wall. The pinna is often swollen, and pain is intense.[55]

In patients who develop folliculitis the rash can be localized if only a limb has been immersed, or generalized, or in intertriginous areas. The rash begins as erythematous papules, evolves to papulopustules (see Fig. 180-3), and eventually heals with fine desquamation and occasional pigmented macules. Pruritus and pain may accompany the lesions along with localized areas of mastitis and external otitis. Serotype 0-11 of *P. aeruginosa* is most commonly involved.[56]

A small outbreak of *P. aeruginosa* 0-11 folliculitis occurred in granulocytopenic patients in a cancer treatment center, but the lesions in these patients, in contrast to those in healthy individuals with swimming pool folliculitis, rapidly became widespread and progressed to bullae, which became necrotic (ecthyma gangrenosum–like) unless systemic antibiotic treatment was begun immediately.[57] Thus, ecthyma gangrenosum (see Septicemia and Cutaneous Involvement) can result from progression of initial folliculitis in an immunocompromised patient as well as from *P. aeruginosa* bacteremia.

Although gangrene of the genitalia and perineum (Fournier gangrene) is almost always caused by a polymicrobial (facultative species and anaerobes) or group A streptococcal infection, exceptional cases have been attributed to *P. aeruginosa*.[58] Necrotizing fasciitis generally has similar causes, but in rare cases monomicrobial *P. aeruginosa* necrotizing fasciitis has occurred, usually involving the vulva or abdominal wall, in children with acute lymphoblastic leukemia.[59] Such patients are febrile; the infected area is painful, erythematous, and edematous, with subsequent skin necrosis; and bacteremia is present. Necrotizing fasciitis due to *P. aeruginosa* has also occurred in an immunocompetent infant (see Chap. 179).[60]

In secondarily infected skin areas, irregular, superficial pustular lesions may be superimposed on underlying skin disease; the margins of these regions are usually sharply defined and may exhibit the characteristic grape-like odor and pigmented exudate.[56] *P. aeruginosa* infection of a chronic ulcer occasionally progresses to *Pseudomonas* cellulitis.[61]

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Nail and skin lesions resulting from *Pseudomonas* infection are recognized by the characteristic pigment. The organisms can be identified as thin Gram-negative rods, or a mixed infection (e.g., with *Candida*) may be observed. Fluorescence, demonstrated with a Wood's lamp, can support the diagnosis. Occasionally, *Aspergillus* infection of the nails produces a greenish color, and there is usually no associated paronychia. A subungual hematoma may superficially resemble *Pseudomonas* nail infection.

COURSE AND PROGNOSIS Patients with minor *Pseudomonas* infections (e.g., onychia and paronychia, toe web inflammation, whirlpool-associated skin rash, and external otitis) usually improve rapidly with topical therapy and drying of the affected area. Malignant external otitis requires the systemic administration of antibiotics directed against *Pseudomonas*, including a fluoroquinolone with or without meropenem or ceftazidime. High dosages and prolonged therapy are combined with surgical débridement to limit spread to bone and nervous system.[49,62]

Septicemia and Cutaneous Involvement

CLINICAL MANIFESTATIONS ***History.*** In individuals with suspected *Pseudomonas* septicemia, history taking is most frequently centered around the underlying problem and antecedent therapy. A premature infant may have required resuscitation and treatment of a non-specific pneumonitis before developing high fever, obtundation, and macular or hemorrhagic vesicular skin lesions. Infants may present initially with omphalitis or severe diarrhea, followed by septicemia and skin lesions. Urinary tract infections complicating exstrophy of the bladder may predispose the infant to bacteremia. In adults, there is usually a background of antibiotic therapy, immunoglobulin deficiency, diabetes mellitus, treatment with glucocorticoid hormones or antitumor agents, or the use of percutaneous catheters. Frequently, the patient is granulopenic, has already had a significant febrile illness, and may still be receiving antibiotics when one of the characteristic cutaneous manifestations develops. The local lesions are rarely painful. Occasionally, hemorrhagic manifestations may develop secondary to platelet reduction or DIC.

Pseudomonal involvement of the gastrointestinal tract, particularly in the tropics, may produce the picture of an acute enteric infection, with headache, high fever, diarrhea, and rose spots (Shanghai fever) resembling typhoid fever. The same enteric syndrome with ecthyma gangrenosum has occurred in previously healthy infants.[63]

Cutaneous Lesions. Skin lesions, the most characteristic physical findings in *Pseudomonas* septicemia, consist of four types[64]:

1. *Vesicles and bullae*. Singly or in clusters, these lesions spread in random fashion over the skin. They become hemorrhagic as they evolve. Occasionally in infants they may be surrounded by large erythematous halos and be mistaken for erythema multiforme.
2. *Ecthyma gangrenosum*. This lesion starts with an erythematous or purpuric macule and develops rapidly into a hemorrhagic bulla that ruptures; becomes a gunmetal gray, infarcted lesion with surrounding erythema (Fig. 180-4); and evolves into a necrotic black or gray-black eschar and surrounding erythema (Fig. 180-5).

▲ **FIGURE 180-4** *Pseudomonas aeruginosa* infection. Ecthyma gangrenosum. Gunmetal gray, painless, infarcted lesions with surrounding erythema.

▲ **FIGURE 180-5** *Pseudomonas aeruginosa* infection. Ecthyma gangrenosum. This 32-year-old man with human immunodeficiency virus infection noted the onset of a very tender plaque on the right buttock associated with fever and malaise. **A.** Five-day-old lesion with a central infarcted, necrotic area surrounded by erythema. **B.** At 5 weeks, the lesions had improved after ciprofloxacin treatment, which was discontinued because of an adverse drug reaction. Without antibiotic treatment, the necrotic area enlarged and was associated with bacteremia. Eventually, the lesion re-epithelialized, but the patient died of pseudomonal pneumonia.

Frequently, the lesion is in the anogenital or axillary region. Noma neonatorum, a gangrenous process of the nose, eyelids, oral cavity, or anal area and genitalia, occurs in premature newborns and other infants.[65] It is similar in appearance to noma, which occurs in young debilitated infants. Whereas the infecting agent in noma is *Fusobacterium*, noma neonatorum is caused by *P. aeruginosa*.

3. *Gangrenous cellulitis*. Sometimes presenting as a sharply demarcated, superficial, painless, necrotic lesion, gangrenous cellulitis may resemble a decubitus ulcer. However, it is located in a nonpressure area and may complicate a prior area of injury, such as a thermal burn. Also, it may begin abruptly, producing local pain, swelling, and erythema, and involving deep subcutaneous tissue and fascia. Local injury or bacteremia may introduce the infection.
4. *Macular or papular nodular lesions*. These lesions are small, oval, and painless, located predominantly over the trunk. They resemble the rose spots of typhoid fever.

Another cutaneous manifestation of *Pseudomonas* septicemia, usually occurring after days or weeks, is suppurative panniculitis. The lesions are red, warm, and sometimes fluctuant, but often situated deeply enough to feel solid. Surgical incision reveals suppuration, and *P. aeruginosa* can be isolated.[64,66] A variation of this manifestation consists of numerous red, nonfluctuant, hot, nontender, subcutaneous nodules that may be accompanied by other characteristic lesions, such as hemorrhagic bullae and ecthyma gangrenosum. Such lesions may be treated successfully by combination antipseudomonal antibiotic therapy.

Other lesions that may appear in systemic *Pseudomonas* infection include petechiae, ecchymoses, dermal Shwartzman-like reactions, and purpura fulminans.

Other Physical Findings. Patients with *Pseudomonas* septicemia frequently exhibit physical findings associated with their underlying diseases: malnutrition, mucous membrane ulcerations, glossitis secondary to antibiotic therapy and granulocytopenia, urinary tract infections, proctitis, adenopathy, hepatosplenomegaly, and hemorrhagic bronchopneumonia.

LABORATORY FINDINGS Hematologic examination may reveal leukocytosis or leukopenia, based on the underlying illness. Platelet levels may be diminished, and levels of fibrinogen and other clotting factors may be reduced in association with DIC, liver disease, or profound malnutrition.

Characteristically, in *Pseudomonas* septicemia aspirated material from bullae, areas of cellulitis, and papular or nodular lesions reveals numerous organisms but few leukocytes, even in patients with leukocytosis. Cultures of these lesions and of blood show *Pseudomonas*.

PATHOLOGY The distinctive finding in *Pseudomonas* lesions is a necrotizing vasculitis in which a myriad of bacteria invade the walls of small arteries and veins.[67] Extravasation occurs around the vessels, edema and bland necrosis in the perivascular and adventitial regions are extensive, and blood flow supplied by the affected vessel is decreased. Organisms tend to spread along the exterior surfaces of vessels and invade the skin. Similarly, bacterial invasion of the blood vessel walls in lungs, liver, and other organs produces nodular necrotic lesions.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS Ecthyma gangrenosum skin lesions in an acutely ill patient suggest the diagnosis of *Pseudomonas* septicemia. The finding of abundant Gram-negative rods with rare granulocytes in vesicle fluid or in association with gangrenous or hemorrhagic cellulitis constitutes further presumptive evidence.

The differential diagnosis of *Pseudomonas* septicemia includes other infections that can produce ecthyma gangrenosum and other skin lesions through direct involvement of blood vessels (e.g., those caused by *N. meningitidis*, *Aeromonas hydrophila*, *Escherichia coli*, *Klebsiella pneumoniae*, *Citrobacter freundii*, *Morganella* sp., *Vibrio vulnificans*, *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, *Moraxella* sp., and fungi of the *Aspergillus*, *Fusarium*, and *Rhizopus* groups).[68] *Chromobacter violaceum*, a saprophyte present in water and soil in tropical and subtropical (e.g., southeastern United States) environments, is a rare cause of ecthyma gangrenosum in the setting of chronic granulomatous disease of childhood, a condition predisposing to infections with this microorganism.[69] Pyoderma gangrenosum and gangrenous herpes simplex may mimic ecthyma gangrenosum.[70]

COURSE AND PROGNOSIS *Pseudomonas* septicemia is frequently the terminal event in a patient with malignant disease or altered defense mechanisms. Therapy may be effective and recovery complete in some instances when septicemia occurs in patients with more favorable underlying problems, such as urinary tract infections, or in patients with venous catheters.

TREATMENT AND PROPHYLAXIS ***Local Infections.*** Superficial skin and toe web infections and onychia usually respond to application of acetic acid, silver nitrate, or gentian violet compresses two to three times daily between long periods of drying. Paronychia is best treated by surgical drainage, nail trimming, and application of 4 percent thymol in chloroform. Acetic acid, polymyxin (0.1 percent) in acetic acid, or glucocorticoids with neomycin are effective for otitis externa. When acetic acid is used topically on chronic ulcers, a 2 percent to 5 percent solution is often effective.[71] In addition, topical silver nitrate (0.5 percent) or silver sulfadiazine may eradicate these organisms in burn patients (see Chap. 94).

Systemic Infections. *Pseudomonas* septicemia requires early systemic bactericidal antimicrobial therapy. Effective agents include the aminoglycosides (gentamicin, tobramycin, amikacin). One of these drugs is combined with ceftazidime or cefepime or an antipseudomonal penicillin and given IV to patients who are acutely ill. In the presence of hypotension or any renal impairment, the dosage of aminoglycoside must be reduced; aminoglycoside serum levels should guide therapy.

In addition to the parenteral administration of antibiotics, surgical drainage is appropriate for nodular and fluctuant lesions. Acute *P. aeruginosa* gangrenous cellulitis/fasciitis requires débridement (often extensive), sometimes with a surgical "second look" 1 or 2 days later. Investigations involving the experimental use of human immune globulins with activity against *P. aeruginosa* or specific *Pseudomonas* exotoxin A antibody preparations are ongoing.[50] The markedly granulocytopenic patient with *P. aeruginosa* gangrenous cellulitis presents a particularly difficult problem, and very prompt surgical débridement in addition to treatment with antimicrobials and granulocyte colony-stimulating factor is required.

SKIN INFECTIONS DUE TO OTHER *PSEUDOMONAS* SPECIES

P. putrefaciens, now renamed *Shewanella putrefaciens*, is a rare cause of cellulitis, particularly chronic infected ulcers of the lower extremities.[72] The natural habitat of the organism is water and soil, and it is a rare cause of cellulitis and bacteremia after contamination of a laceration.[73]

INFECTIONS DUE TO *HAEMOPHILUS INFLUENZAE*

Bacteriology and Pathogenesis

H. influenzae is a small, pleomorphic Gram-negative coccobacillus with fastidious growth requirements, including the presence of heme and nicotinamide nucleoside. There are rough and encapsulated forms, the latter of which are divided into six types (a through f) based on capsular polysaccharide antigens.

Most invasive infections with *H. influenzae*, including meningitis, epiglottitis, and cellulitis, are caused by encapsulated type b strains (Hib). Rough strains do not cause cellulitis but are involved in acute otitis media, exacerbations of chronic bronchitis, and pneumonia.[74] A hyperacute disease, Brazilian purpuric fever, characterized by fever, purpura, and shock, is caused by nontypeable *H. influenzae* biogroup aegyptius strains producing an extracellular hemagglutinin that may be a virulence factor.[75]

Most Hib skin infections are preceded by an upper respiratory tract infection or acute otitis media. The characteristic localization of the cellulitis to the upper part of the body argues for the sequence of upper respiratory tract infection, fallout onto or invasion of the skin locally, and then bacteremia. This sequence is evident in adult as well as in pediatric cases. A primary bacteremic mechanism with secondary localization in the skin would be favored by a more random and widespread distribution of lesions than is seen. Localization of a subclinical bacteremia could follow trauma and has been suggested as a possible predisposing event.

Epidemiology

Humans are the only known natural host for *H. influenzae*. These potentially pathogenic bacteria are carried in the oropharynx and nasopharynx, especially in children up to age 5 years, as part of the normal indigenous flora. However, early immunization using conjugate Hib vaccines has markedly decreased nasopharyngeal carrier rates, increased herd immunity, and caused a dramatic decline in invasive clinical disease.[76] Cellulitis, meningitis, pneumonia, and epiglottitis have all but disappeared in vaccinated populations.

HAEMOPHILUS INFECTIONS OF THE SKIN AT A GLANCE

- *Haemophilus influenzae* cellulitis involves the face, neck, or upper extremities.
- Most cases occur in young children (6 to 24 months of age), but the infection can occur in adults.
- Because of immunization with *H. influenzae* conjugate vaccines, invasive *H. influenzae* disease has nearly disappeared in industrialized countries, but it persists as a major problem in developing countries.

Clinical Manifestations

HISTORY Typically, a nonimmunized young infant or child develops an area of swelling and discoloration on the face or arm after several days of coryza and abruptly rising temperature. Rarely, a similar process occurs in adults as a complication of upper respiratory tract infection.[79]

CUTANEOUS LESIONS The typical lesion is a single, circumscribed, indurated area usually located on the face, neck, upper chest, or upper extremity. Although described in infants as characteristically blue-red to purple-red and surrounded by a zone of edema, the early lesion may be an area of pale edema or erythema (Fig. 180-6). The margins are indistinct, in contrast to the sharply defined borders of erysipelas. Regional adenopathy is rarely present. Occasionally, in children with Hib buccal cellulitis, erythematous buccal mucosal lesions appear on the side of the affected cheek, which suggests direct bacterial spread from the oropharynx into buccal soft tissues.[80]

When *H. influenzae* cellulitis occurs in adults, the infection follows a striking sequence: Marked pharyngitis at first, high fever, then rapidly progressive anterior neck swelling, tenderness, erythema, and dysphagia.[79]

OTHER PHYSICAL FINDINGS Associated otitis media, sinusitis, or epiglottitis as well as pneumonia may occur; occasionally, metastatic infections such as septic arthritis or meningitis develop.

▲ **FIGURE 180-6** Cellulitis caused by *Haemophilus influenzae*. Erythema and edema of the face in a child. (Used with permission from Richard A. Johnson, MD.)

Laboratory Findings

The white blood cell count is elevated, usually in the 20,000/mm^3 range. Results of blood cultures are positive in approximately 50 percent of cases. Aspiration and culture of specimens taken from the margin of the cellulitis have yielded positive results in about half of patients.

Diagnosis and Differential Diagnosis

H. influenzae cellulitis should be suspected when a child aged 3 to 24 months develops an acute facial (buccal) cellulitis with high fever. Immediate confirmation of the diagnosis may be possible from inspection of Gram-stained smears of an aspirate of the lesion. Although upper body cellulitis caused by other microorganisms is more common in adults, Hib also should be considered in patients with respiratory infections, especially adults or young children not fully immunized.[77]

Streptococcal (group A, C, or G) or pneumococcal cellulitis may produce discoloration of the skin similar to that in Hib infection. Erysipelas, which occurs rarely in infants, is usually homogeneously erythematous, and the margins of the plaque-like swelling are distinct, whereas the lesion borders in *H. influenzae* cellulitis are indefinite. The presence of pustules or boils is helpful in identifying *S. aureus* as the etiologic agent.

Course and Prognosis

Most patients do well with antibiotic therapy, even though the disease is often associated with bacteremia. The abrupt onset of high fever and easily observed cellulitis indicates the urgency of the situation. Constant vigil must be maintained for suppurative complications in the upper airways, meninges, lungs, bones, joints, and other organs.

Treatment and Prophylaxis

Third-generation cephalosporins (ceftriaxone or cefotaxime) are currently the drugs of choice in the treatment of Hib disease because of their activity against both ampicillin-susceptible and β-lactamase–producing strains of *H. influenzae* and because of their efficacy in treating any complicating meningeal spread of infection. Infections caused by β-lactamase–negative isolates can be treated with ampicillin given IV in four to six divided doses daily. Because 30 percent to 45 percent of Hib strains show plasmid-mediated ampicillin resistance, however, therapy should begin with a third-generation cephalosporin.

The use of Hib conjugate vaccine (capsular polysaccharide covalently linked to a protein moiety) has dramatically decreased the incidence of invasive Hib disease in the developed world.[76] These vaccines stimulate the production of protective antibodies when given to infants before 6 months of age.

CUTANEOUS MANIFESTATIONS OF *SALMONELLA* INFECTIONS (ENTERIC FEVER)

Bacteriology and Pathogenesis

Isolation of salmonellae from stool is made difficult by the fact that, when present, they represent only a small part of the fecal flora. Extragastrointestinal isolates are easier to identify, because they are usually pure cultures of a given *Salmonella* sp. The use of selective media (e.g., MacConkey agar, *Salmonella-Shigella* agar) that inhibit the growth of Gram-positive organisms, as well as many Gram-negative species, facilitates isolation of the organisms from stool. Salmonellae are Gram-negative bacilli that do not ferment lactose. In stool bacteriologic testing, initial selection of non–lactose-fermenting colonies is followed by biochemical and serologic (agglutination) procedures for identification. There are over 2400 serovars determined by surface and flagellar antigens. Modern molecular biology has established a revised nomenclature, with *S. enterica* the single species, and all others serovars (serotypes) of this single species (e.g., *S. enterica* serotype Typhimurium). Because habits are difficult to change, organisms are usually still referred to as familiar species [e.g., *S. typhi*, *S. paratyphi* (A, B or C), *S. enteritidis*] rather than as serotypes of *S. enterica*.

Epidemiology

People acquire *S. typhi* and other *Salmonella* species causing enteric fever by ingestion of contaminated water or food, often during travel in developing countries. A history of recent travel and of suspicious food or water encounters should be sought in a patient with appropriate clinical manifestations.

Humans are the only hosts for *S. typhi* and *S. paratyphi*. The chronic carrier state that may follow clinical typhoid fever is almost always asymptomatic, except for manifestations of gallbladder disease if cholelithiasis and active cholecystitis are present. Other serotypes of *Salmonella* occasionally can produce an enteric fever syndrome similar to, but usually milder than, that of typhoid fever. Unlike *S. typhi*, these other *Salmonella* serotypes are ubiquitous in nature (occurring in animals, reptiles, and poultry).

SALMONELLA INFECTIONS AND THE SKIN AT A GLANCE

- *Salmonella* organisms are widespread in nature.
- Carried by cold- and warm-blooded animals, they contaminate foods derived from animals and are global in distribution.
- *Salmonella* infections manifest as gastroenteritis, enteric fever, or septicemia.
- Rose spots are the classic skin lesions of systemic *Salmonella* infection.
- These lesions occur in 10 percent to 60 percent of natural (untreated) typhoid fever cases but less frequently in cases of enteric fever caused by other *Salmonella* sp.

Clinical Manifestations

HISTORY Symptoms begin several days to several weeks after the ingestion of contaminated water or food. Headache, fever, generalized aching, abdominal discomfort, cough, and constipation are common. Delirium or mental torpor is not unusual, especially with high fever. Heart rate may be slower than expected for the magnitude of the fever. Symptoms increase in intensity, and fever often reaches 39.4°C to 40.6°C (103°F to 105°F) by the end of the first week. During the second week, rose spots may appear on the trunk, and diffuse abdominal cramping becomes prominent, sometimes accompanied by diarrhea.

CUTANEOUS LESIONS After 7 to 10 days of high fever, the rose spots characteristic of *S. typhi* infection may appear. These lesions are 2- to 3-mm, slightly raised, nontender, pink maculopapules that blanch on pressure. Appearing in crops of approximately 10 to 20 lesions, they are often located between the nipple area and the umbilicus on the anterior trunk, rarely on the back or extremities. Without therapy, the spots usually become brownish as they fade and disappear in 3 to 4 days. New lesions emerge over the ensuing 2 to 3

weeks in untreated patients. Their presence in 63 percent of a group of 62 patients should encourage careful observation for this subtle rash.[82] Early institution of antimicrobial therapy may be responsible for the decreasing incidence of rose spots. The rash is less frequently reported in people of color, but this may be because of the difficulty in detecting the small lesions on dark skin. Rose spots occur infrequently in enteric fevers caused by other *Salmonella* sp.

Other skin changes have been noted during the acute phase of enteric fever. Erythema typhosum, an erythematous confluent rash, may occur during the first week. Erythema nodosum and urticarial lesions have been observed. In several reports from the Indian subcontinent, subcutaneous and cutaneous abscesses and skin ulcers have been described.[83,84] It is distinctly uncommon to observe herpes labialis in enteric fever.

OTHER PHYSICAL FINDINGS During the time cutaneous lesions are appearing, the patient may be disoriented and have signs of pneumonia. The abdomen is often distended, tympanitic, and diffusely tender, with some localization to the right lower quadrant. The spleen is often enlarged but may be difficult to palpate because of abdominal distension and guarding.

Laboratory Findings

Leukopenia is often present, but values range from 3000 to 20,000/mm^3. The percentage of mononuclear cells may be increased, and atypical lymphocytes can appear in small numbers, which suggests a viral illness. Thrombocytopenia and, rarely, hemolysis may occur. During the initial week of illness, blood culture results are usually positive for *Salmonella*. During the second week, or when diarrhea begins, stool culture results become positive for *Salmonella*, and the white blood cell count may increase. Isolation of *S. enterica* serotype Typhi from the blood is the gold standard for diagnosis of typhoid fever.

Histopathology

Histologic examination of a rose spot reveals gross dilatation of capillaries. There is considerable edema and abundant pericapillary infiltration with macrophages. Organisms may be present within these cells.[87]

Diagnosis and Differential Diagnosis

The diagnosis of *Salmonella* enteric fever may be difficult in a sporadic case, especially if the characteristic rash and gastrointestinal symptoms have not yet appeared and there is no history of travel in an endemic area. Headache, cough, and high fever are not very specific findings. However, when these symptoms are associated with delirium, relative bradycardia, and leukopenia with increased numbers of circulating mononuclear cells, the diagnosis of enteric fever should be considered. The diagnosis is usually made by performing blood cultures, which yield positive results for *Salmonella* in approximately 80 percent of untreated cases during the first 10 days. Results of Widal's tests are usually negative during the early phase of the illness. Likewise, enteric fever due to *S. enterica* serotypes other than serotype Typhi can usually be diagnosed through blood cultures. Culture of other material (e.g., bone marrow, rose spots) may be important, especially in patients who have had prior antibiotic therapy. PCR testing of blood may have a role in the latter.

Differential diagnosis includes a wide range of diseases. Prominent cough and severe headache in the early phases may suggest a viral or atypical pneumonia. Typhus and Rocky Mountain spotted fever can usually be excluded by geographic and epidemiologic considerations, serologic studies, the characteristic petechial component of the rash, and its distribution on the distal parts of the extremities. Miliary tuberculosis may begin as an acute febrile illness with similar symptoms, leukopenia, and splenomegaly. The diagnosis may be delayed until a secondary complication such as meningitis occurs. Infectious mononucleosis is suggested by headache, fever, lymphadenopathy, splenomegaly, and a blood profile with leukopenia and some atypical mononuclear cells.

Malaria and toxoplasmosis are two parasitic illnesses that deserve consideration. Epidemiologic information plus intermittency of symptoms usually suggest the former. In generalized toxoplasmosis, manifestations may be very similar to those of early enteric fever: prominent cough, high fever, lymphadenopathy and a truncal rash. The rash tends to be more florid than in enteric fever and has a petechial component. Diagnosis usually requires identification of *Toxoplasma gondii* in biopsy material or a rising antibody titer.

Course and Prognosis

The response of patients with enteric fever to antibiotic therapy is usually gradual, with 3 to 6 days needed for the temperature to return to normal. With prolonged treatment, the incidence of relapse has declined. The major complications in the pre-antibiotic era were bowel perforation and hemorrhage. Although rare, these complications still occur and are responsible for 75 percent of mortality. Deaths have been reduced from 10 percent to 1 percent to 2 percent with antibiotic therapy, although mortality is higher in immunocompromised patients. After recovery from typhoid fever, 1 percent to 4 percent of patients continue to harbor organisms in the gallbladder and to excrete them in the stools, becoming a potential source for spread.

Treatment and Prevention

The emergence of multidrug-resistant *Salmonella*, including *S. typhi*, in many areas of the world has essentially eliminated the use of chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole as first-line antimicrobials.[88] The fluoroquinolones (ciprofloxacin, ofloxacin) are active against drug-susceptible and multidrug-resistant *S. typhi* or other salmonellae causing enteric fever. Blood cultures become sterile promptly on treatment with ciprofloxacin, and this drug has become the treatment of choice for typhoid fever. Ciprofloxacin is administered in 500- to 750-mg doses given orally (or 400 mg given IV) every 12 hours in adults for 7 to 14 days. Ceftriaxone and cefotaxime are alternatives.

Skin Infections Due to Nontyphoidal *Salmonella* Serotypes

Skin infections due to nontyphoidal *Salmonella* serotypes are uncommon and usually take the form of pustular lesions, cellulitis, or bacteremic subcutaneous abscesses. Very uncommonly, *Salmonella* necrotizing fasciitis has been reported, usually in the setting of immunosuppression.[90]

INFECTIONS WITH OTHER GRAM-NEGATIVE BACILLI THAT HAVE CUTANEOUS MANIFESTATIONS

Bacteriology and Pathogenesis

Epidemiology

Cellulitis usually follows contamination of adjacent tissues by bowel contents or a breakdown of skin. Predisposing conditions include (1) bowel perforation, (2) co-

OTHER GRAM-NEGATIVE BACILLARY INFECTIONS AND THE SKIN

AT A GLANCE

- An acute cellulitis, with or without production of gas, may be caused by *Escherichia coli*, *Proteus* sp., *Klebsiella* sp., *Enterobacter* sp., *Serratia marcescens*, and other organisms.
- These infections occur often but not exclusively in the very elderly; in individuals with diabetes; in patients after trauma surgery, bowel or perineal inflammation; and in immunocompromised individuals.
- The infectious process may be limited to the superficial soft tissues or found primarily in the deep fascia.[91]
- Drug addicts develop such infections after "skin popping," which lead to cellulitis and necrotizing fasciitis.
- Rhinoscleroma is a granulomatous infection caused by *K. pneumoniae* subspecies *rhinoscleromatis*. It has a slowly progressive course and may involve the upper airway and tracheobronchial tree.

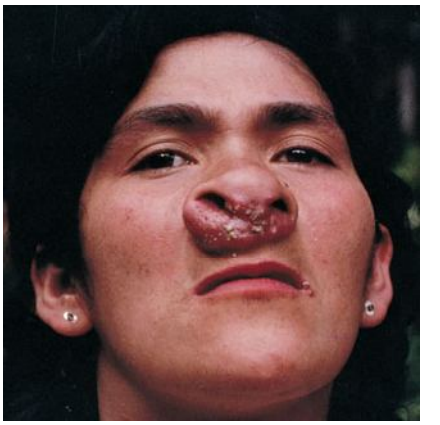
lon surgery, (3) chronic edema, (4) vascular insufficiency, (5) injection of addictive drugs,[92] (6) decubitus ulcers, (7) presence of percutaneous lines, and (8) superficial perineal dermatitis. Poorly controlled diabetes, altered host defenses, and poor nutrition often further predispose to such infections in these patients. Crepitant (gas-containing) cellulitis results from infection with gas-forming strains of bacteria (*E. coli*, *Klebsiella*, *A. hydrophila*), especially in patients with diabetes, or in the presence of *Bacteroides* sp. or anaerobic streptococci.[94,95]

Clinical Manifestations (See Chap. 179)

HISTORY Diabetes mellitus, malnutrition, or a chronic condition (e.g., paraplegia with decubitus ulcers) is usually present at the time of infection. The onset may be insidious or abrupt. Pain, often severe, frequently precedes local skin changes, especially if the infection is at the level of the deep fascia. High fever, shaking chills, increasing pain, and falling blood pressure may follow. Rectal or perineal pain can indicate a local process that may be especially devastating in a patient deficient in granulocytes.

CUTANEOUS LESIONS In the early stages, the skin is rarely discolored beyond a pink hue, and vesicles or bullae are almost never present. At this juncture, unless pain is present, the process may easily be overlooked. As the cellulitis progresses, edema and redness increase; tenderness, crepitus, and hemorrhagic bullae may develop; and areas of cutaneous gangrene may appear (see Figs. 179-5 and 179-6). The cellulitis may remain localized to the skin and superficial subcutaneous tissues, but progression to the deep fascia with necrosis of fat and increasing pain and toxicity suggests a diagnosis of necrotizing fasciitis[100] (see Chap. 179). Although most cases of Gram-negative bacillary necrotizing fasciitis are polymicrobial in etiology, a striking monomicrobial form caused by *Klebsiella* sp. occasionally occurs, almost always in individuals with diabetes mellitus.[101] *Klebsiella* necrotizing fasciitis results from direct inoculation or commonly from hematogenous spread from another site.

SUPERFICIAL NASAL LESIONS *K. pneumoniae* subspecies *rhinoscleromatis* is the etiologic agent of a hypertrophic, granulomatous infection of the external nares known as *rhinoscleroma*. It often produces changes in the overlying nasal skin (Fig. 180-7) and the contiguous surfaces of the respiratory, sinus, and posterior pharyngeal regions. Most cases seen in the United States have been in patients who have emigrated from specific areas of eastern and central Europe, Africa, the Near East, and parts of Central and South America.[102] Dissemination of the organism is by prolonged close contact. Infected individuals can shed organisms for years. The disease has been reported in patients with AIDS.[103] As in leprosy, the disease rarely becomes clinically apparent until early adulthood. Patients complain of fetid, purulent nasal discharge, epistaxis and obstructive symptoms, cutaneous nasal masses, and eventual scarring of



▲ **FIGURE 180-7** *Klebsiella pneumoniae* subspecies *rhinoscleromatis* infection. Rhinoscleroma. The nasal passages and nose are infected, which results in obstructed respiration.

nasal passages. Diagnosis depends on biopsy-based identification of characteristic vacuolated Mikulicz cells and isolation of the organism on routine cultures. Untreated, rhinoscleroma has a slowly progressive course over many years and may extend to involve any portion of the upper airway and tracheobronchial tree.[104]

K. pneumoniae subspecies *rhinoscleromatis* is susceptible to ciprofloxacin, 250 to 500 mg administered twice daily for 1 to 3 months. Alternatively, the combination of rifampin plus trimethoprim-sulfamethoxazole for 6 months may be used.

OTHER PHYSICAL FINDINGS The clinical course is often dominated by systemic manifestations of the underlying illness or decreased mental alertness, hypotension, and dehydration. Abdominal distension and other manifestations of localized or generalized peritonitis may be present. Extreme tenderness of the rectum, with or without a mass, can indicate the local source of a perineal process.

Laboratory Findings

The leukocyte count is usually elevated but may be markedly diminished in the presence of Gram-negative septicemia. Elevated blood glucose values and findings of ketoacidosis are not unusual. In crepitant cellulitis, radiographs or magnetic resonance imaging of the soft tissue may show the depth and extent of the gas-forming process.[105]

Pathology

Edema, gangrene of overlying skin, fat necrosis, and exudate containing poly-

morphonuclear leukocytes are usually present. Gas may be evident in the subcutaneous tissues. Blood vessels are often involved in a necrotic, obliterative, inflammatory reaction.[100] Underlying muscle is usually not involved unless there is septicemia associated with major vascular thrombosis or there is myonecrosis due to an organism such as *A. hydrophila.*

Diagnosis and Differential Diagnosis

A bacteriologic diagnosis can be made by analysis of specimens from needle aspiration of the cellulitis or an overlying bleb. Several Gram-positive as well as Gram-negative organisms may be present. When gas is present, anaerobic cocci and *Clostridia* must also be considered. A foul, fetid odor may accompany the presence of anaerobes in the exudate. Radiologic and surgical evaluation can be helpful in determining a descriptive diagnosis such as crepitant cellulitis or necrotizing fasciitis.

Course and Prognosis

The process may be indolent and may respond quickly to effective antibiotic therapy. In obese diabetic patients with perineal lesions, the progression of necrotizing fasciitis may be astonishingly rapid, even with vigorous antibiotic and surgical therapy. When the process is located centrally, in the perineal-gluteal area, the mortality rate is often as high as 50 percent. Infection of an extremity is frequently treated by antibiotics, drainage, and débridement, or by amputation, with more favorable results. The course is often prolonged and complex.

Treatment

Immediate antibiotic therapy and surgical drainage, guided by Gram-stained smears of the exudate and determinations of the extent of the process, are essential. Incision and drainage of focal collections associated with cellulitis are indicated. In necrotizing fasciitis, débridement of involved skin and subcutaneous tissues should be extended until normal fascia is reached. The adjunctive use of hyperbaric oxygen therapy for necrotizing fasciitis is controversial but may have some rationale in selected cases with a polymicrobial etiology in which anaerobes play an important role.[106] Judgment and experience are vital in surgical decisions.

Patients with necrotizing fasciitis or gangrenous cellulitis should receive initial combination antimicrobial therapy (modified by specific findings of Gram-stained smears and culture): ampicillin, gentamicin and clindamycin; ampicillin, gentamicin, and metronidazole; ampicillin-sulbactam plus gentamicin; or meropenem or imipenem plus gentamicin. Fluoroquinolones can substitute for aminoglycosides in patients with renal impairment. If *P. aeruginosa*, *Klebsiella*, or *Serratia* is suspected in certain hospital-acquired infections, tobramycin or amikacin may be preferred to gentamicin, and a broad-spectrum penicillin (e.g., ticarcillin-clavulanate) or ceftazidime added in place of ampicillin if *Pseudomonas* is a major pathogen. If methicillin-susceptible *S. aureus* is suspected, nafcillin is included; if resistant enterococci or methicillin-resistant staphylococci are suspected, then vancomycin is included.

CHAPTER 181

The Skin in Infective Endocarditis, Sepsis, Septic Shock, and Disseminated Intravascular Coagulation

Laura Korb Ferris
Joseph C. English III

INFECTIVE ENDOCARDITIS

Epidemiology

In the United States, the incidence of native valve endocarditis is 1.7 to 6.2 cases per 100,000 person-years. The highest rate of infective endocarditis (IE) is seen in intravenous drug users, with an incidence estimated at 150 to 2000 per 100,000 person-years. The risk of prosthetic valve IE decreases with time after valve implantation and the cumulative risk is approximately 2 to 3 percent after 60 months.[1]

Etiology and Pathogenesis

IE can be subdivided by native valve versus prosthetic valve infection. The causative organisms in most cases of IE are staphylococci or streptococci, implicating skin as the initial site of infection in many cases. Native valve endocarditis occurs most commonly in the setting of valvular disease or in people who use intravenous drugs. Rheumatic valve disease has been replaced by aortic stenosis and mitral regurgitation as the most common settings in which native valve endocarditis is encountered. At sites of endothelial injury, a sterile thrombus can occur, which is particularly susceptible to seeding of bacteria from transient episodes of bacteremia. This can result in the development of valvular vegetations that can cause local tissue destruction and embolic events.

Intravenous drug users are particularly susceptible to IE even though most have no pre-existing structural heart disease. More than one-half of the cases of IE in injection drug users are right sided, involving the tricuspid valve. The most common causative organism is *Staphylococcus aureus*.

Prosthetic valve endocarditis can be classified as early (in the first 2 months after valve replacement) or late (2 months or later). The newly placed prosthetic valve is particularly susceptible to bacterial colonization because the process of endothelialization does not occur until 2 to 6 months after surgery. Early prosthetic valve endocarditis is most commonly caused by *S. epidermidis* followed by *S. aureus*. Late prosthetic valve endocarditis can be due to a variety of organisms including the so-called *HACEK organisms* (*Haemophilus parainfluenzae, H. aphrophilus, Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kinsella kinasae*).

Most cases of nosocomial endocarditis are secondary to indwelling catheters or to surgical procedures and are caused by streptococci. However, nosocomial endocarditis in dialysis patients is most commonly due to *S. aureus*. Other less common causes of IE include fungi, *pseudomonas,* and *Coxiella burnetii*.

Clinical Findings

HISTORY Patients with IE generally present with non-cardiac complaints of fever, malaise, and anorexia. The presence of a murmur that is new or has changed in character is often present. Unexplained fever in a patient with a prosthetic heart valve should prompt an evaluation for endocarditis. The Duke criteria (Table 181-1)[2] are helpful in making the diagnosis of IE.

CUTANEOUS LESIONS Cutaneous signs of IE are non-specific but may help the clinician in making the appropriate diagnosis. Cutaneous findings are caused either by embolic events, thrombosis or focal vasculitis.

Splinter hemorrhages (Fig. 181-1) are 1- to 2-mm red-brown longitudinal streaks under the nail plate. They are seen in approximately 15 percent of patients with IE and are considered to be of greater diagnostic value if proximally located. Splinter hemorrhages associated with IE are the result of small capillary vasculitis or from microemboli. In the absence of other signs or symptoms of IE, the mere presence of splinter hemorrhage is not specific enough evidence to warrant a workup. Crops of petechiae are commonly seen in the buccal membrane, soft palate, and extremities.

Janeway lesions are painless, irregular, non-blanchable, erythematous maculopapules that appear on the palms and soles and last days to weeks (see eFig. 181-1.1 in on-line edition). Histologically, thrombi are found in small vessels in the absence of vasculitis. Neutrophilic microabscesses can be seen in the dermis with occasional gram-positive organisms. Osler nodes present as painful red papulo-nodules with a pale center on the fingertips lasting days to weeks (see eFig. 181-1.2 in on-line edition). Osler nodes are painful, perhaps due to involvement of the glomus bodies located in the fingertips. Histologically, neutrophilic microabscesses are present in the dermis, and arteriolar microemboli may contain gram-positive cocci.

Septic emboli of valvular vegetation fragments can cause ischemia of distal extremities. Toes are most commonly involved, followed by fingers, and this condition presents as reticulated pur-

INFECTIVE ENDOCARDITIS, SEPSIS, SEPTIC SHOCK, DISSEMINATED INTRAVASCULAR COAGULATION, AND THE SKIN AT A GLANCE

- Infective endocarditis: staphylococcal or streptococcal bacteria most common cause in intravenous drug use setting.
- Sepsis: gram-positive bacteria most common cause; tenth leading cause of death in the United States.
- Disseminated intravascular coagulation: most commonly from sepsis; results from systemic activation of the coagulation cascade.
- Cutaneous manifestations of these entities include: splinter hemorrhages, Janeway lesions, Osler nodules, erythroderma, cellulitis, purpura, hemorrhage, purpura fulminans, and skin necrosis.

TABLE 181-1
Modified Duke Criteria for Infective Endocarditis[2]

- *Clinically definite case* is defined as fulfilling two major, one major plus three minor, or 5 minor criteria
- *Clinically suspicious case* is defined as fulfilling one major and one minor, or three minor criteria
- Major criteria
  - Microbiologic
    - Two separate blood cultures positive for typical microorganism
      or
    - Persistently positive blood culture for typical microorganism
      or
    - Single positive blood culture for *Coxiella burnetii* or a phase I immunoglobulin G antibody titer to *Coxiella burnetii* greater than 1:800
  - Evidence of endocardial involvement
    - New valvular regurgitation
      or
    - Positive echocardiogram showing oscillating echogenic intracardiac mass at the sire of endocardial injury, a periannular abscess, or new dehiscence of a prosthetic valve
- Minor criteria
  - Predisposition to infective endocarditis
  - Fever
  - Vascular phenomena such as Osler nodes or Roth spots
  - Immunologic factors such as a positive rheumatoid factor or glomerulonephritis
  - Serologic evidence of active infection not meeting microbiologic major criteria

pura similar to that seen in cholesterol emboli syndrome (see Chap. 174). Although this condition generally resolves without sequelae, tissue necrosis or gangrene can result.

RELATED PHYSICAL FINDINGS The most common non-cutaneous finding in IE is fever. Signs and symptoms related to the bacterial infection and septic emboli may include splenomegaly, microscopic hematuria, pneumonitis, cerebral vascular accident, meningoencephalitis, brain abscess, retinal hemorrhages (Roth spots), acute abdomen, myocardial infarction, pericarditis and congestive heart failure, arthralgias and arthritis, or chronic wasting disease.

Laboratory Tests

A positive blood culture is the most helpful laboratory test in making the diagnosis of IE. Other tests that may be abnormal in this setting include a positive rheumatoid factor, elevated erythrocyte sedimentation rate, C-reactive protein, leukocytosis, or a urinalysis showing hematuria.

◀ **FIGURE 181-1** Globular proximal splinter hemorrhage and several distal linear splinter hemorrhages in a patient with infective endocarditis. (Photo used with permission from William James, MD, and James Fitzpatrick, MD.)

Special Tests

Echocardiography allows the visualization of the valves and can provide information as to the level of myocardial involvement. Transthoracic echocardiography is less invasive and less expensive than transesophageal echocardiography. However, the sensitivity and specificity of transthoracic echocardiography are 60 percent to 70 percent and 98 percent, respectively, whereas the sensitivity of transesophageal echocardiography is 75 percent and 95 percent without a compromise in specificity.

Differential Diagnosis

The differential diagnosis of splinter hemorrhages is reviewed in Box 181-1. Janeway lesions and Osler nodes can be similar in appearance to septic emboli and neutrophilic eccrine hidradenitis.

Complications

Cardiac complications of IE include congestive heart failure, extension of disease to the myocardium, and pericarditis. Embolic complications include stroke, mycotic intracranial aneurysms, and splenic abscess.[1]

Prognosis and Clinical Course

The overall mortality for IE has dropped by approximately 50 percent over the past 40 years and is currently approximately 28 percent.[2] Prognosis depends on age, the nature of the responsible microorganism, the presence of emboli, and the extent of cardiac damage. Early diagnosis and treatment improve outcome.

Treatment

Appropriate antibiotic therapy should be initiated in suspected cases of IE after blood cultures have been drawn. Long-term (4 to 6 weeks) parenteral antibiotics, usually with a penicillin derivative, are used to treat streptococcal or staphylococcal IE. Antibiotic treatment has been shown to reduce the risk of subsequent embolism. Treatment of IE caused by other organisms is reviewed elsewhere.[1] Indications for surgical treatment include persistent bacteremia despite 7 days of parenteral antibiotic therapy, prosthetic valve endocarditis, the presence of large vegetations, severe valvular dysfunction, and infection with *Pseudomonas*, *C. burnetii*, or fungus.[3]

Prevention

Currently, prophylactic antibiotics for skin surgery are not indicated for procedures performed on non-infected, surgically scrubbed skin regardless of cardiac

history. When a patient falls into a high or moderate risk category and is to have a procedure that involves a clean, contaminated body area (such as the oral cavity, groin, or axilla) or a contaminated or infected wound, antibiotic prophylaxis is recommended.[4]

SEPSIS AND SEPTIC SHOCK

Epidemiology

Sepsis, most commonly from gram-positive bacteria, is the tenth leading cause of death in the United States. A review of approximately 750 million hospitalizations over 22 years in the United States showed that sepsis accounts for 1.3 percent of all hospital admissions. The incidence of sepsis has been steadily increasing since 1971 although the mortality rate has been dropping.[5]

Etiology and Pathogenesis

The prevailing presumption has been that sepsis is a result of uncontrolled activation of the inflammatory response to pathogens. Sepsis is often characterized by an initial burst of immunologic activation, including a surge in tumor necrosis factor-α production. This is thought to be mediated by binding of specific pathogen-associated molecules to Toll-like receptors found on cells of the immune system. Toll-like receptors activate signaling through transcription factors such as nuclear factor-κB that activate the expression of a cascade of inflammatory cytokines. However, this is followed by a relative decrease in immunity with impaired delayed type hypersensitivity, a loss of critical cells of the immune response including B cells, $CD4^+$ helper T cells, and dendritic cells, and the inability to clear infection.

Sepsis is often complicated by impaired organ function. Autopsy studies revealed that even in the setting of profound organ dysfunction, cell death is minimal and not sufficient to account for the clinical picture. Thus, sepsis appears to activate a state of cellular hibernation in which cells reduce their activities to only those required for cell survival. This would explain why organ function is often regained in those patients who recover from sepsis.[6]

Clinical Findings

HISTORY The septic patient is usually febrile, or in some cases hypothermic, with tachycardia and tachypnea. Patients with severe sepsis can also have dysfunction of major organ systems and those in septic shock develop hypotension that is refractory to the administration of fluid.

◀ **FIGURE 181-2** Proximal nail fold purpura from leukocytoclastic vasculitis due to *Clostridium difficile* sepsis.

CUTANEOUS LESIONS The causative organism in sepsis is not always identifiable by routine culture. In some cases, the cutaneous examination can provide clues to the identity of the responsible pathogen, providing a valuable clinical tool in the management of the septic patient.

Erythroderma in the septic patient suggests staphylococcal or streptococcal toxic shock syndrome (TSS). Patients with TSS are usually young and otherwise healthy. Patients with staphylococcal TSS are much more likely to be erythrodermic but much less likely to have positive blood culture than are patients with streptococcal TSS. Streptococcal TSS is commonly associated with a soft tissue infection.

The finding of pustules on the skin of a septic patient, particularly in the neonate or immunocompromised individual, may be suggestive of fungal infection, particularly with *Candida* species. Congenital candidiasis, most often seen in infants born to mothers with vaginal candidiasis, is generally a skin-limited disease. However, in the septic infant with pustules, candidemia should be considered.

The vasculitis and coagulopathy that can occur in the septic patient may cause purpura, sometimes prominent in the nail fold small capillaries (Fig. 181-2). Purpura is particularly prominent in those patients with thrombocytopenia. Such infections are seen most commonly in oncology patients undergoing bone marrow transplantation. In the immunocompromised host, opportunistic fungal infection, such as with *Aspergillus* sp., *Fusarium* sp., and *Candida* sp., often presents as erythematous papules, petechiae, or pustules that progress to purpuric lesions (Fig. 181-3).

Pustules due to disseminated gonococcemia are acrally located, typically tender and a characteristic gun-metal gray color, hemorrhagic, or black and are most commonly seen in the otherwise healthy adolescent or young adult (see eFig. 181-3.1 in on-line edition). Gram stain of the pustule reveals intracellular gram-negative diplococci. In its most extreme form, meningococcemia can cause purpura fulminans (see the section Cutaneous Lesions). Pustules may also be secondary to a local inoculation site, as in the case of staphylococcal sepsis.

A more aggressive local soft tissue infection, necrotizing fasciitis, can be associated with positive blood cultures later in the course of the disease due to hematogenous seeding by the organisms. Clinically, necrotizing fasciitis is rapidly progressive, initially painful, and accompanied by fever and leukocytosis

▲ **FIGURE 181-3** Petechiae from *Fusarium* sepsis in an immunosuppressed patient.

(see Chap. 179). Blood cultures are frequently positive. After several days, the involved area may become anesthetic secondary to destruction of cutaneous nerves.[8] Cellulitis is characterized by intense local inflammation in the presence of relatively few infectious organisms and blood cultures are rarely positive (see Chap. 179). Most commonly occurring on the legs, the affected extremity is typically erythematous, hyperemic, and edematous. The most common causes of cellulitis are *S. aureus* and group A *Streptococcus*. Rarely, anaerobic organisms, including clostridial species and other anaerobic bacteria species such as *Bacteroides*, *Peptostreptococcus* or *Peptococcus,* are the causative organism. In immunosuppressed patients, *Cryptococcus neoformans* can also cause cellulitis, particularly in the setting of AIDS. Patients with liver compromise can develop cellulitis from *Vibrio vulnificus*, a gram-negative bacterium that lives in warm marine environments and becomes concentrated in filter-feeding shellfish. Infection occurs either via consumption of contaminated organisms such as raw oysters, or through contact with infected water. Mortality rates exceed 40 percent in those with *V. vulnificus* sepsis.[7]

Ecthyma gangrenosum (see Chap. 180) begins as an erythematous papule that expands and eventually becomes a necrotic bulla. Lesions are most commonly seen between the umbilicus and the knees. Classic ecthyma gangrenosum represents cutaneous seeding of bacteria, usually *Pseudomonas aeruginosa*, from a hematogenous source and is seen almost exclusively in neutropenic patients, often in association with an underlying malignancy. Non-classic cases have been reported with *Aeromonas hydrophila, E. coli, Citrobacter freundii*, and *Corynebacterium diphtheriae*, fungal infection, including *Candida, Aspergillus, Fusarium,* and mucormycosis-causing species, and even herpes simplex virus.[9]

RELATED PHYSICAL FINDINGS *Sepsis* is defined as infection plus systemic inflammation and is characterized by hyper- or hypothermia, tachycardia, and tachypnea. Sepsis is further subdivided into *severe sepsis*, which is defined as infection with systemic inflammation and organ dysfunction. The organ systems commonly affected in sepsis include the renal, hepatic, central nervous, pulmonary, gastrointestinal, and cardiovascular systems. Septic shock occurs when patients with severe sepsis also have hypotension (systolic blood pressure less than 90) refractory to fluid administration.

Laboratory Tests

The septic patient generally has a white blood cell count greater than 12×10^9/L or less than 4×10^9/L or a bandemia of greater than 10 percent. Elevated C-reactive protein and procalcitonin levels are common. Organ dysfunction can manifest as low cardiac output, elevated creatinine, thrombocytopenia, and elevated international normalized ratio or prothrombin time, or hyperbilirubinemia.[10] Blood cultures can be helpful in guiding treatment of the septic patients, however, only 30 percent to 50 percent of septic patients have positive blood cultures.[11]

Special Tests

Special tests, including imaging studies and culture of suspected involved tissue, can sometimes be helpful in identifying the source of infection in the septic patient.

Differential Diagnosis

The differential diagnosis of skin findings in the septic patient is reviewed in Box 181-2.

Complications

Complications of sepsis include death, loss of limbs due to hypoperfusion, and permanent organ dysfunction.

Prognosis and Clinical Course

The survival rate in sepsis in 2000 was 17.9 percent and organ failure occurred in 33.6 percent of patients with sepsis.[5]

Treatment

Treatment of sepsis is usually done in an intensive care unit and involves the use of antimicrobial drugs, chosen empirically or based on the culture of a particular microorganism, and supportive care to preserve organ function.

Prevention

The prevention of sepsis in a hospital setting is achieved by the implementation of basic infection control measures, including routine hand washing and the minimization and regular replacement of indwelling catheters. In patients who are immunocompromised, particularly in the setting of organ transplantation or AIDS, the use of prophylactic antibiotics can help to reduce the incidence of sepsis.

Box 181-2

Differential Diagnosis of Skin Findings in the Septic Patient

- Erythroderma

DISSEMINATED INTRAVASCULAR COAGULATION

Epidemiology

The incidence of disseminated intravascular coagulation (DIC) is not known. Approximately 15 percent of septic patients may develop DIC.

Etiology and Pathogenesis

DIC represents systemic activation of the coagulation cascade. This leads to fi-

TABLE 181-2
Settings in Which Disseminated Intravascular Coagulation Can Occur

- Sepsis
- Trauma
- Malignancy
- Obstetric complication (amniotic fluid embolism, placental abruption)
- Vascular abnormalities
- Hepatic failure
- Immunologic reaction to drugs or toxins
- Transfusion reactions
- Transplant reaction
- Protein C or S deficiency

brin deposition in the vasculature, which can cause organ ischemia and death. In addition, the consumption of platelets and coagulation factors can lead to bleeding. DIC occurs most commonly secondary to an underlying disorder as listed in Table 181-2.

In DIC, coagulation activation is a tissue factor–dependent (i.e., extrinsic or factor VIIa pathway). Inflammatory cytokines such as tumor necrosis factor-α promote damage to endothelial cells and activation of mononuclear cells. These cells then produce tissue factor, which binds to factor VIIa and activates downstream coagulation cascades. Thrombin generation is amplified by defective anticoagulant mechanisms and results in increased fibrin deposition. The fibrin that is generated fails to be degraded by the fibrinolytic system. In the healthy state, antithrombin regulates thrombin activity. In DIC, antithrombin levels are low due to continuous consumption, degradation by neutrophil elastase and impaired synthesis due to liver failure in some settings. Fibrinolysis is inhibited by plasminogen activator inhibitor type 1 (PAI-1). Studies show that individuals with high plasma levels of PAI-1 are at higher risk of mortality in DIC. This correlates with a mutation in PAI-1 that is associated with higher PAI-1 plasma concentrations. Thus, some individuals may be genetically predisposed to fatal outcomes from DIC due to a point mutation in PAI-1.[12]

The infection most commonly associated with DIC is meningococcal sepsis. However, DIC has been reported after viral and other bacterial infections. Many recent reports suggest an emergence of sepsis due to staphylococcus, particularly those isolates containing exotoxins including staphylococcal enterotoxin serotypes B and C, TSS toxin-1, and Panton-Valentine leukocidin, a leukocyte toxin believed to be important in the pathophysiology of skin and soft-tissue infections and necrotizing pneumonia, as a factor in initiating DIC.[13]

Clinical Findings

HISTORY DIC is always secondary to an underlying condition or disorder and thus the patient generally first presents with the antecedent condition. Often, patients with DIC develop simultaneous bleeding, thrombosis, and multiorgan failure. The onset of DIC in the neonatal period is suggestive of protein C or S deficiency.

CUTANEOUS LESIONS The most characteristic cutaneous finding in DIC is noninflammatory purpura with extensive microvascular occlusion referred to as *purpura fulminans* (Fig. 181-4). Patients have diffuse bleeding, hemorrhagic necrosis of tissue, and skin necrosis (see eFig. 181-4.1 in on-line edition). Patients with purpura fulminans may present with ischemic digits or extremities (see eFig. 181-4.1 in on-line edition; see also Chap. 145) that, left untreated, can progress to gangrene.

RELATED PHYSICAL FINDINGS In its most extreme form, patients with DIC develop the Waterhouse-Friderichsen syndrome, most commonly seen in meningococcal sepsis (see Chap. 180). This is a syndrome of multiorgan failure characterized by a petechiae or purpura, coagulopathy, cardiovascular collapse, and bilateral adrenal hemorrhage.

▲ **FIGURE 181-4** Purpura fulminans from *Escherichia coli* sepsis.

Laboratory Tests

DIC is characterized by laboratory evidence of massive activation of the coagulation cascade and the destruction of platelets. Platelet counts are generally less than 100,000. Because of the high conversion of fibrinogen to fibrin, soluble fibrin monomers and the D-dimer assay are usually elevated. The prothrombin time is usually prolonged to at least 1.2 times the upper limit of normal as well. Several scoring systems exist that assign numeric values to particular laboratory findings and allow the calculation of a single numeric score that is helpful in predicting the presence of and mortality from DIC as reviewed elsewhere.[12]

Differential Diagnosis

The differential diagnosis of DIC includes other conditions causing small- and mid-size vessel thrombotic occlusions leading to organ failure and microangiopathic hemolysis. This includes thrombocytopenic thrombotic purpura, the hemolytic uremic syndrome, and the HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) syndrome seen in obstetric patients.

Complications

Complications of DIC include tissue necrosis and infection, often requiring amputation of limbs or digits, multiorgan failure (particularly the Waterhouse-Friderichsen syndrome), and death.

Prognosis and Clinical Course

The mortality risk is doubled in patients with DIC who are septic or have experienced trauma.

Treatment

Because DIC is always secondary to another condition, the most important factor in the management of DIC is treatment of the underlying cause. However, replacement of components consumed during DIC and inhibition of the coagulation cascade has an important role as well. Despite the conventional wisdom that replacement of platelets and coagulation factors in the patient with DIC adds "fuel to the fire," more recent clinical trials have not shown this to be the case. These stud-

ies have demonstrated a survival benefit to treating patients with DIC with low-dose heparin. Finally, activated protein C, which works by enhancing thrombomodulin activity, has been shown to significantly reduce mortality in patients with DIC.[12]

There is very little published experience regarding the treatment of the cutaneous necrosis seen in DIC. Skin necrosis secondary to DIC is similar to that seen in full thickness cutaneous burns. Possible excision of necrotic tissue and coverage with autografts, and/or amputation of extremities are treatment options.[14]

Prevention

Most interventions in DIC are aimed at minimizing organ damage and bleeding. Prevention of DIC itself can be achieved by the prompt diagnosis and treatment of its causes, particularly sepsis.

CHAPTER 182

Bartonellosis

Timothy G. Berger
Francisco G. Bravo

Bartonella are aerobic, fastidious, Gram-negative bacilli, with the remarkable capacity for intraerythrocyte persistence and the production of bacteremia. The number of identified *Bartonella* sp. has been rapidly expanding. The genus includes three important species that are human pathogens: *B. henselae,* the cause of most cases of cat-scratch disease (CSD) as well as some cases of bacillary angiomatosis (BA), hepatic and splenic peliosis (cystic blood-filled spaces in hepatic lobules or the splenic parenchyma), and endocarditis; *B. quintana,* the cause of trench fever, urban trench fever, BA, and endocarditis; and *B. bacilliformis,* the cause of Oroya fever and verruga peruana. Other potential human pathogens are *B. elizabethae* and *vinsonii,* which cause endocarditis, *B. grahamii,* a cause of neuroretinitis, and *B. washoesis*, which causes myocarditis (Table 182-1).[1] Infections caused by most *Bartonella* are associated with arthropod vectors that may simultaneously carry several species. Asymptomatic bacteremia rates in primary vertebrate (reservoir) hosts may exceed 50 percent. This suggests high prevalence of infection and prolonged and persistent bacteremia as characteristics of *Bartonella* infection.

The genus *Bartonella* contains organisms previously in the genuses *Rochalimaea* and *Grahamella*. *Bartonella* organisms are small aerobic, fastidious, pleomorphic, Gram-negative bacteria; they are difficult to culture from clinical samples. Initial clinical isolates grow slowly and visible colonies may not be detected for weeks, but subsequent passages grow much more rapidly. The organisms are short rods, ranging from 0.3 to 0.5 μm wide by 1.0 to 1.7 μm long. The organisms are best visualized in tissue using modified silver stains (Warthin-Starry). Polymerase chain reaction (PCR) and immunohistochemistry can also detect infection.[2,3]

BARTONELLOSIS AT A GLANCE

- Cat-scratch disease, trench fever/bacteremia, and Oroya fever are caused by these bacteria.
- *Bartonella* sp. are able to live inside erythrocytes, explaining the presence of bacteremia in many of the clinical conditions.
- Bacillary angiomatosis occurs in immunosuppressed hosts, especially acquired immunodeficiency syndrome patients.
- Diagnosis often made by histologic examination or serology due to the difficulty in culturing these bacteria.

CAT-SCRATCH DISEASE

Epidemiology

Approximately 29.2 million households (31 percent) in the United States own a cat, averaging close to two cats per household, for a total household cat population of 57 million. This large population of domestic cats explain the more than 22,000 cases of CSD reported annually. CSD affects persons of all ages, although 60 percent to 90 percent of cases are reported in children and young adults. CSD is seen worldwide and does not appear to have a racial prevalence. Most patients with CSD recall a history of cat contact, but this is not absolute (90.3 percent to 99.1 percent). The incidence of CSD is slightly higher in males and it occurs seasonally, mostly between July and October.[4–6]

CSD is associated with exposure to a cat, usually a kitten. The method of spread from cat to human is usually a scratch or bite. In California, 39.5 percent of cats are bacteremic for *B. henselae* with a single sampling, indicating a very high

CAT-SCRATCH DISEASE AT A GLANCE

- Vast majority of cases caused by *Bartonella henselae*
- Transmitted by the scratch or bite of a cat
- Most common cause of localized, chronic lymphadenopathy in children
- Diagnosis established serologically

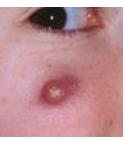
[a]The cat flea transmits *B. henselae* from cat to cat, but not cat to human.



infection rate. Bacteremic cats were more likely to be stray cats, young (less than 1 year old), and flea-infested. Seroprevalence for *B. henselae* is as high in pet cats as in shelter and feral cats.[7] The seroprevalence of *B. henselae* among pet cats in North America is 27 percent overall but highly variable, with a higher seroprevalence in warm rainy regions. When the geographic seroprevalence of *B. henselae* is compared with predicted estimates of cat flea populations based on temperature and humidity, there is considerable overlap, supporting the role of the cat flea (*Ctenocephalides felis*) as the arthropod vector maintaining infection in cats. *B. henselae* can be transmitted from cat to cat via the cat flea, cat fleas contain *Bartonella* organisms after feeding on infected cats, cat flea feces contains viable *Bartonella,* and cats can be experimentally infected by the intradermal injection of infected cat flea feces.[8] The cat flea has not been demonstrated to spread *Bartonella* infection from cats to humans. Rather, cats' claws and teeth may be contaminated by infected flea feces during scratching and grooming allowing for transmission to humans by scratches.

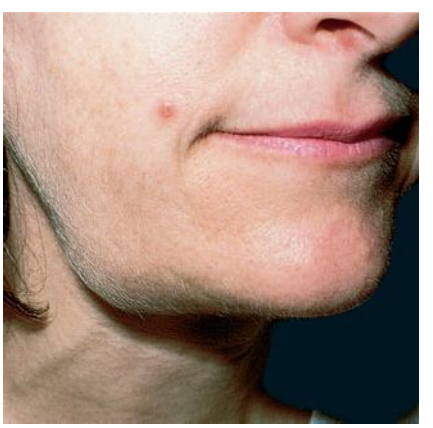
Etiology and Pathogenesis

B. henselae causes the vast majority (more than 95 percent) of cases of CSD. There is one infectious genotype in the United States and two types in Europe, but the disease caused by all is clinically identical. In the immunocompetent host, the organism is, in the majority of cases, well controlled by the immune system, with containment in the primary skin papule and draining lymph node.

Clinical Findings

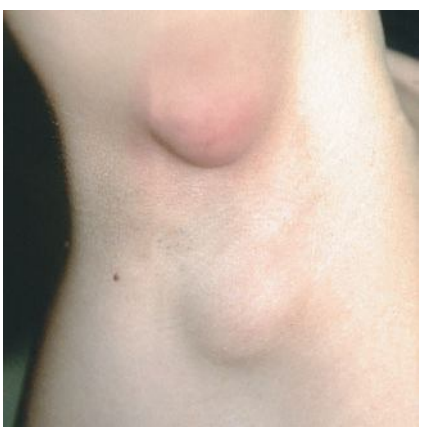
CUTANEOUS LESIONS The clinical spectrum of CSD has expanded since serologic diagnosis has become possible. Typical CSD exhibits two components, the primary inoculation papule and adenopathy proximal to the inoculation site. The papule appears at the site of inoculation within 3 to 10 days of exposure and progresses through an edematous or vesicular and crusted stage. The primary inoculation papule lasts 1 to 3 weeks. The lymphadenopathy, seen in at least 90 percent of patients with typical CSD, develops on average 2 weeks after inoculation (range, 3 to 50 days; Fig. 182-1). The inoculation papule is still present in 60 percent to 90 percent when the adenopathy develops, making it a valuable diagnostic finding.[9] The most commonly affected lymph nodes are axillary, cervical, and submandibular, with 98 percent of patients having involvement of only one anatomic region. The nodes are generally firm, tender and between 1 and 5 cm in diameter (Fig. 182-2). The lymphadenopathy usually remits spontaneously after several months, although in 20 percent of cases, the adenopathy lasts longer than 6 months. Recurrences are uncommon.

Suppuration of clinical significance occurs in less than 10 percent of cases, but when affected nodes are followed with ultrasonography, suppuration is found to be the natural course of resorption of affected nodes in nearly all cases.[9] Surgical drainage is seldom necessary.



▲ **FIGURE 182-1** Cat-scratch disease. Primary lesion adjacent to mouth with associated submandibular lymphadenopathy in a woman.

RELATED PHYSICAL FINDINGS With improved diagnosis, atypical cases of CSD have increased from fewer than 5 percent of cases to more than 30 percent of cases in some series.[10] The exact prevalence of these atypical presentations is not known, as they are often reported as single cases, and the total number of CSD cases from which they come is unknown. In one pediatric series, atypical mononucleosis with pharyngitis and bilateral cervical adenopathy and thrombocytosis was a common presentation of *B. henselae* infection.[11] Fever of unknown origin with or without endocarditis, hepatic and splenic granulomatosis, and massive lymph node enlargement resembling lymphoma are uncommon presentations.[10] Involvement of the terminal ileum may rarely mimic inflammatory bowel disease and intra-abdominal lymphadenopathy may very rarely obstruct the portal vein.[12,13] Ocular complications of *B. henselae* infection have been frequently reported and include neuroretinitis, focal retinochoroiditis, arterial and venous occlusion, iridocyclitis, and mac-



▲ **FIGURE 182-2** Bartonellosis: cat-scratch disease with axillary adenopathy. Acute, very tender, axillary lymphadenopathy in a child; cat scratches were present on the dorsum of the ipsilateral hand. (Used with permission from Howard Heller, MD.)

ular hole.[14,15] The most common neurologic complication of CSD is acute encephalopathy, presenting with seizures in 66 percent and status epilepticus in 10 percent of patients.[16–18]

In one study, up to 20 percent of immunocompetent patients with serologically confirmed CSD had PCR positivity for *B. henselae* in peripheral blood, suggesting bacteremia may be common.[19] Not surprisingly, hematogenous dissemination of *B. henselae* complicating CSD in immunocompetent persons has been reported to affect bone (osteomyelitis), liver and spleen, lungs (pneumonia, pleural effusion, pulmonary nodules), and the optic nerve.[20–22] These lesions may be markedly symptomatic, or, in one case of pulmonary involvement, completely asymptomatic.[20] *B. henselae,* not infrequently causes endocarditis in persons with known valvular heart disease, usually affecting the aortic valve, and 90 percent of patients require valvular surgery as a consequence of severe damage.[23]

Reactive conditions of the skin and joints may be seen in patients with CSD. Two percent of CSD patients develop erythema nodosum.[24] Three percent of patients with CSD suffer a rheumatoid factor–negative arthropathy of the larger joints of the extremities.[25] These patients are older than 20 years of age and two-thirds are female. Twenty percent have lesions of erythema nodosum. In 80 percent the arthropathy resolved in 6 weeks, but in 20 percent there is a more chronic course averaging 2.5 years.

Laboratory Tests

Routine laboratory findings are nonspecific and usually not helpful except to exclude other diseases. Patients with CSD may have a slightly elevated white blood cell count and elevated erythrocyte sedimentation rate during the acute phase. Blood cultures are rarely positive when using current testing techniques. PCR of affected lymph nodes may be positive in 30 percent of cases. Between 80 and 90 percent of cases of CSD have positive serology for *B. henselae* at the time of presentation, and many of the seronegative cases are positive 2 to 8 weeks later. Serologic testing has replaced the CSD skin test as the confirmatory test of choice in cases of CSD.

Histopathology

Histopathologic examination of CSD lymph node lesions is not specific. Lymph nodes undergo three stages in the formation of a granuloma: (1) enlargement with hypertrophy of the germinal centers and thickening of the cortex; (2) formation of granulomas with invasion of lymphocytes and epithelioid cells; and (3) necrosis and infiltration with neutrophils—all of which may be simultaneously present within a single lymph node. Abscess formation may occur. Organisms can be detected in lymph nodes and primary skin lesions, often in clumps or filaments, usually in or adjacent to areas of necrosis.

In primary skin lesions, microscopic examination reveals necrosis of the epidermis and upper dermis, and dermal inflammation ranging from neutrophil and macrophage infiltration to granuloma formation. Conjunctival lesions have similar histologic findings. In a few cases, conjunctival lesions produce proliferating blood vessels and a homogenous eosinophilic to basophilic granular appearance in the background—features similar to those of BA.

Differential Diagnosis (Box 182-1)

Treatment

Virtually all cases of CSD remit spontaneously without therapeutic intervention. In a retrospective study of 202 patients with CSD who were treated with antibiotics, commonly prescribed antibiotics, including macrolides, tetracycline derivatives, and cephalosporins, were ineffective.[23] However, antibiotic susceptibility studies have shown that *B. henselae* is highly sensitive to macrolides, tetracycline derivatives, and second- and third-generation cephalosporins, and is variably sensitive to quinolones. The failure of antibiotics in classic CSD in the immunocompetent host may relate to the small infectious burden and the frequent initiation of therapy once the disease is already improving spontaneously (in its lymphatic phase). In a recent prospective randomized trial, azithromycin for 5 days was demonstrated to reduce the lymph node volume during the first 30 days of observation. Half of azithromycin-treated patients reached 20 percent of baseline lymph node volume by 1 month, as opposed to 7 percent of untreated patients. However, there was no difference in any other symptoms or findings, or in the long-term outcome, and some treated patients had increases in lymph node size after treatment.[9] For complicated CSD of the eye or central nervous system, doxycycline 100 mg twice daily plus rifampin 300 mg twice daily is recommended.

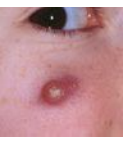
TRENCH FEVER, URBAN TRENCH FEVER, AND BACTEREMIA/ENDOCARDITIS

Epidemiology

B. quintana is the etiologic agent of trench fever, a disease that affected more than 1 million troops of the German and Allied armies during World War I.[27] In the last three decades, *B. quintana* has been identified as a cause of bacteremia and endocarditis in the United States and France (urban trench fever).[23,27] Virtually all of the patients are human immunodeficiency virus–negative, homeless, alcoholic men. Moreover, in cities where urban trench fever has been described, from 15 percent to 50 percent of the indigent alcoholic inner-city male population has serologic evidence of infection with *B. quintana*.[28]

TRENCH FEVER, URBAN TRENCH FEVER, AND BACTEREMIA/ ENDOCARDITIS AT A GLANCE

- Infection transmitted by the body louse
- Etiology: *Bartonella quintana*
- Systemic symptoms: headache, fever, and shin and back pain
- Endocarditis



Etiology and Pathogenesis

Trench fever is caused by *B. quintana*. As opposed to most other *Bartonella* species, humans are the only known reservoir for this organism. The disease is transmitted from human to human by the human body louse (*Pediculus humanus corporis*). Close body contact and unsanitary conditions are associated with outbreaks. The incubation period ranges from 5 to 20 days. The organism can be isolated from patients with the disease and can be transmitted from person to person by direct inoculation or through lice. Recovered patients may be bacteremic for weeks.[27] Bartonella are the only bacterial pathogens able to invade and live inside the human erythrocyte. This may be the reservoir of bacteria in persistently infected persons.[1]

Clinical Findings

Classic trench fever is characterized by a fever lasting approximately 1 week, followed by recurrent fevers every 4 to 8 days, most commonly every 5 days (quintana fever). Clinically, patients complain of severe headaches and neck, back, and shin pain (shin bone fever). There are no specific cutaneous manifestations. Although significant morbidity is associated with the disease, fatalities are rare.

Laboratory Tests

Treatment

For uncomplicated bacteremia, 4 weeks of doxycycline 100 mg bid plus gentamicin 3 mg/kg/day intravenously for 2 weeks is recommended.[1] For documented *Bartonella* endocarditis, doxycycline 100 mg bid for 6 weeks plus gentamicin 3 mg/kg/day for 2 weeks is recommended.[1]

BARTONELLA INFECTION IN THE IMMUNOSUPPRESSED (BACILLARY ANGIOMATOSIS; PELIOSIS OF THE LIVER AND SPLEEN)

Epidemiology

BA is most commonly seen in patients with acquired immunodeficiency syndrome (AIDS) and a CD4 count less than 50 cells/mm^3, with an incidence of 1.2 cases per 1000 at-risk patients (see Chap. 198).[30] Patients with other forms of immunosuppression, including patients with leukemia and recipients of organ transplants, have been reported.[31] Uncommonly, human immunodeficiency virus–negative and nonimmunosuppressed persons develop BA.[32] In the cases of BA in immunocompetent persons, however, although the lesions were proliferative vascular papules, they were limited in number, the affected persons had limited or no systemic involvement and a benign course. There is no predisposition in terms of race, sex, or age.

BACILLARY ANGIOMATOSIS AT A GLANCE

- Etiology: *Bartonella henselae* and *B. quintana*
- Acquired from infected cats
- Most commonly in patients with acquired immunodeficiency syndrome but also in other forms of immunosuppression
- Pyogenic granuloma–like and subcutaneous nodules
- Hyperpigmented plaques in African Americans
- May be associated with hepatic and systemic lesions
- Treatment: erythromycin or doxycycline

Etiology and Pathogenesis

Both *B. henselae* (the CSD bacillus) and *B. quintana* (the agent of trench fever) have been identified as causative agents of BA. At one end of the clinical spectrum, classic CSD is seen in young, immunocompetent hosts as a limited infection. At the other end, BA is seen in patients who are severely immunocompromised as a systemic disease. Thus, it is the immunocompetence of the host and the bacterial load that dictates the clinical manifestations of the disease. Moreover, immunocompromised patients with BA develop an angioproliferative response in response to intracellular hypoxia. The presence of intracellular bacilli induces hypoxia-inducible factor-1 that in turn induces vascular endothelial cell growth factor, leading to vascular proliferation.[29] BA caused by *B. henselae* is acquired from infected cats and is a manifestation of CSD in the immunocompromised host. Peliosis hepatitis is exclusively associated with *B. henselae* infection.[33] In contrast, patients with BA caused by *B. quintana* develop subcutaneous masses and lytic bone lesions.

Clinical Manifestations

CUTANEOUS LESIONS The incubation period for BA is unknown. In AIDS patients, the clinical constellation includes fever, cutaneous or subcutaneous vascular lesions, lymphadenopathy, and/or abdominal symptoms. The most common cutaneous morphologies of BA are (1) pyogenic granuloma–like lesions, (2) subcutaneous nodules, and (3) hyperpigmented indurated plaques. The same patient may have several morphologies. Lesions resembling pyogenic granuloma can range in size from 1 mm to many centimeters and are dusky-red in color with a collarette of scale and peripheral satellite lesions (Fig. 182-3). The lesions are firm, bleed easily, and are often tender. They occur on skin and mucosa. Subcutaneous nodules can range from distinct nodules to diffuse swell-

◀ FIGURE 182-3 Bacillary angiomatosis. Multiple, grouped, dusky-red, and violaceous papules and nodules that resemble pyogenic granulomas.

- Basal cell carcinoma
- Dermatofibroma protuberans
- Merkel cell carcinoma

ings with or without induration and are also often tender. Hyperpigmented plaques are most commonly seen in African Americans with BA and are oval in shape; they are several centimeters in diameter with indistinct borders. Large, fungating masses rarely occur. Patients with BA may have few to thousands of lesions with the number of lesions gradually increasing over time. Additional immunosuppression with chemotherapeutic agents may be followed by a shower of miliary skin lesions.

RELATED PHYSICAL FINDINGS In addition to cutaneous lesions, other organ systems may be affected. Hepatic and splenic vascular lesions can occur concomitantly with or independently of cutaneous lesions and can be a cause of significant blood loss and anemia. *Bartonella* infection, especially that caused by *B. quintana,* can affect bone and soft tissues. Lesions of the central nervous system have been reported and can result in neurologic and psychiatric disorders. Bacteremia, chronic fevers, and pulmonary and gastrointestinal lesions have also been reported. Radiologic studies usually identify areas of systemic involvement. Ocular vascular proliferative lesions can produce loss of vision.[34]

There are several reports of patients with other cutaneous diseases concomitant with BA, as well as the simultaneous existence of BA and another infection within the same lesion. Several patients have been reported with both BA and Kaposi sarcoma. Cytomegalovirus, Epstein-Barr virus, *Cryptococcus neoformans,* and *Mycobacterium avium-intracellulare* have been found within lesions of BA.

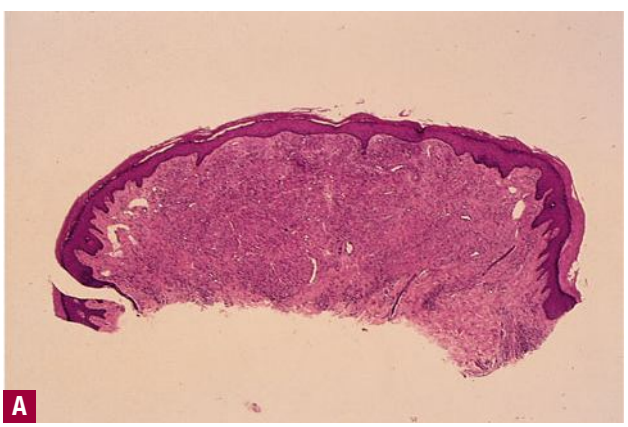
Differential Diagnosis (Box 182-2)

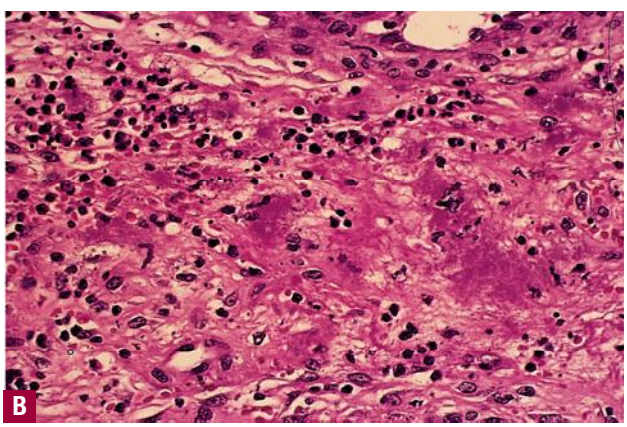
Laboratory Findings

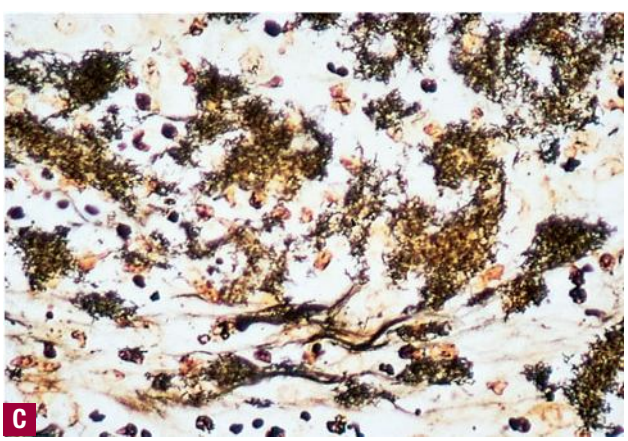
Patients with AIDS and BA are anemic and may have elevated liver function tests (characteristically, lactic acid dehydrogenase and alkaline phosphatase are more elevated than hepatocellular enzymes). Blood cultures are positive for *Bartonella* sp. in approximately one-half of BA patients. *B. henselae* and *B. quintana* can be cultured from skin lesions. The organisms grow slowly and may not be detected without prolonged culture (more than 1 month). PCR of affected tissue is virtually always positive if lesions are histologically characteristic. The vast majority of cases are diagnosed histologically, with identification of the causative bacteria by Warthin-Starry staining.

Histopathology

Lesions of BA have the general features of a lobular capillary hemangioma (pyogenic granuloma) (Fig. 182-4), but in contrast to a pyogenic granuloma, the endothelial cells are often larger and polygonal; they may have marked atypia. There is a prominent inflamma-

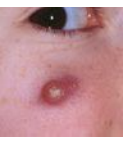






▲ **FIGURE 182-4** Histology of bacillary angiomatosis. **A.** Low-power magnification showing the architectural features of a lobular capillary hemangioma. **B.** High-power magnification showing new capillary formation and endothelial cells with cytological atypia, a prominent inflammatory infiltrate, and leukocytoclastic debris. **C.** Warthin-Starry stain showing numerous pleomorphic bacteria. (Used with permission from P. LeBoit, MD.)

tory infiltrate, with significant numbers of neutrophils as well as leukocytoclastic debris (see Fig. 182-4B). Polymorphonuclear leukocytes (PMNs) are scattered throughout the lesion, as opposed to classic pyogenic granuloma lesions in which the PMNs are at or near the surface, even if the pyogenic granuloma is eroded and impetiginized. There is usually a finely granular pink to purple material in areas of PMN infiltration adjacent to blood vessels. This represents large clumps of bacteria, best visualized with a modified Warthin-Starry stain (see Fig. 182-4C). Standard tissue Gram stain and the Warthin-Starry stain used for syphilis do not stain the organisms. If the diagnosis cannot be confirmed with special stains, electron microscopy may be used. The lack of spindle cells, atypically shaped vascular channels, and hyaline globules distinguish BA from Kaposi sarcoma. Lesions of BA in tissues other than liver show similar histologic features.



Clinical Course

In the immunocompromised host, the natural history of untreated BA is gradually progressive disease, with increasing numbers of skin lesions and involvement of many visceral organs. Untreated, severely immunocompromised patients might die of their infection.

Treatment

Erythromycin, 500 mg four times a day, or doxycycline, 100 mg twice a day for 3 months, is the treatment of choice for BA. Other antibiotics thought to be effective are minocycline, tetracycline, chloramphenicol, azithromycin, and roxithromycin. For peliosis hepatis, 4 months of treatment is recommended. Some patients require life-long suppressive therapy. Relapses have been reported, especially with shorter treatment courses.[33] A Jarisch-Herxheimer reaction not uncommonly occurs after initiation of therapy. Most patients respond rapidly to antibiotic therapy. The rapid disappearance of the vascular lesions may relate to the effects of the macrolides and tetracyclines on protein synthesis, stopping the production of vascular growth factors. If patients are not treated for a sufficient period, they are likely to relapse, despite the fact that their skin lesions vanish after a few weeks of treatment. The additional treatment is required to sterilize visceral or hematologic reservoirs of bacteria.

OROYA FEVER AND VERRUGA PERUANA

Epidemiology

Oroya fever and verruga peruana are restricted to the South American Andes, from 2°5' latitude north to 13° south of the equator, including southern Colombia, parts of Ecuador, and Peru. Most cases have been reported in regions of altitude ranging from 500 to 3200 meters above sea level. Recent epidemics have been reported in previously nonendemic areas of Peru, suggesting the endemic area is expanding to lower highland jungle areas near the Amazon basin.[35] Sea surface temperature warming is associated with higher minimum daily temperatures, and an increase in the arthropod vectors. El Niño–related climate changes resulted in up to a four-fold increase in *B. bacilliformis* infection in some geographic regions.[36] Humans are the only known reservoir for *B. bacilliformis,* and asymptomatic bacteremia occurs in 0.5 percent of persons in endemic regions. In one endemic area, the annual incidence of infection was 12.7 percent in the overall population, 38 percent in children, and 1 percent in those 60 years of age or older. Cases cluster in households.[35]

Etiology and Pathogenesis

The disease was named after Daniel Carrión, who, as a Peruvian medical student in 1885, inoculated himself with a lesion of verruga peruana and died of the acute phase of Oroya fever, showing that both diseases are caused by the same agent. The causative organism of these diseases is *B. bacilliformis*. The arthropod vector is most commonly a sandfly, particularly *Lutzomyia verrucarum*.

Clinical Manifestations

Endemic bartonellosis had been considered a biphasic disease with an acute form (acute hematic bartonellosis or Oroya fever) and a chronic form with skin lesions called *verruga peruana*. With the ability to culture the causative organism and do serologic testing, the disease spectrum has expanded. In a prospective study in an endemic area, 1 percent of patients presented with acute hematic disease, 37 percent with verruga peruana and symptoms of acute hematic disease, 32 percent with verruga peruana without systemic symptoms, and 20 percent have asymptomatic infection with seroconversion only.

OROYA AND VERRUGA PERUANA AT A GLANCE

- Etiology: *Bartonella bacilliformis*
- Arthropod vector: Sandfly—*Lutzomyia*
- Geographically restricted to South American Andes and lower highland jungles
- Biphasic disease: Acute hematic bartonellosis (Oroya fever) and verruga peruana

After an incubation period between 10 and 210 days (average, 60 days), the acute stage (acute hematic bartonellosis) develops. Patients have severe fevers, headache, abdominal pain, malaise, adenopathy, and a profound paleness. Other signs of hemolysis may also be present. Patients may develop signs of neurologic involvement, including coma. During the acute state, the patients are extremely susceptible to superinfection, either bacterial (classically *Salmonella*) or parasitic (classically *Toxoplasma*). After acute hematic bartonellosis, the patients may experience recurring episodes of fever and transitory bone, joint, and muscle pain.

Patients often present with the eruptive lesions of verruga peruana having had no preceding acute phase. Verruga peruana are highly vascular lesions, identical to BA (see Fig. 182-4). Three patterns of cutaneous lesions have been described: miliary, nodular, and mular. In the miliary form, lesions are about 3 mm in diameter (Fig. 182-5). Mular lesions are larger, fewer in number, and either sessile or pedunculated, with su-

▲ **FIGURE 182-5** Bartonellosis (verruga peruana). Multiple small papules on the extremities. The lesions may ulcerate.

perficial erosion. Nodular lesions are deep dermal or subcutaneous papules and nodules may not have overlying erythema. Mucosal lesions may occur.

Laboratory Findings

During the acute hemolytic phase, a profound anemia may be present. Red blood cell counts can fall below 106/mm^3 (two-thirds of patients have a hematocrit below 20). Oroya fever is one of the few bacterial diseases in which the agent can actually be seen on peripheral blood smears. However, only one-third of patients have positive smears.

Histopathology

Lesions of verruga peruana are histologically identical to those of BA, showing the distinct angioproliferative pattern with areas of neutrophilic collection within the stroma. The pattern of proliferation varies with the type of lesion. In miliary lesions, it is in the papillary and superficial reticular dermis, and in nodular and mular lesions, it is in the deeper dermis. Old verrugas tend to lose the inflammatory component, retaining the vascular frame. At that point, the lesion may look very similar to a pyogenic granuloma. In contrast to BA, the purple bodies of bacteria are hardly seen in verruga peruana lesions. However, the organisms can be seen in the tissue with modified silver stain techniques.

Box 182-3

Differential Diagnosis of Verruga Peruana

Most Likely
- Pyogenic granuloma
- Bacillary angiomatosis

Consider
- Cutaneous tuberculosis
- Nocardiosis

Always Rule Out
- Angiosarcoma
- Skin cancer (especially melanoma)

Differential Diagnosis (Box 182-3)

Treatment

Untreated, Oroya fever is a fatal disease in 40 percent to 90 percent of cases. Because of the frequent concomitant infection with *Salmonella,* the treatment of choice for Oroya fever is chloramphenicol (50 to 75 mg/kg/day, maximum 3 g/day) for 14 days plus a β-lactam antibiotic. Ciprofloxacin, 500 mg bid for 10 days, also appears effective. Rifampin, 10 mg/kg/day for 14 days, is the treatment of choice for verruga peruana, although the macrolides and tetracyclines are also effective. Ciprofloxacin, 500 mg bid for 7 to 10 days, is an alternative.[1] Verruga peruana may also regress spontaneously.

CHAPTER 183

Miscellaneous Bacterial Infections with Cutaneous Manifestations

Scott A. Norton

This chapter focuses on a group of unrelated bacterial diseases that are rarely encountered in a conventional urban or suburban setting but are acquired after a distinctive environmental exposure, such as saltwater immersion, animal bites, handling of an infected animal carcass, or travel to specific areas around the world. Several of these diseases present primarily as cutaneous disorders with rare systemic involvement (e.g., erysipeloid); others present primarily as systemic disorders with rare cutaneous involvement (e.g., brucellosis). Several of the pathogens can be aerosolized and disseminated for respiratory transmission, naturally or with human intervention. The ease of dissemination and the potential virulence of several organisms makes them suitable for intentional spread as biologic weapons. The intentional spread of these diseases is discussed in greater detail in Chap. 213.

In this chapter, these infections are grouped by their most common, natural means of transmission to humans: atraumatic exposure to animals, animal bites, and contact with contaminated water (Fig. 183-1).

ANTHRAX

Etiology and Epidemiology

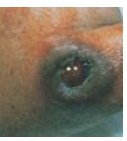
Anthrax is a zoonotic infectious disease caused by *Bacillus anthracis*, a large aerobic, spore-forming Gram-positive rod.[1] Anthrax occurs naturally in ruminant mammals, such as sheep, cattle, and goats. Human disease is seen most often in agrarian, livestock-dependent regions. Consequently, human anthrax usually follows agricultural or industrial exposure, either through direct handling of infected animals or contaminated soil or through the processing of hides, wool, hair, or meat.[2] The clinical presentation of human anthrax depends on the route of inoculation. In 95 percent of human cases, the disease is acquired through percutaneous inoculation of anthrax spores. Human anthrax can also be acquired as inhalational and gastrointestinal disease. Each form has distinctive clinical, epidemiologic, and prognostic features.[3] Anthrax has potential as a class A bioweapon (Table 183-1; see also Chap. 213).

Clinical Findings

HISTORY After an incubation period of 1 to 7 days, patients may experience low-grade fever and malaise and develop a

ANTHRAX AT A GLANCE

- A large Gram-positive rod, *Bacillus anthracis*, changes into dormant spores under environmentally harsh conditions. Spores are infectious particles that revert to active bacillary form in host tissues.
- Natural pathogen of livestock, especially sheep, goats, and cattle. Most human disease is occupationally related to exposure to live animals or animal products.
- Cutaneous anthrax is the most common form and is associated with the lowest morbidity. Inhalational and gastrointestinal anthrax are more virulent and frequently lethal.
- Cutaneous lesions arise from percutaneous spore inoculation, usually unnoticed. They present as painless edematous papules or plaques that develop jet-black central eschars.
- The organism is a Centers for Disease Control and Prevention Category A bioweapon in aerosolizable micro-powder form. There is no human-to-human transmission.



painless papule at the exposed site. As the lesion enlarges, the surrounding skin becomes increasingly edematous. Pain, if present, is usually due to edema-associated pressure or secondary infection.

CUTANEOUS LESIONS Cutaneous anthrax develops when spores enter minor breaks in the skin, especially on exposed parts of the hands, legs, and face (Fig. 183-2). In the hospitable environment of human skin, spores revert to their rod forms and produce their toxins. A dermal papule, often resembling an arthropod bite reaction, develops over several days, and then progresses through vesicular, pustular, and escharotic phases. Lesions are surrounded by varying degrees of edema. Depending on the manner of inoculation, one to several lesions may appear, and there may be regional lymphadenitis, malaise, and fever. Individual lesions may appear pustular, leading to the name "malignant pustule," but they do not suppurate. In anthrax, true pustules are rare; a primary pustular lesion is unlikely to be cutaneous anthrax.

The lesion enlarges into a glistening pseudobulla that becomes hemorrhagic with central necrosis and may be umbilicated (see Fig. 183-2). The necrotic ulcer is usually painless, which is an important feature in differentiating it from a brown recluse spider bite. There may be small satellite papules and vesicles that may extend along lymphatics in a sporotrichoid manner. An area of brawny, non-pitting edema ("malignant edema") often surrounds the main lesion. Lesional progression is due to toxins and is unaffected by antibiotic therapy. Fatigue, fever, chills, and tender regional adenopathy may cause an ulcero-glandular syndrome. The eschar dries and separates in 1 to 2 weeks.[9–13]

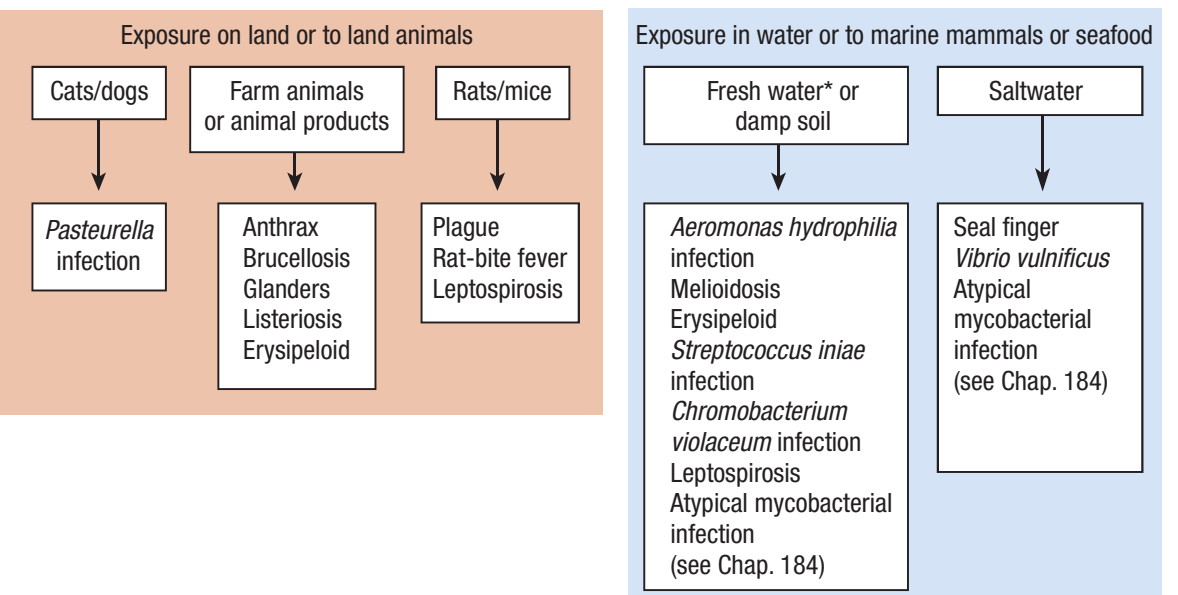
RELATED PHYSICAL FINDINGS Cutaneous anthrax may cause fever, tachycardia, and hypotension.

Histopathology

The prominent features are hemorrhagic edema, dilated lymphatics, and epidermal necrosis. Bacilli may be found in the eschar. Anthrax is toxin mediated and induces scant inflammatory infiltrate. Immunohistochemical stains are quite useful.[14]

Treatment

Naturally occurring anthrax is treated with penicillin or doxycycline. Weaponized anthrax, on the other hand, may be resistant to these antibiotics, and, therefore, a fluoroquinolone is recommended for the initial treatment of confirmed or suspected bioterrorism-associated anthrax, even in pregnant women and children. Once drug sensitivities have been established, the patient may be switched to another antibiotic as clinically indicated. Antibiotics will kill activated *B. anthracis* bacilli but will not alter tissue damage already caused by toxins.[15,16]



▲ **FIGURE 183-1** Algorithm for identifying cutaneous infections usually contracted in specific environmental settings. *Brackish water may harbor the same organisms.

TABLE 183-1
Overview of Bacterial Infections

Infection	Expected Demographic Distribution	Typical Presentation (Skin)[a]	Typical Exposure	Bioweapon Potential[b]	Treatment
Anthrax	Worldwide, especially developing agrarian areas	Painless edematous plaque with central black ulcer or eschar	Goats, sheep, cattle, or products made from them	A	PCN, doxy, ciprofloxacin
Tularemia	North America, Europe	Ulcero-glandular: painful papule that ulcerates and forms eschar	Tick bites, rabbits, rodents	A	Streptomycin, genta, TCN
Plague	Worldwide, especially United States Southwest, India	Buboes (tender regional lymphadenopathy) followed by purpura and gangrene	Flea bites, spread from infected rodents	A	Streptomycin, genta, doxy
Brucellosis	Worldwide, especially developing agrarian areas	Variable; skin manifestations present in < 5% of patients	Cattle, sheep, goats, or untreated milk	B	Doxy plus genta or rifampin
Glanders	Rare and focal in Asia, Middle East	Nodule with cellulitis that ulcerates; later, deep abscesses and sinuses	Donkeys, mules, horses	B	Sulfadiazine, genta, doxy
Pasteurella infection	Worldwide	Rapid onset of cellulitis at bite site followed by necrosis	Dog or cat bite	NR	Amoxicillin plus CA
Rat-bite fever (streptobacillary)	Worldwide, especially Asia	Morbilliform eruption with fever followed by arthritis	Rats or their excreta	NR	Amoxicillin plus CA
Seal finger	Cool coastal regions worldwide	Extremely painful nodule on finger	Seals or sea lions	NR	TCN
Listeriosis	Worldwide	In neonates, generalized petechiae, papules, and pustules	In neonates, infected mother with transfer in utero or shortly after birth	NR	Ampicillin or PCN IV
Vibrio vulnificus infection	Worldwide	Necrotizing fasciitis, hemorrhagic bullae often beginning as a wound infection	Warm saltwater or brackish water or undercooked seafood	NR	Doxy and ceftazidime IV, débridement of lesions
Aeromonas hydrophila infection	Worldwide	Cellulitis evolving to abscess formation, often beginning as a wound infection	Fresh or brackish water, contaminated fish	NR	Third-generation cephalosporins, fluoroquinolones
Melioidosis	Wet tropical areas, especially Southeast Asia and northern Australia	Indolent abscesses; suppurative parotitis (in children)	Wet soil (classically rice paddies), flooded regions	B	Ceftazidime plus TMP-SMX IV, then amoxicillin CA
Erysipeloid	Worldwide	Tender violaceous plaque on hand at site of injury	Contaminated fish, shellfish, poultry, meat, and animal products	NR	PCN, ampicillin, third-generation cephalosporin
Streptococcus iniae infection	Worldwide, especially freshwater fish farms	Rapid onset of hand cellulitis following a puncture wound	Contaminated farm-raised fish	NR	PCN, cephalosporin
Leptospirosis	Worldwide, especially the tropics	Papules, petechiae, jaundice	Contaminated freshwater, moist soil, or animal urine	NR	Doxy, PCN
Diphtheria	Worldwide where immunization is not practiced	Pustule or superinfected abrasion, evolving to an ulcer with gray membrane at base	Asymptomatic human carriers	NR	PCN IV or erythromycin plus antitoxin

A = highest (systemic disease, often fatal); B = substantial (severe systemic disease, sometimes fatal); CA = clavulanic acid; doxy = doxycycline; genta = gentamicin; NR = not rated; PCN = penicillin; TCN = tetracycline; TMP-SMX = trimethoprim-sulfamethoxazole.
[a]For many entities, multiple presentations are possible depending on the route of inoculation (percutaneous entry, oral ingestion, or inhalation). See text.
[b]If aerosolized, per criteria of the Centers for Disease Control and Prevention.

Prognosis and Clinical Course

TULAREMIA (*FRANCISELLA TULARENSIS* INFECTIONS)

Etiology and Epidemiology

Tularemia is a zoonotic infectious disease caused by *Francisella tularensis*, a pleomorphic Gram-negative coccobacillus found in many species of mammals, most important, lagomorphs (rabbits and hares) and rodents, and in their immediate environments. The bacteria are highly infectious, can be transmitted in many ways, and cause at least eight different patterns of disease.

Tularemia occurs solely in temperate and cold regions of the Northern Hemisphere. The most common form in the United States is ulcero-glandular disease in which organisms are inoculated directly into the skin by minor trauma or by bites of infected arthropods that maintain the enzootic cycle. Before 1950, most U.S. infections occurred in hunters

▲ **FIGURE 183-2** Anthrax. The classic cutaneous lesion of a primary infection in anthrax is a painless papule that evolves into a hemorrhagic bulla with surrounding brawny non-pitting edema. Note the typical localization on the hand. The name *anthrax* comes from the Greek word ανθραξ *(anthrax)*, meaning coal, which refers to the coal-black hue of the lesions of cutaneous anthrax.

who handled infected rabbits and hares. Two incidence peaks each year corresponded with summer and winter hunting seasons. Currently, 100 to 200 U.S. cases occur each year, mostly in Arkansas, Missouri, Oklahoma, and South Dakota, with transmission of the organism largely via tick bites. The most common tick vectors are *Dermacentor* sp., *Amblyomma americanum*, and, in Europe, *Ixodes* sp.[20,21]

Clinical Findings

HISTORY Duration of incubation varies with size of inoculum, ranging from 2 to 10 days. All forms of tularemia present as a sudden flu-like illness characterized by fever, headache, malaise, and myalgias.

CUTANEOUS LESIONS In ulcero-glandular tularemia, a painful red papule appears at the inoculation site (Fig. 183-3). It enlarges rapidly and evolves into a necrotic chancriform ulcer often covered by a black eschar. Regional lymph nodes are large and tender.[24] Bacteremia may cause sepsis and virulent pneumonia.

RELATED PHYSICAL FINDINGS In oculoglandular tularemia, organisms are introduced directly into the conjunctivae, for example, after handling an infected tick or rabbit. This causes purulent conjunctivitis with pain, edema, and local adenopathy. In a recent outbreak in Bulgaria, more than 90 percent of cases were oropharyngeal, reflecting transmission via contaminated well water.

TULAREMIA AT A GLANCE

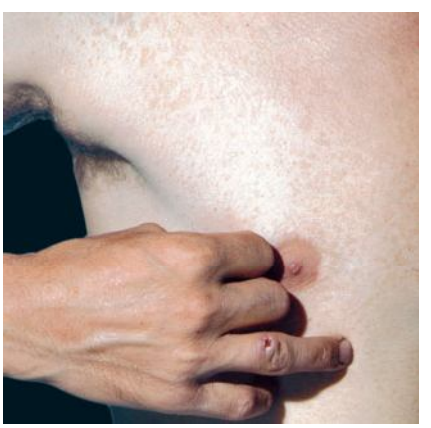
- Caused by *Francisella tularensis*, a Gram-negative coccobacillus found in rabbits, rodents, other mammals, and their immediate environments in temperate and cold regions of North America.
- Has diverse clinical presentations related to route of transmission. Ulcero-glandular disease after tick bites is most common.
- Bacteria are easily aerosolized and highly infectious in small inocula; therefore, tularemia poses risks of laboratory accidents or use as a bioweapon.

Swallowing the organism may cause ulcerative pharyngotonsillitis with cervical adenopathy or may cause "typhoidal" tularemia.[23] Pulmonary tularemia may be primary (i.e., due to inhalation of organisms) but is more often due to bacteremic spread from another focus.

Laboratory Findings

Histopathology

The pathogen survives intracellularly in phagocytes, and small granulomas develop in lymph nodes, liver, and spleen. Some lesions may caseate and progress to frank abscess formation. Hepatic granulomas may resemble tuberculosis or brucellosis.



▲ **FIGURE 183-3** Tularemia. A chancre-like ulcer with raised margins on the dorsum of the fourth digit with accompanying axillary lymphadenopathy. The rash on the chest is unrelated and is pityriasis versicolor.

Differential Diagnosis

Treatment

A presumptive diagnosis of tularemia on clinical and epidemiologic grounds is sufficient to initiate treatment while awaiting serologic confirmation (see Table 183-1). Streptomycin is effective against all forms of tularemia when started promptly. Gentamicin appears to be an acceptable alternative. Patients improve within 24 to 48 hours, but treatment should continue for at least 7 to 10 afebrile days. Tetracycline and chloramphenicol are other acceptable alternatives but should be given for longer periods to reduce the risk of relapse.

Prognosis, Clinical Course, and Complications

Prevention

PLAGUE

Etiology and Epidemiology

Plague is a severe, acute, febrile zoonosis caused by the aerobic Gram-negative bacillus *Yersinia pestis*. Plague exists in an enzootic cycle, infecting humans through contact with rodent reservoirs or flea vectors. Human plague has three clinical forms: (1) bubonic; (2) bubonic-septicemic, a more virulent form due to secondary bacteremia and sepsis; and (3) pneumonic (fulminant disease due to respiratory spread). Distal purpura and gangrene associated with septicemic plague likely gave rise to the term *black death*.

In this country, human disease is almost always transmitted by fleas. Direct handling of infected rodents, rabbits, or their carcasses can also transmit plague. Some cases are transmitted by direct contact with pet dogs or cats that became ill after contact with infected wild animals. Between 1990 and 2005, 107 plague cases, more than 80 percent bubonic, were reported in the United States, averaging 7 per year, mostly in summertime. In western states, winter cases are often linked with handling of animal carcasses while hunting. In recent years, epizootics have occurred among prairie dogs, and sporadic human cases were seen on several Indian reservations. Rarely, bactere-

PLAGUE AT A GLANCE

- Focal enzootic sites worldwide, including the southwestern United States. Human disease is caused by bites from infected fleas or direct contact with rodent reservoirs.
- The bubonic form is the most common, producing large tender lymph nodes (buboes) proximal to the site of flea bite. All forms can lead to sepsis, distal gangrene (origin of the term *black death*), and death.
- Pneumonic plague due to respiratory spread of aerosolized *Yersinia pestis* has a high mortality and is a possible weapon of bioterrorism.

mic bubonic disease may evolve into pneumonic plague and further initiate respiratory spread to others.[27,28]

The flea associated with epidemic plague in the Old World is *Xenopsylla cheopis*, but fleas in other genera (e.g., *Anomiopsyllus*, *Aetheca*, *Pulex*) are also vectors in the United States.

Because *Y. pestis* can be aerosolized, is devastatingly lethal, and can spread from person to person, it is considered a Category A biologic weapon (see Table 183-1). *Y. pestis* produces an intracellular toxin and virulence factors (see Chap. 213).

Clinical Findings

HISTORY Bubonic plague incubates for roughly 2 to 6 days, followed by the sudden onset of high fever, prostration, malaise, myalgias, backache, and tachycardia. Primary pneumonic plague has a shorter incubation time.

CUTANEOUS LESIONS In bubonic plague, the initial skin lesion is related to the flea bite and may appear as papular urticaria. However, the hallmark of bubonic plague is prominent, exquisitely tender regional lymphadenopathy with extensive subcutaneous edema.

Any form of plague can lead to overwhelming endotoxic septicemia accompanied by disseminated intravascular coagulopathy (DIC) (see Chap. 145). Subsequent purpura and gangrene are most severe on distal extremities.[29]

RELATED PHYSICAL FINDINGS Primary septicemic plague lacks buboes and presents with typical Gram-negative sepsis. Many patients also have severe abdominal pain, nausea, vomiting, and bloody diarrhea. Pneumonic plague has an abrupt onset with high fever, tachycardia, tachypnea, chest pain, and dyspnea. Within 24 hours of onset, the patient is critically ill and producing bloody sputum laden with *Y. pestis*. Meningitis may complicate all forms of plague.

Laboratory Findings

Organisms can be cultured from lymph node aspirates, cerebrospinal fluid (CSF), sputum, and, in pneumonic plague, tracheal washes. In septicemic plague, bacilli can sometimes be seen on stained buffy coat smears. Leukocytosis occurs in all forms of the disease. Renal failure and DIC may occur in severe cases. Bacteria can be cultured on standard blood agar media. Direct fluorescent antibody assays, enzyme-linked immunosorbent assay, and polymerase chain reaction testing are useful when available, but serologic tests are less reliable.[29,30] Histopathologically, acute inflammatory changes are seen in the involved nodes. Immunohistochemical stains of tissue biopsy specimens may show organisms.[31]

Differential Diagnosis

Treatment

Because the drug of choice, streptomycin, is not widely available, another aminoglycoside antibiotic, gentamicin, is the preferred treatment (although the U.S. Food and Drug Administration has not approved it for this indication) (see Table 183-1). Doxycycline and fluoroquinolones are also effective. Patients with pneumonic plague must be placed in respiratory isolation to prevent further transmission. A course of treatment, irrespective of medication, is 10 days. Ordinarily, buboes should not be drained until they are well localized and antibiotic therapy has been started.[32]

Prognosis and Clinical Course

Prevention

BRUCELLOSIS

BRUCELLOSIS AT A GLANCE

- Zoonosis transmitted by contact with infected animals or consumption of contaminated dairy products.
- May be transmitted via aerosolized bacteria, hence the concern regarding the use of *Brucella* in bioterrorism.
- Usually presents with undulant fever and can involve all organ systems, especially the joints, reproductive organs, liver, and central nervous system. Endocarditis can be fatal.
- Cutaneous lesions are seen in fewer than 5 percent of patients, usually children. Variable morphologies include vasculitis, erythema nodosum, panniculitis, abscesses, and polymorphous papules, pustules, and papulosquamous lesions. Children with acute brucellosis may have a violaceous papulonodular eruption primarily on the trunk and lower extremities.

Etiology and Epidemiology

Brucellosis is caused by any of four species of *Brucella*, which ordinarily infect livestock, especially cattle, sheep, and goats. It is transmitted to humans by contact with infected animals or animal products, ingestion of contaminated dairy products, and, rarely, by inhalation of aerosolized bacteria. Worldwide there are approximately 500,000 human cases per year. The highest incidence is in underdeveloped agrarian areas where there are poor health controls for herds and where people consume raw dairy products. These regions include East Africa, grazing areas of upland South and Central America, and the belt of nations extending from Spain and Portugal across the Mediterranean basin, through Asia from Turkey and the Middle East, and across the former Soviet republics to Mongolia. Domesticated animals are reservoirs for *Brucella*, and the four species that infect humans are *B. melitensis* ("from Malta," where the disease was first described), *B. suis*, *B. abortus*, and *B. canis*.[33–36]

In the United States, brucellosis has largely been eliminated by proper animal husbandry practices. Still, there are 100 to 200 cases annually, mostly in travelers who ate raw dairy products in endemic areas or in people who consume illegally imported unpasteurized Mexican dairy products. Those at high risk include herders, farmers, veterinarians, and abattoir workers. Hunters who handle carcasses of large game such as deer, elk, and wild pigs are also at risk.

Clinical Findings

HISTORY The incubation period varies and is usually 1 to 3 weeks, but may be 2 months or longer. The disease presents either as an acute febrile, flu-like bactere-

mic syndrome or as a chronic disease with non-specific signs and symptoms such as weakness, anorexia, headache, and low-grade fever. Relapses occur in approximately 15 percent of patients, often after an ineffective antibiotic regimen.

CUTANEOUS LESIONS Skin manifestations occur in fewer than 5 percent of patients and are more common in children than in adults. Furthermore, skin lesions, when present, vary widely, appearing as vasculitis, erythema nodosum, panniculitis, abscesses, and polymorphous papules, pustules, and papulosquamous lesions. Children with acute cutaneous brucellosis typically have a violaceous papulonodular eruption primarily on the trunk and lower extremities. Rarely, *Brucella*-related osteomyelitis or suppurative lymph nodes may create cutaneous abscesses or sinuses.[37–41]

RELATED PHYSICAL FINDINGS Brucellosis can involve every organ system, although there are no pathognomic clinical findings. Joints, reproductive organs, liver, and the central nervous system are, in order, the most frequently involved. Nearly all patients have a characteristic undulant fever (alternating pattern of several febrile days followed by several afebrile days). Arthritis can be axial (e.g., sacroiliitis) or peripheral. The disease shows a predilection for reproductive organs, which leads to miscarriages, stillbirths, mastitis, prostatitis, orchitis, and epididymitis. Spinal osteomyelitis is well described, and endocarditis can be fatal. Persistent neuro-psychiatric findings occur in 5 percent of patients.

Laboratory Findings

Histopathology

The papulonodular eruption shows focal perivascular and periadnexal lymphohistiocytic granulomatous inflammation. Macular lesions have a non-specific mild lymph perivascular infiltrate. The panniculitis usually shows septo-lobular inflammation with abundant plasma cells. Hepatic and splenic lesions contain small, noncaseating granulomas. Caseation necrosis and calcification may occur in *B. suis* infections.[34,36]

Differential Diagnosis

Treatment

Brucellosis requires prolonged multidrug therapy with antimicrobials that penetrate into cells. Standard therapy consists of doxycycline combined with either streptomycin or gentamicin. Similar results are found with a combination of doxycycline and rifampin (see Table 183-1). Treatment should last at least 6 weeks; shorter courses carry a risk for relapse.

Prognosis and Clinical Course

Prevention

GLANDERS

Etiology and Epidemiology

Glanders is a rare zoonosis caused by the Gram-negative bacillus *Burkholderia mallei* (formerly *Pseudomonas mallei*). Glanders occurs mostly in horses, mules, donkeys, and related species, and exists focally in Asia and the Middle East. The disease is usually fatal in donkeys and mules but may cause a chronic suppurative condition, called *farcy*, in horses. Human cases are usually the result of direct exposures to animal reservoirs. In endemic areas, animal handlers, veterinarians, and abattoir workers have the greatest risks of exposure.[43,44]

Clinical Findings

HISTORY Human glanders may present in several ways, depending whether the disease is transmitted via cutaneous inoculation or respiratory inhalation[45,46]: acute localized infection, chronic cutaneous infection, acute pulmonary disease, and septicemia. Most cases are acquired transcutaneously, and a local ulcer develops within 1 to 5 days. Regional lymph nodes may then enlarge, producing a ulcero-glandular syndrome.

CUTANEOUS LESIONS In acute glanders, a nodule surrounded by cellulitis appears at the site of inoculation (see Table 183-1). Local swelling and suppuration occur, the lesion ulcerates, and regional lymphadenopathy develops. The ulcer is painful and has irregular edges with a gray-yellow base. Nodules rapidly develop along lymphatics that drain the initial lesion. These become necrotic and ulcerated, forming sinuses. Widespread dissemination quickly follows, with multiple nodular necrotic abscesses in subcutaneous tissues and muscle. Lesions frequently coalesce into gangrenous areas.

During bacteremic spread, patients have fevers, rigors, and night sweats. The characteristic eruption is composed of crops of papules, bullae, and pustules. These may be generalized or localized to the face and neck, in which case involvement of the nasal mucosa, either initially or by secondary spread, is prominent. Mucopurulent, bloody nasal discharge is common. Infection may spread to the paranasal sinuses, pharynx, and lungs.

In chronic glanders, cutaneous and subcutaneous nodules appear on the extremities and occasionally on the face. The lesions ulcerate, and draining sinuses develop. Ulceration of the hard palate and perforation of the nasal septum can occur. If the organisms are inhaled, pulmonary disease may produce pneumonia, pulmonary abscesses, or pleural effusions. Septicemic glanders is usually fatal.

GLANDERS AT A GLANCE

- Rare zoonosis caused by the Gram-negative bacillus *Burkholderia mallei* (formerly *Pseudomonas mallei*), found focally in Asia and the Middle East.
- Animal glanders occurs in horses, mules, and donkeys. Humans are infected through direct occupational exposure to animal reservoirs.
- Most human cases are acquired by direct inoculation into skin or contact of open skin with an infected animal or its secretions. Inhalational transmission is rare.
- A cutaneous ulcer develops after a 1- to 5-day incubation period, followed by several presentations: ulcero-glandular syndrome, localized abscesses (acute or chronic), or bacteremic dissemination (often fatal).

Laboratory Findings

Histopathologic examination of the skin and other involved organs shows a suppurative, necrotic process containing numerous intracellular and extracellular bacteria. Chronic glanders causes granulomatous changes.

Differential Diagnosis

Treatment

The Centers for Disease Control and Prevention recommends treatment with sulfadiazine, although in vitro data indicate that *B. mallei* is susceptible to ceftazidime, gentamicin, doxycycline, imipenem, and ciprofloxacin. Patients with subcutaneous or visceral abscesses

may require treatment for up to 1 year.[45–47] Because the disease has largely disappeared, few evidence-based recommendations are available.

Prognosis, Clinical Course, and Complications

Prevention

PASTEURELLA MULTOCIDA INFECTIONS

Etiology and Epidemiology

Pasturella multocida is a small, ovoid, Gram-negative rod that can cause local skin infection with regional adenitis after a superficial animal bite, scratch, or lick,[48] or septic arthritis and osteomyelitis after a deeper animal bite. Respiratory infections unassociated with trauma occur in rare cases, and bacteremia may accompany meningitis or osteomyelitis.

P. multocida commonly colonizes the oropharynx and nasopharynx of healthy cats, dogs, rats, mice, livestock, and poultry. Nearly all patients with *P. multocida* infection have had animal exposure, most commonly a dog or cat bite. Cat teeth are often longer and sharper than those of dogs and therefore may penetrate more deeply to cause septic arthritis or osteomyelitis. Compromising conditions such as cirrhosis, malignancy, and chronic obstructive pulmonary disease co-exist in most severe cases.[49–53]

Clinical Findings

HISTORY Local pain and swelling occur within a few days of an animal bite or contact exposure. Fever is uncommon.

CUTANEOUS LESIONS Redness, swelling, ulceration, and seropurulent drainage develop at the bite site. Cellulitis may progress rapidly and extensively, producing lymphangitis. Local necrosis may follow, and necrotizing fasciitis with septic shock has been reported.[49,54]

RELATED PHYSICAL FINDINGS Regional adenopathy may be present. Deep bites may introduce organisms into a joint or beneath periosteum and cause septic arthritis or osteomyelitis.

Laboratory Findings

Mild leukocytosis is present. After several weeks, a radiograph of underlying bone may show osteomyelitis. The organism is Gram negative, and Wright-Giemsa stain reveals a bipolar appearance. Histopathologically, an acute pyogenic response is seen.[50]

PASTEURELLA MULTOCIDA INFECTIONS AT A GLANCE

- Normal flora in oropharynx of many domestic animals. Most human infections are due to dog or cat bites.
- Local pain and swelling appear rapidly, usually less than 2 days after exposure.
- Gram-negative organism; nevertheless, infection is treated with penicillin or presumptively with amoxicillin/clavulanic acid.

Differential Diagnosis

Treatment

Because most animal bite wounds show polymicrobial contamination, an amoxicillin/clavulanic acid preparation should be started after a dog or cat bite. Although *P. multocida* is a Gram-negative organism, most strains are susceptible to penicillin, which is the drug of choice if only *Pasteurella* is cultured. If one suspects that the bite reached periosteum, parenteral penicillin should be given until the local lesion is well healed. *P. multocida* is also susceptible to doxycycline, later-generation cephalosporins, and trimethoprim-sulfamethoxazole (see Table 183-1).

Prognosis and Clinical Course

Prevention

RAT-BITE FEVER

Etiology and Epidemiology

The term *rat-bite fever* applies to two clinically similar zoonoses that are both attributable to contact with rats or their excreta. The more common form is caused by *Streptobacillus moniliformis*, a pleomorphic Gram-negative rod found in the nasopharyngeal flora of most wild and laboratory rats, which are asymptomatic carriers. Carnivores that prey on wild rodents may also transmit infection. Infections with *S. moniliformis* arise in two ways: direct contact with infected animals, usually through a bite, or ingestion of food or drink contaminated by rat urine, feces, or other secretions.[56] In both forms, patients have an acute flu-like infection characterized by a clinical triad of fever, polyarthralgias or arthritis, and rash. In 1926, an outbreak in Haverhill, Massachusetts, caused by consumption of milk tainted by rat excreta led to the designation *Haverhill fever* or *erythema arthriticum epidemicum*.

The other pathogen implicated in rat-bite fever is *Spirillum minus*, a Gram-negative spirochete. Spirillary rat-bite fever differs in its geographic distribution, incubation period, and milder arthritis. It occurs almost exclusively in East Asia. Its Japanese name is *sodoku*.[57]

RAT-BITE FEVER AT A GLANCE

- Rat-bite fever refers to two clinically similar zoonoses caused by *Streptobacillus moniliformis* and *Spirillum minus*.
- Infection is usually acquired through rat bite or ingestion of rat-contaminated food or drink.
- The disease is characterized by the classic triad of fever, polyarthralgias, and rash.

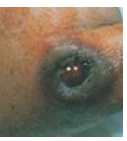
Clinical Findings

HISTORY Streptobacillary disease has an asymptomatic incubation period of 1 to 7 days, and, in rare cases, as long as 3 weeks. Often, the rat bite has healed by the time a flu-like illness begins with fever, chills, headache, stiff neck, and myalgias. A rash begins to appear several days later. Spirillary rat-bite fever has an incubation period of longer than 14 days.

CUTANEOUS LESIONS Approximately 75 percent of patients with streptobacillary fever develop a morbilliform eruption, usually 2 to 3 days after the fever. Individual lesions can be macular, morbilliform, or petechial. Lesions are most prominent on the palms, soles, and around joints but may become generalized, resembling measles.[58–60] Notably, when the rash appears, the rat bite has usually healed and only rarely shows evidence of infection, inflammation, or regional adenopathy. A week or so after resolution of the disease, the palms and soles have a characteristic desquamation

that may resemble Kawasaki disease. In contrast, the bite producing spirillary fever is usually tender, red, indurated, or ulcerated when the rash appears.[61] Cutaneous lesions are larger and are prominent on the abdomen, thus resembling the rose spots of typhoid.

RELATED PHYSICAL FINDINGS Within a week of the febrile symptoms, arthritis usually develops, predominantly involving large joints. The arthritis may be an asymmetric polyarthritis resembling rheumatoid arthritis but is rarely suppurative. Regional lymphadenopathy may be present.



Laboratory Findings

Differential Diagnosis

Treatment

The treatment of choice for someone who becomes ill after a rat bite is amoxicillin/clavulanic acid. In patients allergic to penicillins, doxycycline is acceptable. Once *S. moniliformis* is identified, penicillin is the drug of choice. In general, rat bites should be cleansed promptly and thoroughly. Tetanus immunization status should be checked. Although there are no established guidelines, one might consider a prompt prophylactic course of penicillin or doxycycline after any rat bite.[56]

Prognosis, Clinical Course, and Complications

Prevention

SEAL FINGER

Etiology and Epidemiology

Seal finger is an occupational zoonosis that occurs only after direct contact with seals, sea lions, and similar marine mammals (order Pinnipedia), transmitted via bites or through open skin after handling seals or their carcasses. Seal finger is characterized by intensely painful red nodules, usually on the distal phalanx. Untreated, it can evolve into tenosynovitis, osteitis, and joint destruction.[62,63] Although this has not been fully confirmed, seal finger appears to be caused by a group of *Mycoplasma* that is part of the normal oropharyngeal flora of pinnipeds.[64]

SEAL FINGER AT A GLANCE

- Occupational zoonosis after contact with seals or sea lions. Occurs worldwide in marine environments.
- Usually presents as an exquisitely painful nodule on the distal phalanx of the finger that may progress to tenosynovitis or joint destruction.
- The pathogen is likely to be a marine *Mycoplasma* found in the seal's normal oropharyngeal flora. The infection responds quickly to tetracyclines.

Clinical Findings

People at risk include hunters, zookeepers, and marine biologists. Seal finger is common in coldwater coastal areas around Scandinavia, Greenland, Newfoundland, and similar environments in the Southern Hemisphere. Most cases occur during the spring sealing season. Incubation is usually approximately 4 days, rarely as long as 2 weeks. A furuncle-like lesion appears at the inoculation site, followed by severe pain, marked swelling, and stiffness.[65–67]

Differential Diagnosis

Treatment

Seal finger does not respond to the β-lactam antibiotics frequently prescribed presumptively for cellulitis caused by *Staphylococcus*, *Streptococcus*, or *Erysipelothrix*. The lack of response to β-lactams further suggests seal finger. Tetracyclines are the treatment of choice and must be continued for 4 to 6 weeks (see Table 183-1). Older accounts describe occasional sealers who amputated their own fingers to rid themselves of the excruciatingly painful digit.[62]

LISTERIOSIS (*LISTERIA MONOCYTOGENES* INFECTIONS)

Etiology and Epidemiology

Listeria monocytogenes is an anaerobic Gram-positive bacillus found widely in soil, water, vegetation, and the gut flora of humans and other animals. Exposure to this organism occurs through fecal-oral contamination, but the disease has an opportunistic nature, appearing in very young, very old, pregnant, or immunocompromised individuals. *L. monocytogenes* is found in the feces of many domestic and wild animals and birds, and is therefore widespread in the environment. Typically, livestock become infected by eating manure-contaminated silage; this can cause abortions, septicemia, and a peculiar form of encephalitis called *circling disease*.[68]

Human listeriosis is uncommon but occurs in three typical settings: sporadic disease in pregnant women and neonates; sporadic disease in acquired immunodeficiency syndrome patients; and food-borne outbreaks. Humans usually become infected by eating contaminated, unpasteurized, or improperly pasteurized dairy products. In adults, the disease can present as septicemia, meningitis, vaginal infection, pneumonitis, or oculoglandular syndrome and can cause miscarriages and stillbirths.[45] Infantile listeriosis presents acutely with septicemia, meningitis and meningoencephalitis, and septic granulomatosis.

The highest incidence of human listeriosis is seen among infants in the perinatal period, which suggests that the transmission occurs in utero or at birth. One-fourth of adult cases occur in pregnant women. Many other adult cases occur in patients with altered cellular immunity, such as those with Hodgkin disease, leukemia, or acquired immunodeficiency syndrome or those who have undergone organ transplantation. Hepatic disorders such as cirrhosis and iron overload also predispose to infection.

LISTERIOSIS AT A GLANCE

- Caused by anaerobic Gram-positive bacillus transmitted in fecal-oral manner through consumption of contaminated dairy products.
- Human listeriosis is most common in pregnant women, neonates, and patients with acquired immunodeficiency syndrome, and in food-borne outbreaks. May cause miscarriages, stillbirths, and virulent neonatal infections.
- Generalized petechiae, papules, or pustules may be seen in neonatal listeriosis, especially in meconium-stained newborns.

Clinical Findings

HISTORY Early-onset neonatal listeriosis develops in infants infected in utero by

untreated bacteremic mothers shortly before labor begins. Findings are evident at birth or become apparent within the first few days. These neonates are acutely ill and have generalized pustular, papular, or petechial skin lesions. Late-onset neonatal listeriosis occurs several weeks after a healthy birth, is presumably acquired postpartum, and usually presents as meningitis.[70,71]

Listeriosis from food-borne organisms usually causes outbreaks of acute gastroenteritis in families or communities. Patients have fever, vomiting, and non-bloody diarrhea, but this form lacks skin lesions.

CUTANEOUS LESIONS In septic infants, cutaneous lesions appear as generalized petechiae, papules, or pustules. Veterinarians or farmers who handle infected bovine fetuses may develop an acute febrile illness with headache, malaise, and regional adenopathy. Tender red papules develop on exposed surfaces and may evolve into pustules over 2 to 3 days. These contain the characteristic Gram-positive rods.

RELATED PHYSICAL FINDINGS

Laboratory Findings

L. monocytogenes is a small pleomorphic bacillus that often appears coccoid in infected tissues and body fluids. Pustules, meconium, CSF, or blood cultures reveal the characteristic Gram-positive rods. The organism is β-hemolytic when cultured on sheep blood agar and exhibits a characteristic tumbling motility when grown in broth. In adults with meningitis, the CSF contains neutrophils, but about one-third of meningitic infants have a mononuclear response.

Histopathology

Differential Diagnosis

Treatment

Neonates with listeriosis should be treated with intravenous ampicillin (or penicillin) (see Table 183-1).

Prognosis, Clinical Course, and Complications

Prevention

VIBRIO VULNIFICUS INFECTIONS AT A GLANCE

- Non-cholera *Vibrio* organisms are found in warm saltwater worldwide. Exposures occur via percutaneous injury, often minor (e.g., while ocean fishing) or via ingestion of filter-feeding shellfish, which concentrate organisms.
- Severe illness presents with necrotizing fasciitis, hemorrhagic bullae, and hypotensive shock. Cirrhosis and other liver diseases predispose to a virulent, often fatal, course.

VIBRIO VULNIFICUS INFECTIONS

Etiology and Epidemiology

Vibrio are facultatively anaerobic, pleomorphic, Gram-negative rods found in marine waters, estuaries, brackish lakes, and their sediments wherever the water temperature is above 20°C (68°F). The most well-known vibriosis is cholera, caused by antigenic strains of *V. cholerae*. Although cholera organisms do not infect the skin, many other *Vibrio* do. The most important of these, *V. vulnificus*, can cause fulminant cellulitis, myositis, necrotizing fasciitis, and death.[72]

People become infected with *V. vulnificus* through oral or percutaneous exposure. After eating contaminated raw or undercooked seafood, people who have chronic liver disease or diabetes mellitus, or who are otherwise immunocompromised, are at risk for primary septicemia. Percutaneous infections are acquired by handling raw seafood, by entering saltwater with an open wound, or by experiencing skin trauma while in or around saltwater. Immunocompromised individuals are again at increased risk for secondary septicemia.[73,74]

V. vulnificus lives in warm seawater, where it colonizes the skin of fish and is concentrated in filter-feeding shellfish, such as oysters. Infections are particularly common along the Gulf of Mexico and, because of global warming, are now found in increasingly higher latitudes, such as on the Baltic Sea.[75–77]

Clinical Findings

HISTORY There is nearly always a history of contact with saltwater, injury while ocean fishing, or consumption or handling of shellfish. After oral exposure, primary septicemia often begins with watery diarrhea, fever, chills, nausea, vomiting, and abdominal pain. People with wound infections usually recall an open skin lesion present before the saltwater exposure or a percutaneous injury during the exposure. *Vibrio* cellulitis is painful and has a rapid onset within 12 to 24 hours of exposure. Secondary bacteremia with sepsis may occur several days later.[79]

CUTANEOUS LESIONS Infected wounds may present as pustules, lymphangitis, or cellulitis. These infections may be mild or may develop into rapidly progressive, painful cellulitis with extensive skin necrosis, myositis, and necrotizing fasciitis (Fig. 183-4). Secondary bacteremia may cause metastatic cutaneous lesions.[73,80] In septic patients, large hemorrhagic bullae commonly arise on the extremities or trunk and usually progress to necrotic ulcers and

▲ **FIGURE 183-4** *Vibrio vulnificus* cellulitis with hemorrhagic plaque and bullae on the legs of an older diabetic patient with cirrhosis.

necrotizing fasciitis (see Table 183-1; see also Chap. 179).

RELATED PHYSICAL FINDINGS *V. vulnificus* septicemia causes high fever, tachycardia, and hypotension. One-third of patients develop Gram-negative septic shock.

Laboratory Findings

Differential Diagnosis

Treatment

Primary or secondary septicemia due to *V. vulnificus* (or other *Vibrio* sp.) requires prompt management of hypotensive shock, parenteral administration of antibiotics, and vigorous débridement of necrotic lesions. Amputation of the affected limb may be necessary. The antibiotics of choice are a combination of doxycycline and ceftazidime (see Table 183-1). Alternatives to doxycycline include chloramphenicol, ciprofloxacin, and minocycline. Alternatives to ceftazidime include cefotaxime. Application of compresses with modified Dakin's solution (0.025 percent sodium hypochlorite) may help arrest the progression of the cutaneous lesions.[81]

Prognosis, Clinical Course, and Complications

Prevention

OTHER CUTANEOUS *VIBRIO* INFECTIONS

AEROMONAS HYDROPHILA INFECTIONS

Etiology and Epidemiology

Aeromonas hydrophila is a facultatively anaerobic, Gram-negative bacillus that causes opportunistic human infections. Except for the freshwater habitat of *Aeromonas*, its taxonomic, ecologic, and epidemiologic profiles resemble those of *Vibrio* sp. Aeromonads are found in fresh and brackish water worldwide and are natural pathogens of many aquatic animals, including fish, amphibians, and reptiles. Human *Aeromonas* infections are usually associated with exposure to contaminated fresh or brackish water. The organism is typically linked with gastroenteritis,[82] but in an increasing number of cases, it has been implicated in skin, soft-tissue, and muscle infections, as well as in septicemic disease. An increasing number of soft-tissue infections are associated with the medical use of leeches.[83,84]

AEROMONAS HYDROPHILA INFECTIONS AT A GLANCE

- Caused by a facultatively anaerobic Gram-negative bacillus found in fresh and brackish water worldwide.
- Usually presents as cellulitis after exposure to fresh or brackish water but may cause necrotizing fasciitis or myonecrosis.
- Sepsis risk in cirrhotic and immunocompromised patients.

Clinical Findings

HISTORY The key historical feature is the contact of open skin with fresh or brackish water. In healthy individuals, *Aeromonas* infections may remain localized, but compromised hosts are at risk for severe soft-tissue and septicemic disease.[54,85]

CUTANEOUS LESIONS The most common presentation is cellulitis associated with a laceration, often followed by abscess formation or spread to deeper subcutaneous tissues. Myonecrosis or necrotizing fasciitis may mimic clostridial gas gangrene in its rapid onset (1 to 2 days after exposure) and swift progression with severe pain, marked swelling, serosanguineous bullae, crepitation, and systemic toxicity. The exudate often has a foul or fishy odor. Occasionally, bacteremia produces ecthyma gangrenosum–like lesions.[54,87,88]

RELATED PHYSICAL FINDINGS

Laboratory Findings

Gram-stained aspirates from abscesses or bullae may contain Gram-negative bacilli. Wound cultures yield multiple microbes in more than 50 percent of cases, and specimens should be plated on both sheep blood agar and MacConkey's agar. Blood cultures are rarely positive for the organism. A radiograph may detect gas in deeper soft tissues.

Differential Diagnosis

Prognosis and Clinical Course

Treatment

Prompt surgical exploration and débridement are essential, guided radiographically, if possible. *A. hydrophila* produces β-lactamase and is resistant to first-generation penicillins and cephalosporins. Most isolates are susceptible to third-generation cephalosporins, fluoroquinolones, and aminoglycosides (but not streptomycin). Consideration must be given to the polymicrobial nature of these infections, so results of Gram staining and culture should guide antimicrobial selection. Two other less pathogenic species of *Aeromonas*, *A. caviae* and *A. sobria*, have similar antibiotic sensitivity profiles.[54,87]

Prevention

MELIOIDOSIS

Etiology and Epidemiology

Melioidosis is caused by *B. pseudomallei* (formerly *P. pseudomallei*), a motile, pleomorphic, Gram-negative aerobic bacillus. The organism is a natural saprophyte found in freshwater and damp soil in the humid tropics. Melioidosis infects humans, a variety of birds, and domestic and wild mammals in endemic areas, but animals are not regarded as reservoirs for human infection. Although sporadic cases occur pantropically, melioidosis has its greatest incidence in Southeast Asia, especially Singapore and northeastern Thailand, and in coastal areas of Australia's Northern Territory. Apart from rare laboratory-acquired infections, cases of melioidosis in the United States and Europe have occurred only in people previously exposed in endemic areas.[89–91]

Most cases of melioidosis are transmitted by exposure of open skin to contaminated soil or water. The frequency of pulmonary disease suggests that melioidosis may also be acquired by inhalation of contaminated droplets, soil, or dust.[92,93]

During the Vietnam War, extensive immersion in rice paddies and similar conditions led to cases of melioidosis among American servicemen. Several cases were Vietnam veterans whose disease appeared decades later, and the only plausible exposure was to rice paddies long before.[101]

MELIOIDOSIS AT A GLANCE

- Caused by *Burkholderia pseudomallei* (formerly *Pseudomonas pseudomallei*), a Gram-negative aerobic bacillus that lives as a saprophyte in freshwater and damp soil.
- Occurs in humans and animals, primarily in wet tropical areas such as Southeast Asia and coastal northern Australia. People who develop melioidosis elsewhere usually had prior exposure in endemic areas.
- Rice farmers, particularly if compromised by diabetes mellitus or chronic renal disease, are most susceptible.
- The disease is acquired after exposure to contaminated soil or water, either directly via the skin or through inhalation of particulate soil or dust.
- Clinical presentation ranges from focal indolent cutaneous and subcutaneous abscesses to fulminant pneumonia with septicemia.
- On the Centers for Disease Control and Prevention's Category B list of possible bioweapon agents.

Direct human-to-human transmission is rare. *B. pseudomallei* is infectious when aerosolized and is regarded as a Category B bioweapon for its potential use on livestock or humans. If an individual without characteristic travel or exposure history develops melioidosis, or if there is a cluster of cases, deliberate exposure may have occurred.[102]

Clinical Findings

HISTORY Melioidosis has two principal clinical presentations: (1) acute melioidosis with suppurative skin lesions, pneumonia, or septicemia; and (2) chronic melioidosis, the more common form of the disease, with involvement of the lungs, skin (subcutaneous abscesses and draining sinuses), bones, joints, liver, and spleen. Approximately 50 percent of cases involve the lungs, caused either by inhalation of pathogens or by bacteremia from a cutaneous exposure, although most patients have no obvious breaks in the skin. Human immunodeficiency virus infection does not appear to increase either the risk of acquiring the disease or its severity.[89,103]

The incubation period can be as brief as 2 to 3 days. Acute pneumonic melioidosis usually starts abruptly with fever, chills, cough, dyspnea, and chest pain. Acute septicemic melioidosis may also arise from a cutaneous focus. In one-half the patients, no source for the bacteremia can be identified, but many individuals have minor abrasions on their feet.[90]

CUTANEOUS LESIONS Cutaneous manifestations are non-specific. Acute septicemia may follow minor cutaneous disease. Disseminated disease can produce multiple superficial pustules or, more rarely, ecthyma gangrenosum or necrotizing fasciitis. In chronic melioidosis, draining sinuses and subcutaneous abscesses, particularly of the scalp, are common. In children, a common presentation is acute suppurative parotitis, usually unilateral, associated with parotid pain and fever.[89–91,104–107]

RELATED PHYSICAL FINDINGS

Laboratory Findings

Differential Diagnosis

Treatment

Antibiotic susceptibility must be determined for each isolate. The combination of ceftazidime plus trimethoprim-sulfamethoxazole is the initial therapy of choice. After a 10- to 14-day course of intravenous antibiotics, oral antibiotics, usually amoxicillin/clavulanic acid, should be continued for 2 to 6 months (or longer in the case of osteomyelitis or multiple suppurative foci) to reduce the risk of relapse.[91,110] Abscesses should be drained surgically, but only after the patient is taking appropriate antibiotics to help prevent bacteremia.

Prognosis, Clinical Course, and Complications

Prevention

ERYSIPELOID

Etiology and Epidemiology

Erysipeloid, an acute infection of traumatized skin caused by *E. rhusiopathiae* (formerly *E. insidiosa*), occurs most frequently in fishermen, butchers, kitchen workers, and others who handle raw fish, poultry (especially turkey), and meat products.[13] The disease occurs primarily during the summer months.

ERYSIPELOID AT A GLANCE

- An occupational zoonosis caused by *Erysipelothrix rhusiopathiae* and associated with percutaneous trauma while handling raw fish or poultry.
- Classic dermatologic presentation is localized non-suppurative purple-red plaques on the dorsal hands. Rare chronic and bacteremic forms exist.

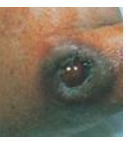
E. rhusiopathiae is a thin, Gram-positive, microaerophilic, nonmotile bacillus that is hardy enough to survive putrefaction of tissue and exposure to saltwater or freshwater. The organism is found in rats, birds, the slime on saltwater fish, and crabs and other shellfish, and is associated with poultry, meats, hides, and bones.

Clinical Findings

HISTORY The patient is usually employed in the fishing or animal product industry. After inoculation, there is an incubation period of 2 to 7 days. Initially, burning pain occurs at the injured site, then a violaceous dermal plaque develops. Lymphangitis and regional adenopathy occasionally occur, as well as low-grade fever and malaise. Bacteremia and endocarditis are rare but serious sequelae. Untreated, erysipeloid usually heals on its own within 3 weeks.

CUTANEOUS LESIONS The distinctive erysipeloid lesion is usually on a finger or the back of the hand; is violaceous, warm, and tender; and has well-defined, raised margins with an angular or polygonal border (Fig. 183-5). It often involves the web spaces but spares the terminal phalanges and does not progress beyond the wrist. The borders usually expand, whereas the central region clears without desquamation or ulceration. Rarely, multiple lesions distant from the original site of injury arise, presumably through bacteremic spread. Post-inflammatory hyperpigmentation may persist after the lesion resolves.

RELATED PHYSICAL FINDINGS Arthritis may be associated with the local lesion, and,



▲ **FIGURE 183-5** Erysipeloid. Characteristically, the violaceous, sharply marginated lesion is composed of macules and plaques and is located on the hand.

in rare cases, distant joints are involved. Sepsis produces typical peripheral stigmata, including signs of endocarditis.[112]

Laboratory Findings

Histopathology

Differential Diagnosis

Treatment

The treatment of choice for erysipeloid is high-dose penicillin or ampicillin for 7 to 10 days. Patients who cannot take penicillins may be treated with a third-generation cephalosporin, imipenem, or ciprofloxacin (see Table 183-1). This recommendation is based primarily on in vitro studies, not clinical experience. If arthritis, septicemia, or endocarditis is present, the penicillin dosage should be increased and the drug should be administered intravenously for several weeks.[112]

Prognosis, Clinical Course, and Complications

Prevention

STREPTOCOCCUS INIAE INFECTIONS

Etiology and Epidemiology

S. iniae is a recently recognized Gram-positive coccus that colonizes the skin of freshwater fish, particularly those raised in intense aquaculture.

STREPTOCOCCUS INIAE INFECTIONS AT A GLANCE

- Caused by a recently recognized streptococcal species that colonizes or infects freshwater fish, such as tilapia, grown in intense aquaculture.
- Most human clinical cases present as cellulitis of the hand after an accidental puncture wound during preparation of live fish for cooking.
- Bacteremia commonly occurs.

In humans, *S. iniae* infection usually causes hand cellulitis after the handling of live freshwater fish, particularly farm-raised tilapia (*Tilapia* sp. and *Oreochromis* sp.). Most cases have been reported in cities in China and in Asian communities in North America, particularly Toronto, where the practice of buying live fish for home preparation, rather than buying fresh fish that have already been killed and cleaned, is common.[117]

Clinical Findings

HISTORY AND CUTANEOUS LESIONS The key element in the history is the rapid onset of hand cellulitis within 1 to 3 days after the handling of live farm-raised fish. Lymphangitis and fever are early features, but neither skin necrosis nor bullae occur.[118]

RELATED PHYSICAL FINDINGS Bacteremia frequent complicates *S. iniae* cellulitis and may lead to septic arthritis, meningitis, osteomyelitis, and endocarditis.[118]

Laboratory Findings

Differential Diagnosis

Prognosis and Treatment

The infection will respond within 2 to 4 days to penicillin, the treatment of choice. The pathogen is also susceptible to cephalosporins, macrolides, quinolones, and vancomycin but is resistant to tetracyclines. Treatment should be maintained for 10 days or longer if there are extra-cutaneous complications.[118]

Prevention

CHROMOBACTERIUM VIOLACEUM INFECTIONS

Chromobacterium violaceum is a facultatively anaerobic, Gram-negative, motile, flagellated bacillus found as a saprophyte in tropical and sub-tropical freshwater and soil. It is rarely pathogenic except to people with disorders of neutrophil function, especially inherited chronic granulomatous disease. Infection occurs after open skin is exposed to a contaminated source, such as stagnant or muddy water. Nearly all U.S. cases have occurred in southeastern states during the summer months. After exposure, cellulitis and fevers soon develop. Pustules and nodules may appear, followed by regional adenopathy. The organisms may disseminate hematogenously, causing ecthyma gangrenosum, visceral abscesses, abdominal pain, septic shock, and death.

LEPTOSPIROSIS

Etiology and Epidemiology

Leptospirosis is a waterborne zoonosis caused by *Leptospira interrogans*. The disease is found worldwide, except in the polar regions, wherever animal urine can contaminate bodies of freshwater. Rodents are the most important reservoirs, although over 160 species of mammals are known to harbor *Leptospira*, including wild, farm, pet, and laboratory animals. Infected humans can also serve as transient reservoirs, particularly in urban slums in the wet tropics. Reservoir animals excrete leptospires in their urine, which contaminate the environment. Humans generally acquire the disease through broken skin after direct contact with an infected animal or exposure to contaminated water or soil. People are infected less commonly through mucous membranes, ingestion of contaminated water, or inhalation of fomites.[123–128]

Clinical Findings

HISTORY Patients usually have had recent occupational or recreational contact with contaminated water or mud. Most human infections are asymptomatic, self-limited, and detectable only on serologic surveys. Ill patients have one of two clinical forms of the disease: a mild anicteric form that resolves without complications, or a severe, icteric form (Weil disease).

After several relatively asymptomatic days, the second phase of illness begins

LEPTOSPIROSIS AT A GLANCE

- Waterborne zoonosis with worldwide distribution caused by serovars of *Leptospira interrogans*, which are excreted in urine of reservoir animals, especially rodents. Outbreaks during rainy seasons or after flooding in areas with poor sanitation.
- Most human cases are mild or sub-clinical. In severe cases there may be fever, hepatic and renal failure, jaundice, hemorrhage, and death.
- Cutaneous findings include jaundice, conjunctival suffusion, petechiae, and non-specific papules.

with low-grade fever. In severe cases rash, meningitis, uveitis, and hepatic and renal failure may develop.

CUTANEOUS LESIONS In the first week of illness, the conjunctivae become suffused (red but not exudative). Skin lesions occur in fewer than 50 percent of cases. These consist of non-specific macules, papules, urticaria, and petechiae, mostly on the trunk. Desquamation and infarcts have been observed on the hands or feet of some infected children. Weil disease has prominent hepatic (jaundice) and renal (hematuria, azotemia) components. Hemorrhages occur in a variety of organs, including the skin, and petechiae are common on the palate. A variant called *pretibial fever* or *Fort Bragg fever*, caused by *L. interrogans* serovariant *autumnalis*, has a distinctive rash that appears on the fourth or fifth day of illness, consisting of slightly raised, 1- to 5-cm, tender, erythematous papules on the shins. The rash subsides within 4 to 7 days.[128]

RELATED PHYSICAL FINDINGS

Laboratory Findings

Differential Diagnosis

Treatment

Public health authorities in endemic areas recommend starting antibiotic therapy early, perhaps presumptively, to reduce the risk of severe disease while laboratory confirmation is awaited. Doxycycline is effective and can be taken prophylactically for short-term exposure in a hyperendemic area. Penicillin has also been recommended, although controlled studies are lacking, and it may precipitate a Jarisch-Herxheimer reaction (see Table 183-1).

Prognosis, Clinical Course, and Complications

Prevention

DIPHTHERIA

Etiology and Epidemiology

Diphtheria is an acute febrile illness caused by *Corynebacterium diphtheriae* that in 90 percent of cases affects the pharynx and mucous membranes of the upper respiratory tract. The clinical manifestations of diphtheria are caused by (1) acute membranous obstruction of the airway, and (2) the tardive effects of a potent exotoxin on the myocardium and on cranial and peripheral nerves. The classic oropharyngeal lesion is a gray, leathery membrane along the tonsils and soft palate. Cutaneous diphtheria, which is far less common, can present either as a primary skin lesion or as a secondary infection of an existing break in the skin. Cutaneous diphtheria occurs most commonly in people living in or returning from tropical areas.[131]

Although diphtheroids are widespread in nature, humans are the only natural host for *C. diphtheriae*, which colonizes the pharynx of asymptomatic individuals. Disease occurs when a nonimmune person, usually someone very young or very old, is infected by a toxigenic strain of *C. diphtheriae*. Epidemics occur when such strains become widespread among nonimmune individuals. Diphtheria has been largely controlled in Western nations by routine childhood immunization, which is directed against diphtheria's exotoxin, not against the bacteria itself.

Clinical Findings

HISTORY Classic diphtheria presents with pharyngitis and low-grade fever 2 to 5 days after exposure to a carrier or, much more rarely, to fomites. A thick or leathery grayish white membrane adheres to pharyngeal walls and tonsillar pillars, and usually spreads asymmetrically onto the soft palate and uvula. As the disease progresses, the patient's neck becomes painful and swollen. There is often a unilateral bloody nasal discharge. Patients appear to have a toxic process, and ensuing tracheal

DIPHTHERIA AT A GLANCE

- Classic diphtheria produces adherent gray membranous pharyngeal lesions, which may cause lethal airway obstruction. Exotoxin may cause latent peripheral neuritis or lethal cardiomyopathy.
- Cutaneous diphtheria usually affects the legs and begins as tender pustules that break down to punched-out ulcers covered by gray membranes. It is primarily found in the tropics or in travelers returning from these areas.
- Diphtheria can be prevented with toxoid immunization. It is treatable with antibiotics and antitoxin.

edema may obstruct the airway, causing lethal suffocation.

Cutaneous diphtheria typically affects the lower extremity, involves one or more sites, and may occur with or without concomitant pharyngeal disease. In roughly one-third of patients with cutaneous diphtheria, the same strain of *C. diphtheriae* can be recovered from the respiratory tract, which suggests inadvertent autoinoculation as the cause of the skin lesions.

CUTANEOUS LESIONS There are two types of skin involvement. The first is primary cutaneous diphtheria, which starts acutely as a tender pustule and then breaks down to form an enlarging oval punched-out ulcer with a gray membrane at the base (see Table 183-1). Later, the membrane becomes dark brown, and the ulcer's border acquires edematous, rolled, bluish margins.[131,133,134]

Wound diphtheria is a secondary infection by *C. diphtheriae* of an existing break in the skin. This type accounts for almost all cases of cutaneous diphtheria reported in the United States. Pre-existing skin lesions affected include those caused by abrasions, chronic dermatoses (e.g., eczema or scabies), and common pyodermas already infected with *Staphylococcus* or *Streptococcus*. A painful ulcer is partly covered by a brownish gray membrane, drains pus, and is surrounded edema and erythema. In the outbreak in Seattle among indigent alcoholics, co-infection with *S. pyogenes* occurred in 73 percent of diphtheritic skin lesions.[132] *C. diphtheriae* has been recovered from lesions resembling impetigo, ecthyma, and infected insect bites. Whether these are truly infected or merely colonized is not clear.

Mucosa of the nose, conjunctivae, or vagina can exhibit membranous diphtheria, although these cases are quite rare.

RELATED PHYSICAL FINDINGS

Laboratory Findings

C. diphtheriae can be isolated from either the skin ulcer or pharyngeal membrane. It is a Gram-positive, club-shaped rod that exhibits metachromatic bipolar granules on staining with methylene blue. The organism grows well on standard culture media, but other bacteria may obscure it. Therefore, selective media such as Löffler or tellurite agar should be used. The histopathologic features of cutaneous diphtheria are non-diagnostic, and the membrane is composed of coagulation necrosis and inflammatory cells. Not all strains of *C. diphtheriae* produce diphtheria toxin, so it is recommended that the pathogen be sent to a reference laboratory to determine the toxigenicity of the particular strain.

Differential Diagnosis

Treatment

Pharyngotonsillar diphtheria requires treatment with antibiotics (to kill the bacteria) and antitoxin (to neutralize the exotoxin). Treatment should be started on clinical suspicion without awaiting culture confirmation, because toxin produced in the interim might damage the myocardium irreversibly.

Cutaneous diphtheria must be treated with antibiotics and antitoxin (see Table 183-1). The antibiotic of choice is high-dose intravenous penicillin or, for those unable to take penicillin, erythromycin. Diphtheria antitoxin, available from the Centers for Disease Control and Prevention, is administered intravenously after careful testing for horse serum hypersensitivity. Injection of antitoxin subcutaneously around and under the ulcer, along with superficial application to the lesion, may be beneficial, but data are incomplete. After antitoxin and antibiotics are administered, the membrane should be débrided and the ulcer kept clean. Patients with either form of the disease should be isolated for roughly 14 days.

Prognosis, Clinical Course, and Complications

Prevention

CHAPTER 184

Tuberculosis and Infections with Atypical Mycobacteria

Gerhard Tappeiner

The genus *Mycobacterium* is estimated to cause more suffering for humans than all other bacterial genera combined. Twenty-five years ago it was assumed that tuberculosis would become extinct in the developed countries, because its incidence decreased at an average rate of 6 percent in the United States and 10 percent in Europe between 1953 and 1985. However, by 1983 tuberculosis was declared a "global emergency" by the World Health Organization because of a sharp increase in incidence elsewhere (e.g., a doubling in sub-Saharan Africa) largely due to the human immunodeficiency virus infection pandemic, poverty, and social disruption. One-third of the world's population is thought to be infected. In the United States, the figure is estimated at 15 million. Currently, an estimated 8 million new cases of tuberculosis and 3 million tuberculosis-related deaths occur each year, 98 percent of them in developing countries. There are also 1.5 million new cases and 500,000 deaths per year among children. Tuberculosis has the highest morbidity and mortality rates of all infectious diseases and is thought to be responsible for 25 percent to 30 percent of avoidable deaths.

The so-called *atypical mycobacteria* (mycobacteria other than *M. tuberculosis*, or MOTT) cause skin disease more frequently than does *M. tuberculosis*. They exist in various reservoirs in the environment. Among these organisms are obligate and facultative pathogens as well as non-pathogens. In contrast to the obligate pathogens, the latter do not cause disease by person-to-person spread.

CLASSIFICATION OF MYCOBACTERIA[1]

MYCOBACTERIA AND THE ACQUIRED IMMUNODEFICIENCY SYNDROME PANDEMIC

The pandemic of acquired immunodeficiency syndrome (AIDS), with its profound and progressive suppression of cellular immune functions, has led to a resurgence of tuberculosis and the appearance or recognition of new mycobacterial pathogens. The *M. avium-intracellulare* complex is the most common cause of disseminated bacterial infections in patients with AIDS in the United States, but is much less frequently so in Europe. In AIDS patients *M. kansasii* is more common than *M. tuberculosis*. The incidence of tuberculosis

TUBERCULOSIS AT A GLANCE

- Infection with *Mycobacterium tuberculosis* (and other very closely related strains, the "*M. tuberculosis* complex") and the inflammatory reaction of the host define the disease (tuberculosis, or TB).
- One-third of the world's population is infected with TB. Nine million new infections and 2 million disease-related deaths occur per year. TB is the main cause of death of patients infected with human immunodeficiency virus. In the United States, there are 10.8 cases per 100,000 in black non-Hispanic individuals and 1.3 cases per 100,000 in white non-Hispanic individuals.
- TB usually affects the lung, but virtually all other organ systems may be involved.
- TB of the skin is a relatively rare manifestation with a wide spectrum of clinical findings depending on the source of infection and the immune status of the host.
- Diagnosis is based on clinical manifestations, histopathologic analysis, demonstration of the relevant mycobacteria in tissue or in culture and host reaction to *M. tuberculosis* antigen.
- Treatment is with standard multidrug regimens; cases of multidrug-resistant TB or extensively multidrug-resistant TB require special attention.
- Course and prognosis depend on the immune status of the host. Treatment is curative except for patients with a breakdown of the immune system.

in patients with AIDS is almost 500 times that in the general population.

The sharp increase in pulmonary and bacteremic or disseminated mycobacterial infections has not been paralleled by an equal increase in skin disease. Cutaneous disease in AIDS patients is frequently caused by MOTT.

TUBERCULOSIS OF THE SKIN

Definition and Classification

Tuberculosis of the skin is caused by *M. tuberculosis*, *M. bovis*, and, under certain conditions, bacille Calmette-Guérin (BCG), an attenuated strain of *M. bovis* originally developed for vaccination. Classification is based on the mode of infection and the immunologic state of the host (Table 184-1).

TABLE 184-1
Classification of Cutaneous Tuberculosis

	Host Immune Status	Clinical Disease
Exogenous infection	Naive	Primary inoculation tuberculosis
	Immune	Tuberculosis verrucosa cutis
Endogenous spread	High	Lupus vulgaris
		Scrofuloderma
	Low	Acute miliary tuberculosis
		Orificial tuberculosis
		Metastatic tuberculous abscess (tuberculous gumma)
Tuberculosis due to bacille Calmette-Guérin	Naive	Normal primary complex–like reaction
		Perforating regional adenitis
		Postvaccination lupus vulgaris
Tuberculids	Not clear	Tuberculids:
		Lichen scrofulosorum
		Papulonecrotic tuberculid
		Facultative tuberculids:
		Nodular vasculitis
		Erythema nodosum

Epidemiology

Mycobacteria are neither very virulent nor very infectious. Tuberculosis of the skin has a worldwide distribution. Once more prevalent in regions with a cold and humid climate, it now occurs mostly in the tropics. In European and North American countries, the incidence of skin tuberculosis has declined steadily over the past decades, paralleling the decreasing incidence of pulmonary tuberculosis. So far, there has been no increase in skin tuberculosis proportional to the resurgence of pulmonary tuberculosis.

The two most frequent forms of skin tuberculosis are lupus vulgaris (LV) and scrofuloderma. In the tropics, LV is rare, whereas scrofuloderma and verrucous lesions predominate. LV is more than twice as common in women than in men, whereas tuberculosis verrucosa cutis is more often found in men. Generalized miliary tuberculosis is seen in infants (and adults with severe immunosuppression or AIDS), as is primary inoculation tuberculosis. Scrofuloderma usually occurs in adolescents and the elderly, whereas LV may affect all age groups.

Etiology and Pathogenesis

THE MYCOBACTERIUM Mycobacteria multiply intracellularly and are initially found in large numbers in the tissue.

M. tuberculosis, *M. bovis*, and, under certain conditions, the attenuated BCG organism cause all forms of skin tuberculosis.

In LV, the bacteria often have a virulence as low as that of the BCG. Large numbers of bacteria can be found in the lesions of a primary chancre or of acute miliary tuberculosis; in the other forms, their number in the lesions is so small that it may be difficult to find them.

M. tuberculosis may become dormant in the host tissue.

New diagnostic tools are emerging.[4,5]

THE HOST The human species is quite susceptible to infection by *M. tuberculosis*, with big differences among populations and individuals. Populations that have been in long-standing contact with tuberculosis are, in general, less susceptible than those that have come into contact with mycobacteria more recently. Age, state of health, environmental factors, and particularly the immune system are of importance. In Africans, tuberculosis frequently takes an unfavorable course, and tuberculin sensitivity may be more pronounced than in whites.

TUBERCULIN REACTION (KOCH PHENOMENON) An extract of *M. tuberculosis* (tuberculin) was shown to produce a different skin reaction in sensitized individuals than in naive individuals, and this difference became the basis of a widely used diagnostic test. This reaction is a delayed-type hypersensitivity reaction, induced by mycobacteria during primary infection. This "old tuberculin" has now been replaced by purified protein derivative

(PPD). More recently, purified species-specific antigens have been developed.

Local intradermal injection (the method most widely used) leads to the local tuberculin reaction, which usually reaches its maximum intensity after 48 hours. It consists of a sharply circumscribed area of erythema and induration, and in highly hypersensitive recipients or after large doses, a pallid central necrosis may appear.

In an attempt to quantify the tuberculin reaction, an assay to measure specific antigen-driven interferon-γ synthesis by whole blood cells has been developed. Its usefulness remains to be determined.[6]

Tuberculin sensitivity usually develops 2 to 10 weeks after infection and persists throughout life. The state of sensitivity of an individual infected with *M. tuberculosis* is of considerable significance in the pathogenesis of tuberculosis skin lesions.

In patients with clinical tuberculosis, an increase in skin sensitivity usually indicates a favorable prognosis, and in tuberculous skin disease accompanied by high levels of skin sensitivity, the number of bacteria within the lesions is small. Tuberculin sensitivity is not necessary for immunity, however, and sensitivity and immunity do not always parallel each other. There is evidence that a high degree of tuberculin sensitivity may even be antagonistic to protection.

ROUTE OF INFECTION Cutaneous inoculation leads to a tuberculous chancre or to tuberculosis verrucosa cutis, depending on the immunologic state of the host.

Spread of mycobacteria may occur by continuous extension of a tuberculous process in the skin (scrofuloderma), by way of the lymphatics (LV), or by hematogenous dissemination (acute miliary tuberculosis of the skin or LV).

Histopathology

The hallmark of tuberculosis and infections with some of the slow-growing atypical mycobacteria is the tubercle: an accumulation of epithelioid histocytes with Langhans-type giant cells among them and a varying amount of caseation necrosis in the center, surrounded by a rim of lymphocytes and monocytes. Although this tuberculoid granuloma is highly characteristic of several forms of tuberculosis, it may be mimicked by deep fungal infections, syphilis, and leprosy, as well as other diseases. As in leprosy, the histopathologic features of skin tuberculosis may be reflective of the host's immune status.

Polymerase Chain Reaction Procedure

The polymerase chain reaction (PCR) procedure has been used increasingly to ascertain the presence of mycobacterial DNA in skin specimens.[7] Although the detection of specific DNA in tissues has yielded valuable information and will conceivably gain importance in the future, interpretation of the results of these tests in individual patients is still problematic.[8] In one study,[9] samples from 16 of 20 patients with sarcoidosis contained mycobacterial DNA, both tuberculous and nontuberculous. In another study[7] of patients with confirmed or highly probable cutaneous tuberculosis or with erythema induratum, PCR testing showed 100 percent sensitivity and specificity in multibacillary disease, but only 55 percent combined sensitivity and specificity in paucibacillary disease, and showed an 80 percent correlation with response to antituberculosis therapy.

SKIN DISEASES CAUSED BY *MYCOBACTERIUM TUBERCULOSIS/BOVIS* INFECTION

Infection with *M. tuberculosis* used to be thought to result in characteristic clinical features.[10] However, with increasing numbers of cases in immunocompromised individuals and improved diagnostic tools, many quite uncharacteristic manifestations have been discovered.

Primary Inoculation Tuberculosis (Tuberculous Chancre, Tuberculous Primary Complex)

Tuberculous chancre and affected regional lymph nodes constitute the tuberculous primary complex in the skin. The condition is believed rare, but its incidence may be underestimated. In some regions with a high prevalence of tuberculosis and poor living conditions, primary inoculation tuberculosis of the skin is not unusual. Children are most often affected. Sites of predilection are the face, including the conjunctivae and oral cavity, as well as the hands and lower extremities.

PATHOGENESIS Tubercle bacilli are introduced into the tissue at the site of minor wounds. Oral lesions may be caused by bovine bacilli in nonpasteurized milk and occur after mucosal trauma or tooth extraction. Primary inoculation tuberculosis is initially multibacillary but becomes paucibacillary as immunity develops.

▲ **FIGURE 184-1** Primary inoculation tuberculosis. Note tuberculous chancre on the thigh and regional lymphadenopathy. A positive tuberculin reaction is noted on the arm.

CLINICAL MANIFESTATIONS The chancre initially appears 2 to 4 weeks after inoculation and presents as a small papule, crust, or erosion with little tendency to heal. A painless ulcer develops, which may be quite insignificant or may enlarge to a diameter of more than 5 cm (Fig. 184-1). It is shallow with a granular or hemorrhagic base studded with miliary abscesses or covered by necrotic tissue. The ragged edges are undermined and of a reddish blue hue. As the lesions grow older, they become more indurated, with thick adherent crusts.

Wounds inoculated with tubercle bacilli may heal temporarily but break down later, giving rise to granulating ulcers. Mucosal infections result in painless ulcers or fungating granulomas. Inoculation tuberculosis of the finger may present as a painless paronychia. Inoculation of puncture wounds may result in subcutaneous abscesses.

Slowly progressive, regional lymphadenopathy develops 3 to 8 weeks after the infection (see Fig. 184-1) and may rarely be the only clinical finding. After weeks or months, cold abscesses may develop that perforate to the surface of the skin and form sinuses. The lymph nodes draining the primary glands may also be involved. Body temperature may be slightly elevated. The disease may take a more acute course, and in half the patients, fever, pain, and swelling simulate a pyogenic infection.

HISTOPATHOLOGY Early, there is an acute non-specific inflammatory reaction in both skin and lymph nodes, and mycobacteria are easily detected by Fite stain. After 3 to 6 weeks, the infiltrate and the regional lymph nodes acquire a tuberculoid appearance and caseation may occur.

Box 184-1

Differential Diagnosis of Primary Inoculation Tuberculosis

- Syphilis
- Tularemia
- Bartonellosis
- Sporotrichosis
- Other mycobacterioses

DIAGNOSIS Any ulcer with little or no tendency to heal and unilateral regional lymphadenopathy in a child should arouse suspicion. Acid-fast organisms are found in the primary ulcer and draining nodes in the initial stages of the disease. The diagnosis is confirmed by bacterial culture. The PPD reaction is negative initially and later converts to positive (see Fig. 184-1).

The differential diagnosis encompasses all disease with a primary complex (Box 184-1).

COURSE Untreated, the condition may last up to 12 months. Rarely, LV develops at the site of a healed tuberculous chancre. The regional lymph nodes usually calcify.

The primary tuberculous complex usually produces immunity, but reactivation of the disease may occur. Hematogenous spread may give rise to tuberculosis of other organs, particularly of the bones and joints. It may also lead to acute miliary disease with a fatal outcome. Erythema nodosum occurs in approximately 10 percent of cases.

Tuberculosis Verrucosa Cutis (Warty Tuberculosis)

PATHOGENESIS Tuberculosis verrucosa cutis is a paucibacillary disorder caused by exogenous re-infection (inoculation) in previously sensitized individuals with high immunity.

Inoculation occurs at sites of minor wounds or, rarely, from the patient's own sputum. Members of professional groups handling infectious material are at risk. Children may become infected playing on contaminated ground.

CLINICAL MANIFESTATIONS AND COURSE Lesions usually occur on the hands or, in children, on the lower extremities as a small asymptomatic papule or papulopustule with a purple inflammatory halo. They become hyperkeratotic and are often mistaken for a common wart. Slow growth and peripheral expansion lead to the development of a verrucous plaque with an irregular border (Fig. 184-2). Fissures discharging pus extend into the underlying brownish red to purplish infiltrated base. The lesion usually is solitary, but multiple lesions may occur. Regional lymph nodes are rarely affected.

▲ **FIGURE 184-2** Tuberculosis verrucosa cutis on the back of the hand.

Lesions progress slowly and, if untreated, persist for many years. Spontaneous involution eventually occurs, leaving an atrophic scar.

HISTOPATHOLOGY The most prominent histopathologic features are pseudoepitheliomatous hyperplasia with marked hyperkeratosis, a dense inflammatory infiltrate, and abscesses in the superficial dermis or within the pseudoepitheliomatous rete pegs. Epithelioid cells and giant cells are found in the upper and middle dermis. Typical tubercles are uncommon, and the infiltrate may be non-specific.

DIFFERENTIAL DIAGNOSIS (Box 184-2)

Lupus Vulgaris

LV is an extremely chronic, progressive form of cutaneous tuberculosis occurring in individuals with moderate immunity and a high degree of tuberculin sensitivity.

Box 184-2

Differential Diagnosis of Tuberculosis Verrucosa Cutis

- Warts or keratoses
- Hyperkeratotic lupus vulgaris
- Blastomycosis
- Chromomycosis
- Bromoderma
- Lesions due to other mycobacteria
- Hypertrophic lichen planus
- Tertiary syphilis

Once common, LV has declined steadily in incidence. It has always been less common in the United States than in Europe. Females appear to be affected two to three times as often as males; all age groups are affected equally.

PATHOGENESIS LV is a postprimary, paucibacillary form of tuberculosis caused by hematogenous, lymphatic, or contiguous spread from elsewhere in the body. Spontaneous involution may occur, and new lesions may arise within old scars. Complete healing rarely occurs without therapy.

CLINICAL MANIFESTATIONS Lesions are usually solitary, but two or more sites may be involved simultaneously. In patients with active pulmonary tuberculosis, multiple foci may develop. In approximately 90 percent of patients, the head and neck are involved. LV usually starts on the nose, cheek, earlobe, or scalp and slowly extends onto adjacent regions. Other areas are rarely involved.

The initial lesion is a brownish red, soft or friable macule or papule with a smooth or hyperkeratotic surface. On diascopy the infiltrate exhibits a typical apple jelly color. Progression is characterized by elevation, a deeper brownish color (Fig. 184-3A), and formation of a plaque (see Fig. 184-3B). Involution in one area with expansion in another often results in a gyrate outline border. Ulceration may occur. Hypertrophic forms appear as a soft nodule (see eFig. 184-3.1 in on-line edition) or plaque with a hyperkeratotic surface (see eFig. 184-3.2 in on-line edition). Involvement of the nasal or auricular cartilage may result in extensive destruction and disfigurement (Fig. 184-4). Atrophic scarring, with or without prior ulceration, is characteristic, as is recurrence within a scar. Fibrosis may be pronounced and mutilating.

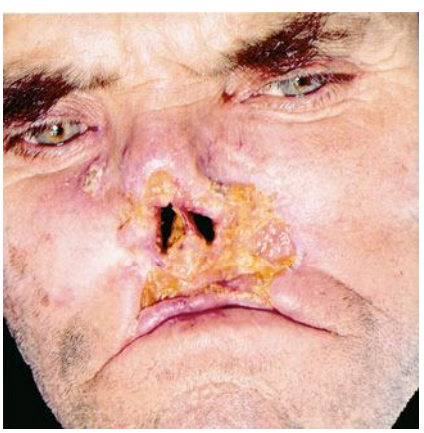
The mucosae may be primarily involved or become affected by the extension of skin lesions. Infection is manifest as small, soft, gray or pink papules, ulcers, or friable granulating masses. Dry rhinitis is often the only symptom of early nasal LV, but lesions may also destroy the cartilage of the nasal septum. Scarring of the soft palate and laryngeal stenosis also occur.

After a transient impairment of immunity, particularly after measles (thus the term *lupus postexanthematicus*), multiple disseminated lesions may arise simultaneously in different regions of the body as a consequence of hematogenous spread from a latent tuberculous

▲ **FIGURE 184-3** **A.** Slightly raised, brownish plaque of lupus vulgaris. **B.** Large plaque of lupus vulgaris of 10 years' duration involving the cheek, jaw, and ear.

focus. During and after the eruption, a previously positive tuberculin reaction may become negative but will usually revert to positive as the general condition of the patient improves.

HISTOPATHOLOGY The most prominent histopathologic feature is the formation of typical tubercles. Secondary changes may be superimposed: epidermal thinning and atrophy or acanthosis with excessive hyperkeratosis or pseudoepitheliomatous hyperplasia. Acid-fast bacilli are usually not found. Non-specific inflammatory reactions may partially conceal the tuberculous structures. Old lesions are composed chiefly of epithelioid cells and may be impossible to distinguish from sarcoidal infiltrates (see eFig. 184-4.1 in on-line edition).



▲ **FIGURE 184-4** Lupus vulgaris of long duration that has led to the destruction of the nose. Ulcerating squamous cell carcinoma has developed on the upper lip.

DIAGNOSIS Typical LV plaques may be recognized by the softness of the lesions, brownish red color, and slow evolution. The apple jelly nodules revealed by diascopy are highly characteristic; finding them may be decisive, especially in ulcerated, crusted, or hyperkeratotic lesions. The result of the tuberculin test is strongly positive except during the early phases of postexanthematic lupus. Bacterial culture results may be negative, in which case the clinical diagnosis can usually be supported by positive PCR results for *M. tuberculosis* (Box 184-3).

COURSE LV is a very long-term disorder and without therapy progresses over many years to functional impairment and disfiguration (see Fig. 184-4). Long-standing LV may lead to the development of carcinoma (see Fig. 184-4). Squamous cell carcinomas outnumber basal cell carcinomas by far, and the risk of metastases is high. In 40 percent of patients there is associated tuberculous lymphadenitis, and 10 percent to 20 percent have active pulmonary tuberculosis or tuberculosis of the bones and joints.[11] Pulmonary tuberculosis is 4 to 10 times more frequent in patients with LV than in the general population.

Scrofuloderma (Tuberculosis Colliquativa Cutis)

Scrofuloderma is subcutaneous tuberculosis leading to cold abscess formation and a secondary breakdown of the overlying skin. It may be either multibacillary or paucibacillary.

Scrofuloderma represents contiguous involvement of the skin overlying another site of infection (e.g., tuberculous lymphadenitis, tuberculosis of bones and joints, or tuberculous epididymitis). Prevalence is higher among children, adolescents, and the aged.

Box 184-3

Differential Diagnosis of Lupus Vulgaris

- Sarcoidosis
- Lymphocytoma
- Discoid lupus erythematosus
- Tertiary syphilis
- Leprosy
- Blastomycosis or other deep mycotic infections
- Lupoid leishmaniasis

CLINICAL MANIFESTATIONS Scrofuloderma most often occurs in the parotidal, submandibular, and supraclavicular regions and may be bilateral. It first presents as a firm, subcutaneous nodule, usually well defined, freely movable, and asymptomatic. As the lesion enlarges it softens. After months, liquefaction with perforation occurs, causing ulcers and sinuses (Fig. 184-5). The ulcers are linear or serpiginous with undermined, inverted, bluish edges and soft, granulating floors. Sinusoidal tracts undermine the skin. Clefts alternate with soft nodules. Scar tracts develop and bridge ulcerative areas or even stretches of normal skin. Tuberculin sensitivity is usually pronounced.

HISTOPATHOLOGY Massive necrosis and abscess formation in the center of the lesion are non-specific. However, the periphery of the abscesses or the margins of the sinuses contain tuberculoid granulomas.

DIAGNOSIS If there is an underlying tuberculous lymphadenitis or bone and joint disease, the diagnosis usually presents no difficulty (Box 184-4). Positive results on culture confirm the diagnosis.

COURSE Spontaneous healing does occur, but the course is very protracted and it may be years before lesions have been completely replaced by scar tissue. Presence of the typical cribriform scars permits a correct diagnosis, even after the process has become quiescent. LV may develop at or near the site of scrofuloderma.

▲ **FIGURE 184-5** Scrofuloderma in the clavicular region. Note abscess formation, ulceration, and extrusion of purulent and caseous material.

Box 184-4

Differential Diagnosis of Scrofuloderma

- *Mycobacterium avium-intracellulare* lymphadenitis
- *M. scrofulaceum* infection
- Syphilitic gummas
- Sporotrichosis
- Actinomycosis
- Severe forms of acne conglobata
- Hidradenitis suppurativa

Metastatic Tuberculous Abscess (Tuberculous Gumma)

Orificial Tuberculosis (Tuberculosis Ulcerosa Cutis et Mucosae)

PATHOGENESIS Orificial tuberculosis is a rare form of tuberculosis of the mucous membranes and orifices that is caused by autoinoculation of mycobacteria from progressive tuberculosis of internal organs.

The underlying disease is far advanced pulmonary, intestinal, or, rarely, genitourinary tuberculosis. Mycobacteria shed from these foci in large numbers are inoculated into the mucous membranes.

CLINICAL MANIFESTATIONS A small yellowish or reddish nodule appears on the mucosa and breaks down to form a soft ulcer with a typical punched-out appearance, undermined edges, and circular or irregular border (Fig. 184-6). The ulcer floor often exhibits multiple yellowish tubercles and bleeds easily. The surrounding mucosa is edematous and inflamed. Lesions may be single or multiple and are extremely painful, resulting in dysphagia.

The tongue is most frequently affected, particularly the tip and the lateral margins, but the soft and hard palates are also common sites. In advanced cases the lips are involved, and the oral condition often represents an extension of ulcerative tuberculosis of the pharynx and larynx. In patients with intestinal tuberculosis, lesions develop around the anus, and in females with active genitourinary disease, the vulva is involved.

▲ **FIGURE 184-6** Orificial tuberculosis in advanced cavitary pulmonary tuberculosis.

HISTOPATHOLOGY There is a massive non-specific inflammatory infiltrate and necrosis, but tubercles with caseation may be found deep in the dermis. Mycobacteria are easily demonstrated.

DIFFERENTIAL DIAGNOSIS (Box 184-5)

COURSE Orificial tuberculosis is a symptom of advanced internal disease and usually portends a fatal outcome.

Acute Miliary Tuberculosis of the Skin (Tuberculosis Cutis Miliaris Disseminata)

Sequelae of Bacille Calmette-Guérin Inoculation

Vaccination with attenuated bovine BCG appears to protect infants and young children from the more serious forms of tuberculosis, but its ability to prevent disease in adults remains uncertain. In the United States guidelines for BCG immunization have been developed.

In the normal course of BCG vaccination, an infiltrated papule develops after approximately 2 weeks, attains a size of approximately 10 mm after 6 to 12 weeks, ulcerates, and then slowly heals, leaving a scar. Vaccination may provoke an accelerated reaction in a previously infected person. The regional lymph nodes may enlarge but usually heal without breaking down. Tuberculin sensitivity appears 5 to 6 weeks after vaccination.

The true incidence of complications caused by the BCG organism[12] is difficult to ascertain, but it is extremely low in comparison to the great number of vaccinations performed in Europe in the past 50 years. Problems include the following:

Box 184-5

Differential Diagnosis of Orificial Tuberculosis

- Syphilitic lesions (not painful)
- Aphthous ulcers
- Squamous cell carcinoma

- Lupus vulgaris at or near the vaccination site (latency of months to years)
- Koch phenomenon in individuals sensitive to tuberculin [see Tuberculin Reaction (Koch Phenomenon)]
- Regional adenitis, sometimes severe and with systemic symptoms, more often in children
- After deep injection, local abscesses, excessive ulceration
- Scrofuloderma with suppuration for 6 to 12 months
- Generalized tuberculid-like reactions (rare)
- Generalized adenitis, osteitis, organ tuberculosis (e.g., in the joints) occasionally

Nonfatal generalized complications occurr in 1 or 2 persons per million; a perforating regional adenitis appeared in 2 percent of vaccinated children in Denmark; and the incidence of postvaccination LV is estimated to be from 5 to 10 per million. Fatal disease caused by generalized BCG tuberculosis occurs in 1 in 10 million immunizations.

THE TUBERCULIDS

Lichen scrofulosorum, erythema induratum, papulonecrotic tuberculids, lupus miliaris disseminatus faciei, and other eruptions with rather exotic designations were originally included in the tuberculids (Table 184-2).

With the sharp decline in incidence and the effective treatment of tuberculosis in developed countries, the tuberculids also became rare. This does not apply to areas in which tuberculosis is still common, however, and with the recent resurgence of tuberculosis associated with AIDS in some Western countries, some tuberculids are also being observed again.

The pathogenic relationship of the tuberculids to tuberculosis is still poorly understood. Although there is no doubt that such a relationship exists for some tuberculids, in other cases it appears highly unlikely.

PCR testing revealed *M. tuberculosis* DNA in skin lesions of erythema induratum/nodular vasculitis and papulonecrotic tuberculid in one series of patients,[13] but in another results were uniformly negative.[14] Thus, *M. tuberculosis* infection may be responsible directly or indirectly for some cases of these diseases but not all, and the usefulness of lesional PCR testing may vary among clinical settings. Consistent with this statement, antituberculosis drugs are beneficial in some cases but not all; spontaneous involution may occur, and some patients appear to respond well

TABLE 184-2
Tuberculids

TERMINOLOGY/RELATIONSHIP TO TUBERCULOSIS	ENTITIES
Tuberculids: conditions in which *Mycobacterium tuberculosis/bovis* appears to play a significant role	Lichen scrofulosorum Papulonecrotic tuberculid
Facultative tuberculids: conditions in which *M. tuberculosis/bovis* may be one of several pathogenic factors	Nodular vasculitis/erythema induratum of Bazin Erythema nodosum
Non-tuberculids (conditions formerly designated as tuberculids; there is no relationship to tuberculosis)	Lupus miliaris disseminatus faciei Rosacea-like tuberculid Lichenoid tuberculid

to other therapies. It should be noted that, although not considered a tuberculid, sarcoidosis has been postulated to result from an immunologic reaction to mycobacterial antigens.[15]

The following discussion includes only those conditions for which a preponderance of the evidence supports a tuberculous etiology (see Table 184-2).

Lichen Scrofulosorum

EPIDEMIOLOGY AND PATHOGENESIS Lichen scrofulosorum is an uncommon lichenoid eruption ascribed to hematogenous spread of mycobacteria in an individual strongly sensitive to *M. tuberculosis*. Usually associated with chronic tuberculosis of the lymph nodes, bones, or pleura, it has also been observed after BCG vaccination and in association with *M. avium-intracellulare* infections.[16]

CLINICAL MANIFESTATIONS Lesions are usually confined to the trunk and occur most often in children and adolescents with active tuberculosis. The lesions are asymptomatic, firm, follicular or perifollicular flat-topped yellowish or pink papules, sometimes with fine scale. Lichenoid grouping is pronounced, and lesions may coalesce to form rough, discoid plaques. Lesions persist for months, but spontaneous involution eventually occurs. Antituberculosis therapy results in complete resolution within weeks.

HISTOPATHOLOGY Superficial tuberculoid granulomas develop around hair follicles or independent of the adnexa. Mycobacteria are not seen in the sections and cannot be cultured from biopsy material.

Box 184-6
Differential Diagnosis of Lichen Scrofuloderma

- Lichen planus
- Lichen nitidus
- Lichenoid secondary syphilis
- Micropapular forms of sarcoidosis

DIFFERENTIAL DIAGNOSIS (Box 184-6)

Papulonecrotic Tuberculid

Papulonecrotic tuberculid is a symmetric eruption of necrotizing papules, appearing in crops and healing with scar formation, that occurs preferentially in children or young adults. It is rarely reported but may not be uncommon in populations with a high prevalence of tuberculosis.

PATHOGENESIS As a rule, bacteria cannot be demonstrated in lesions. In most cases, the tuberculin test shows a positive reaction, and associated pulmonary or extrapulmonary tuberculosis is common. LV has been reported to evolve with papulonecrotic tuberculid. Lesions are reported to respond promptly to antituberculosis therapy whether or not a tuberculous focus is identified.

In studies of skin lesions in patients with papulonecrotic tuberculid, *M. tuberculosis* DNA was detected in approximately 50 percent of patients.[17–19] *M. kansasii* infection was documented in one patient.[20]

Some cases of papulonecrotic tuberculid have been associated with discoid lupus erythematosus, arthritis, or erythema nodosum and may therefore be triggered by antigens unrelated to *M. tuberculosis*.

CLINICAL MANIFESTATIONS Sites of predilection are the extensor aspects of the extremities, buttocks, and lower trunk (Fig. 184-7), but the eruption may become widespread. Distribution is symmetric and consists of disseminated crops of livid or dusky red papules with a central depression and an adherent crust over a crater-like ulcer. There is spontaneous involution, which leaves pitted scars.

HISTOPATHOLOGY Characteristically, a wedge-shaped necrotic area in the upper dermis extends into the epidermis. The inflammatory infiltrate surrounding this necrotic area may be nonspecific but is usually tuberculoid. Involvement of the blood vessels is a cardinal feature and consists of an obliterative and sometimes granulomatous vasculitis leading to thrombosis and complete occlusion of the vascular channels.

DIFFERENTIAL DIAGNOSIS (Box 184-7)

Nodular Vasculitis/Erythema Induratum of Bazin (See Chap. 68)

Erythema Nodosum (See Chap. 68)

TREATMENT OF CUTANEOUS TUBERCULOSIS

In general, the management of cutaneous tuberculosis is similar to that of tuberculosis of other organs.[21–24] Chemotherapy is usually the treatment of choice (Table 184-3), but ancillary measures may be required. Vaccines against *M. tuberculosis* are under development.[2]

Although they are not yet established as a therapeutic option, cytokines such

as interleukin 2, interferon-γ, interleukin 12, and granulocyte-macrophage colony-stimulating factor may help to control intracellular pathogens and thereby shorten the duration of therapy and overcome drug resistance.[25] The immunomodulatory drug thalidomide (see Chap. 236) may prove to be useful in controlling problems related to the inflammatory response that may follow treatment of multibacillary infection and could become a useful adjunctive drug, as it is in the treatment of leprosy.

Special Considerations in Treating Tuberculosis of the Skin

In contrast to systemic infection, for which triple-drug therapy is recommended, tuberculosis verrucosa cutis and localized forms of LV without evidence of associated internal tuberculosis may be treated with isoniazid alone for up to 12 months. Total doses of 80 to 140 g may be required. Because viable mycobacteria have been found in clinically healed lesions, treatment should be continued for at least 2 months after complete involution of the lesions. Surgical intervention is quite helpful in scrofuloderma, because it reduces morbidity and shortens the required length of chemotherapy. Small lesions of LV or tuberculosis verrucosa cutis are also best excised, but tuberculostatics should be given concomitantly. Plastic surgery is important as a corrective measure in cases of longstanding LV with mutilation.

DISEASES CAUSED BY MYCOBACTERIA OTHER THAN *M. TUBERCULOSIS*

MOTT were identified as human pathogens in 1938 (*M. fortuitum*), in 1948 (*M. ulcerans*), and in 1954 (*M. marinum*). Overshadowed by the infectious disease burden due to *M. leprae* and *M. tuberculosis*, however, the pathogenic potential of slow-growing MOTT species has been recognized only in recent decades. Because MOTT infections usually closely mimic infections with *M. tuberculosis* and the bacteria have strict and often unusual requirements for culture, they are still probably underdiagnosed.

Identification of Mycobacteria Other Than *M. tuberculosis*

As with other infectious diseases, the diagnosis of mycobacterial infection depends on the identification of the microorganism isolated from the host. Specimens for culture should be sent to a special laboratory familiar with the special growth requirements of these organisms.

Antigens for intradermal skin testing (PPDs) for many of the clinically relevant mycobacterial species have been prepared in analogy to PPD from *M. tuberculosis*, but their accessibility is very limited and they are therefore little used.

Histopathologic analysis is supportive but cannot distinguish among mycobacterial species, because all share similar histopathic features.[26]

Treatment is summarized in Table 184-4. Importantly, some MOTT organisms are resistant to standard tuberculosis therapy. PCR testing for mycobacterial DNA is not yet reliable enough to play a role in the diagnosis of disease but can sometimes be useful in distinguishing among species.

TABLE 184-3
Therapy Guidelines for *Mycobacterium tuberculosis* Infections

	Option 1		Option 2			Option 3
Antituberculosis Drugs	Initial 8 wk	Then 16 wk	Initial 2 wk	Then 6 wk	Then 16 wk	9 mo
Rifampin 10 mg/kg	Daily	2–3×/wk	Daily	Daily	Daily	3×/wk
Isoniazid 5 mg/kg	Daily	2–3×/wk	Daily	Daily	Daily	3×/wk
Pyrazinamide 30 mg/kg	Daily		Daily	Daily		3×/wk
Ethambutol 15 mg/kg	Daily		Daily	2×/wk		3×/wk
or						
Streptomycin 15 mg/kg						

Total duration of treatment is 6 mo except in patients with human immunodeficiency virus infection, in whom treatment duration is at least 9 mo.
Proof of culture conversion cannot be expected in the majority of cases of tuberculosis of the skin.

DISEASES CAUSED BY MYCOBACTERIA OTHER THAN *M. TUBERCULOSIS* AT A GLANCE

- A heterogeneous group of diseases caused by a variety of obligate or facultatively pathogenic mycobacteria other than those of the *Mycobacterium tuberculosis* complex.
- Involvement depends on the type of mycobacterium, the route of infection, and the immune status of the host.
- Various organs may be involved.
- Mycobacteria other than *M. tuberculosis* (MOTT) are more often the cause of skin disease than *M. tuberculosis*.
- Diagnosis relies on histopathologic analysis and the results of culture.
- Incidence is unknown, but endemic areas exist for certain types of MOTT.
- Treatment is unlike that of tuberculosis, and no strict international guidelines have been developed. Effective antibiotics are known for each mycobacterial species but should be checked by sensitivity testing.

Pathology and Pathogenesis

MOTT are widely distributed in nature and are usually commensals or saprophytes rather than pathogens. Atypical mycobacteria are usually acquired from environmental sources such as water or soil, and their role in disease reflects their natural distribution and, possibly, local lifestyles. These organisms are thought to cause mycobacterial skin disease more often than does *M. tuberculosis*. Cases tend to be sporadic, but certain types of exposures may lead to small community outbreaks.[1,3] Any organ or organ system may be affected

(Table 184-5), but MOTT seem much less likely to disseminate than *M. tuberculosis*, and infections usually run a more benign and limited course. As a rule, MOTT are much less responsive to antituberculosis drugs but may be sensititve to other chemotherapeutic agents.

Only two organisms, *M. ulcerans* and *M. marinum*, produce a characteristic clinical picture. An immunosuppressed state of the host or damage to a particular organ (e.g., in *M. kansasii* infection of the lung) facilitates these infections.

New mycobacterial pathogens are described from time to time, which suggests that their full pathogenic potential is not yet appreciated.

Skin Infections with Mycobacteria Other Than *M. tuberculosis*

MYCOBACTERIUM ULCERANS The natural habitat of *M. ulcerans* is still not known, and it has never been found outside the human body, but *M. ulcerans* infection occurs in wet, marshy, or swampy areas and seems to have to do with contaminated water. *M. ulcerans* is the third most frequent mycobacterial pathogen, after *M. tuberculosis* and *M. leprae*.

Clinical Manifestations. The disease is found most often in children and young adults, and affects females more often than males. A subcutaneous nodule gradually enlarges and eventually ulcerates. A blister may develop before ulceration. The ulcer is deeply undermined, and necrotic fat is exposed (Fig. 184-8). The preceding nodule as well as the ulcer is painless, and the patient continues to feel well. The lesions may occur anywhere on the body but tend to be limited to the extremities in adults. They may be large, involving a whole limb. The ulceration may persist for months and years, and healing and progression of the ulceration may occur in the same patient. This process may lead to appreciable and sometimes disabling scarring and lymphedema. Neither lymphadenopathy nor any constitutional signs appear at any time unless the disease process is complicated by bacterial superinfection.

▲ **FIGURE 184-8** *Mycobacterium ulcerans* infection in a child in Uganda. The knee bears an ulcer with an infiltrated undermined margin and a base of necrotic adipose and connective tissue. (Used with permission from M. Dietrich, MD.)

Box 184-8

Differential Diagnosis of *Mycobacterium ulcerans* Lesions

- Early lesions
  - Foreign body granuloma
  - Phycomycosis
  - Nodular fasciitis
  - Panniculitis
  - Nodular vasculitis
  - Sebaceous cyst
  - Appendageal tumor
- Late lesions
  - Necrotizing cellulitis
  - Blastomycosis or other deep fungus infection
  - Pyoderma gangrenosum
  - Suppurative panniculitis

Differential Diagnosis. (Box 184-8)

MYCOBACTERIUM MARINUM (MYCOBACTERIUM BALNEI) *M. marinum* occurs in freshwater and saltwater, including swimming pools and fish tanks.

Clinical Manifestations. Risk factors for *M. marinum* infection are a history of trauma and water- or fish/seafood-related hobbies and occupations. The disease begins as a violaceous papule at the site of a trauma 2 to 3 weeks after inoculation. Patients may have a nodule or a psoriasiform or verrucous plaque at the site of inoculation, usually the hands, feet, elbows, or knees (Fig. 184-9). The lesions may ulcerate. Usually the lesions are solitary, but occasionally sporotrichoid spread occurs. They may heal spontaneously within 1 to 2 years, with residual scarring. Occasionally the lesions are suppurative rather than granulomatous and may be multiple in both normal or immunosuppressed hosts.

Differential Diagnosis. (Box 184-9)

MYCOBACTERIUM KANSASII *M. kansasii* is the atypical mycobacterium most closely related to *M. tuberculosis*. It is usually acquired from the environment. Endemic areas include Texas, Louisiana, the Chicago area, California, and Japan. Skin disease caused by *M. kansasii* usually occurs in adults and is more common in individuals with underlying immunosuppression caused by Hodgkin disease, treatment for organ transplantation, or AIDS. Inoculation is usually attributable to minor trauma such as a puncture wound.

Clinical Manifestations. *M. kansasii* infection may present in several forms. Most frequently, there are papules in a sporotrichoid distribution. Sometimes, subcutaneous nodules extend to deeper structures and may result in a carpal tunnel syndrome or joint disease. An ulcerated plaque may also develop as a metastatic lesion. Disseminated disease caused by *M. kansasii* infection occurs in immunosuppressed patients, and such patients have cellulitis and abscesses rather than granulomatous lesions. The most commonly affected organ is the lung, usually in patients with other pulmonary conditions (silicosis, emphysema). Infection may also cause cervical lymphadenopathy. As with *M. tuberculosis*, *M. kansasii* present in nasopharyngeal secretions can lead to periorificial cutaneous infection. These infections usually progress slowly, although a chronic stable lesion or even spontaneous regression may occur. Drug therapy should be initiated as soon as the diagnosis is made.

▲ **FIGURE 184-9** **A.** *Mycobacterium marinum* infection on the back of the hand. Granulomatous nodular lesion with central ulceration at the site of inoculation. (Used with permission from A. Kuhlwein, MD.) **B.** Verrucous, violaceous plaque with central spontaneous clearing occurring at the site of an abrasion sustained in a fish tank. The lesion was caused by *M. marinum*.

- Blastomycosis
- Coccidioidomycosis
- Histoplasmosis
- Sporotrichosis
- Nocardiosis
- Tertiary syphilis
- Yaws

Differential Diagnosis. (Box 184-10)

MYCOBACTERIUM SCROFULACEUM *M. scrofulaceum* is widely distributed in the environment.

Clinical Manifestations. The usual manifestation of *M. scrofulaceum* infection is cervical lymphadenitis, frequently unilateral, in children, mainly between the ages of 1 and 3 years. Submandibular and submaxillary nodes are typically involved, rather than the tonsillar and anterior cervical nodes as is characteristic for *M. tuberculosis* infection. There are no constitutional symptoms. Involved lymph nodes enlarge slowly over several weeks and eventually ulcerate and develop fistulae. There rarely is evidence of lung or other organ involvement. In most cases, the disease is benign and self-limited.

Differential Diagnosis. The differential diagnosis includes other forms of bacterial lymphadenitis; viral infections, including mumps and mononucleosis; and malignancy, including solid tumors, lymphoma, and leukemia.

MYCOBACTERIUM AVIUM-INTRACELLULARE *M. avium-intracellulare* encompasses organisms with a wide variety of microbiologic and pathogenic properties. Well over 20 sub-types can be separated by immunologic techniques, although this is not necessary for clinical purposes.

Box 184-10

Differential Diagnosis of *Mycobacterium kansasii* Lesions

- Sporotrichosis
- Tuberculosis
- Other granulomatous infections of the skin

These organisms are usually grouped together with *M. scrofulaceum* in the so-called *M. avium-intracellulare–scrofulaceum* complex but are separated here for clinical reasons. Whereas *M. scrofulaceum* produces only a benign, self-limited lymphadenopathy with no organ involvement, *M. avium-intracellulare* infection usually causes lung disease or, less frequently, osteomyelitis. It may also produce a cervical lymphadenitis with sinus formation that is clinically indistinguishable from tuberculous scrofuloderma.

Clinical Manifestations. Primary skin disease caused by *M. avium-intracellulare* has been reported in rare instances, presenting as single or multiple painless, scaly yellowish plaques, sometimes resembling LV, or as subcutaneous nodules with a tendency to ulceration and a slowly progressive, chronic course. Sometimes, skin involvement occurs secondary to disseminated infection with *M. avium-intracellulare*. Skin lesions have included generalized cutaneous ulcerations, granulomas, infiltrated erythematous lesions on the extremities, pustules, and soft-tissue swelling. *M. avium-intracellulare* infections are an important cause of morbidity in patients with AIDS (see Chap. 198).

MYCOBACTERIUM SZULGAI, MYCOBACTERIUM HAEMOPHILUM, MYCOBACTERIUM GENAVENSE *M. szulgai*, *M. haemophilum*, and *M. genavense* are rarely found to cause human disease in cases of otherwise unexplained cervical lymphadenitis, cellulitis, draining nodules and plaques, bursitis, pneumonia and subcutaneous granulomatous eruptions.

MYCOBACTERIUM FORTUITUM, MYCOBACTERIUM CHELONAE, MYCOBACTERIUM ABSCESSUS *M. fortuitum*, *M. chelonae*, and *M. abscessus*, three species of fast-growing, facultative pathogenic mycobacteria, were previously grouped in the *M. fortuitum* complex but are now recognized as distinct species. These organisms seem to be widely distributed and can commonly be found in soil and water. Contamination of various materials, including surgical supplies, occurs but does not always result in clinical disease.

Clinical Manifestations. *M. fortuitum*, *M. chelonae*, and *M. abscessus* cause similar clinical diseases. Infection usually follows a puncture wound or a surgical procedure. The disease manifests itself as a painful red infiltrate at the site of inoculation; there are no signs of dissemination and no constitutional symptoms. Cold postinjection abscesses, especially in the tropics, may also be caused by fast-growing mycobacteria.

The lesion is a dark red nodule, often with abscess formation and clear fluid drainage. Healthy children and adults may become infected, but disseminated disease usually occurs in hemodialysis patients or other immunologically compromised individuals. The disease course consists of multiple recurrent episodes of abscesses on the extremities or a generalized macular and papular eruption. Internal organs may be involved.

Histopathology. There is simultaneous occurrence of polymorphonuclear leukocyte microabscesses and granuloma formation with foreign body–type giant cells, the so-called *dimorphic inflammatory response*. There is usually necrosis but no caseation. Acid-fast bacilli may occasionally be found within microabscesses.

Diagnosis and Treatment. Organisms of the *M. fortuitum* complex may be identified by special laboratories to permit a rational treatment.

CHAPTER 185

Actinomycosis, Nocardiosis, and Actinomycetoma

Francisco G. Bravo
Roberto Arenas
Daniel Asz Sigall

Actinomyces and *Nocardia* are a group of filamentous bacteria belonging to the same class, Actinobacteria, and same order, Actinomycetales. They cause human disease with prominent skin involvement. Microorganisms under this category were wrongly classified as fungi for a long time, because of their tendency to produce branching filaments, mimicking radiating hyphae (form the Greek *actino*, meaning *sun*). Their taxonomy is still evolving, resulting in continuous reclassification of different species in old and new families. Anaerobic endogenous *Actinomyces*, part of our normal respiratory, intestinal, and genito-urinary flora, will cause localized suppurative disease with fistula formation that is analogous to the lumpy jaw of cattle. Aerobic environmental *Nocardia* sp. causes diseases ranging from cellulitis to paronychia to abscesses, with the most striking presentation being a lymphocutaneous, sporotrichoid syndrome. In addition, other aerobic environmental species of *Nocardia* and *Actinomyces* will cause one of the two known forms of mycetoma, the actinomycetoma.

The sulfur granule or grain, a clumping of filamentous bacteria seen in infected living tissue, is considered characteristic of the infection by these microorganisms, but is not always present and is also not specific (Table 185-1). Practicing dermatologists should be aware of the various morphologic variants of these diseases, so that measures may be taken to ensure the appropriate culturing techniques required for isolation.

ACTINOMYCOSIS AT A GLANCE

- Worldwide distribution, relatively uncommon.
- Actinomyces are part of normal upper respiratory, intestinal, and genitourinary flora.
- *Actinomyces israelii* is the most common causative agent, usually as a polymicrobial infection, mixed with Gram-positive cocci and anaerobes.
- Classical presentation is a chronic, localized infiltrative process with abscess fistula formation and draining sinuses.
- Most common location is cervico-facial (related to dental pathology), followed by abdominal, pelvic, and chest wall involvement.
- Pathologic findings include a chronic inflammatory infiltrate with granulation tissue or granuloma formation.
- Grains (sulfur granules) are characteristic but neither invariably present nor pathognomonic.

ACTINOMYCOSIS

Epidemiology

Described by Israel in 1878, the disease has a worldwide distribution. It is more commonly seen in males, ages 20 to 60 years old, with females affected at a younger age. In the pre-antibiotic era, the incidence in the Netherlands and Germany was 1:100,000 inhabitants/year; in the 1970s, the reported incidence in Cleveland, Ohio, was 1:300,000 inhabitants/year, and in 1984, in Cologne, Germany, it was estimated to be 1:40,000 inhabitants/year.[1] Recently, an increased incidence of genitourinary actinomycosis has been described in females, related to the use of intrauterine devices (IUDs). Nowadays, there is a tendency to subtle cases with more limited involvement, many of them circumscribed to the oral cavity. Diagnosis in such circumstances requires a high index of suspicion.

Etiology and Pathogenesis

The term *actinomycosis* implies disease produced by endogenous, anaerobic, or microaerophile, Gram-positive, non-spore–forming bacteria, belonging to the families Actinomycetaceae and Propionibacteriaceae, of the order Actinomycetales; and Bifidobacteriaceae, of the order Bifidobacteriales.[1] Their normal habitat is human and animal mucosal surfaces, with considerable host specificity, from the mouth to the upper respiratory, gastrointestinal, and female genital tract. Species known to cause disease in humans include *A. israelii*, *A. naeslundii*, *A. gerencseriae*, *A. viscosus*, *A. odontolyticus*, and *A. meyeri*, as well as *Propionibacterium propionicum* and *Bifidobacterium dentium*. The disease in most cases is mixed with other microorganisms sharing the same habitat, so it should be considered a synergistic infection, with the *Actinomyces* playing the role of guiding organism, defining the course, the symptoms, and the ultimate prognosis. Accompanying organisms may vary in number, from one to nine different species, and may include coagulase negative staphylococci, *Staphylococcus aureus*, α- and β-hemolytic streptococci, microaerophile and anaerobic streptococci, *Fusarium* and *Bacteroides* sp., and even *Propionibacterium* sp. other than *P. propionicum*.[1] This concomitant flora may be in part responsible for the course of the process. If pyogenic bacteria are involved, such as *S. aureus* or β-hemolytic streptococci, the lesion will be acutely inflammatory and painful. If, on the contrary, anaerobes predominate, the course will be subacute and insidious. A particular more chronic course is seen when *A. israelii* or *A. gerencseriae* is accompanied by *Actinobacillus actinomycetemcomitans*. In recent years, with better culturing techniques, more than one *Actinomyces* have been isolated from one single lesion in several patients, underlying the possibility that single bacterial isolation, common in the past, was a technical artifact.

The infection has its portal of entry at a break on a mucous membrane. Most of

cervical and facial cases originate from periapical abscesses or after dental procedures. Thoracic cases represent involvement of the chest wall by continuity either from pleural or lung disease acquired by obstruction or aspiration. The same mechanism of spreading applies to disease of the abdominal wall, secondary to gut or genital pathology, following appendicitis, diverticulitis, surgery, or trauma. Perineal disease occurs as a consequence of involvement of the internal organs of the pelvis, secondary to use of an intravaginal device or IUD. The only exception to the endogenous origin of the infection is hand involvement that follows fist or bite trauma.[2]

In tissue, the bacteria cluster in filamentous aggregates, the so-called *sulfur granules* (grains; see Table 185-1). They are commonly surrounded by acute and chronic inflammation, usually neutrophils, granulation tissue, and fibrosis. Granuloma formation is unusual. The fistula formation may give way to drainage of granules, although under no circumstances should their presence be considered by itself specific for this disease.

Clinical Findings

Actinomycosis should always be suspected when dealing with one of three features: a mass-like inflammatory infiltrate of the skin and subcutaneous tissue, sinus formation with drainage, and a relapsing or refractory clinical course after short-term therapy with antibiotics. Actinomycotic granules may be seen macroscopically.

Cervical actinomycosis is the most frequent form of disease,[3] accounting for approximately 55 percent of cases. Commonly, there is a history of poor dental hygiene, dental or periodontal disease, dental procedure, surgery, or penetrating trauma through the oral mucosa. Most of the infections start as a periapical abscess. The most common location is on the jaw angle and high cervical area (60 percent), followed by the cheek (16 percent), the chin (13 percent), and less commonly, the temporo-mandibular joint and the retro-mandibular area. The lesion starts as a solid mass in any of those locations, and initially may be confused with a neoplastic process (Fig. 185-1). It may eventually progress to form recurring abscesses and later will spread to adjacent structures, with no sparing of anatomic planes. Propagation to lymph nodes is uncommon but eventually may involve the orbit, cranium, spine, and even vascular structures. The lesion is sometimes reported as painless, but pain may be present, as well as fever and leukocytosis. With extension to the skin surface, sinus tracts appear (Fig. 185-2). The overlying skin may have a purplish red hue. Trismus may develop. Bone involvement is present in 10 percent of cases, mostly the jaw. More limited disease may produce a mass or an ulcer, affecting any structure in the mouth or the nasopharyngeal region. Extension to the ear may present as chronic otitis media or mastoiditis. In addition to orbital involvement, there are reported cases of lacrimal canaliculitis and endophthalmitis.

▲ **FIGURE 185-1** Cervico-facial actinomycosis. A solid mass on the mandibular angle that can be confused with a neoplastic process.

▲ **FIGURE 185-2** Typical cervico-facial actinomycosis: a lump with sinus formation. (Used with permission from Wilson Delgado, DDS; and Lepoldo Meneses, DDS; Universidad Peruana Cayetano Heredia, Lima.)

Thoracic actinomycosis comprises 15 percent of cases. The common source of infection is the aspiration of microorganism from the oropharynx, although other routes are possible, such as propagation of cervico-facial disease to the mediastinum. The disease may involve the lung, pleura, mediastinum, and chest wall. The course is indolent, with chest pain, fever, weight loss, cough, and less frequently, hemoptysis, mimicking tuberculosis. Radiologically, the disease will present as a mass or pneumonia, with pleural involvement by continuity. Relevant to dermatologists, up to 26 percent of cases will have chest wall involvement,[4] with the developing of a cutaneous abscess and sinus formation (Fig. 185-3). Parenchymal, pleural, and chest wall disease occurring together will make actinomycosis a most likely diagnosis. Mediastinal actinomycosis may show either as anterior chest wall disease (rarely sternum involvement), or paraspinal abscess. Involvement of breast tissue and breast implants has also been described.

Abdominal actinomycosis represents about 20 percent of all cases. It presents as a consequence of spreading from the gastrointestinal tract or from the female genital tract, linked to IUD use. Appendicitis and diverticulitis is a common precipitating event. Any organ in the peritoneal cavity may be affected; by continuity, the disease may spread to the abdominal wall. An inflammatory mass may appear in the skin surface of the abdominal region or the perineum, with later development of sinuses. In the perianal area, multiple abscesses and fistula formation may occur. From there on, spreading to buttocks, thigh, scrotum, or groin may follow.

Primary pelvic disease most commonly originates from ascending infection from the female genital tract and less common, following abdominal disease. The role of IUD as a risk factor has been well established and is usually associated to prolonged use, 8 years on average.

Punch or fist actinomycosis represents a particularly uncommon but interesting clinical presentation.[2] It usually follows blunt trauma of a closed fist against an adversary's mouth; similar findings may originate from a human bite. It usually involves the proximal phalanges and

▲ **FIGURE 185-3** Thoracic actinomycosis from a patient who died from disseminated disease.

metacarpal bones. First a soft tissue infection, it will eventually spread to the bony structures. Grains are commonly seen in this particular form.

Actinomycosis of the central nervous system (CNS) may present as brain abscess, meningitis, meningoencephalitis, subdural empyema, actinomycoma, and spinal abscess. It is usually secondary to hematogenous spread.

Laboratory tests considered useful include direct examination of draining material, culture, and biopsy. Direct examination will show the presence of filamentous *Actinomyces* on Gram stain. The isolation of *Actinomyces* in culture should be considered diagnostic, if coming from a sterile site. However, positive culture rates are as low as 35 percent in some series. The processing should be done in anaerobic conditions, and when all techniques available today are used, the percentage of isolates that cannot to be identified is as low as 2.8 percent.[1]

The presence of granules, either microscopically or macroscopically, is very relevant, especially if obtained from tissues not connected to mucosal surfaces. Grains are usually yellow (hence the name *sulfur granules*), but can be white, pinkish gray, gray, or brown. In tissue samples, special stains, such as Brown-Brenn, Gram, Giemsa, or Gomori stains, are required to demonstrate filamentous structures. The number of grains is usually scanty: only one single granule was identified from 25 percent of specimens in a study of 181 cases.[3] The Splendore-Hoeppli phenomenon, a rim of eosinophilic material, may surround the granules in tissue cuts. The lack of staining with Fite modified acid-fast stain separates *Actinomyces* from *Nocardia* sp. Eumycetoma granules stain positive with periodic acid-Schiff and Gomori, whereas granules from Botryomycosis should show clumps of bacteria. Direct immunofluorescent staining is available for some species, including *A. israelii* (see Table 185-1).

Differential Diagnosis

Depending on the site affected, the differential diagnosis will include infections such as tuberculosis, non-infectious inflammatory processes such as hidradenitis and inflammatory bowel disease, and neoplasia (Box 185-1).

Box 185-1

Differential Diagnosis of Actinomycosis (Site-Specific)

Most Likely

- Face: tuberculosis, odontogenic abscesses, parotid tumors
- Chest: tuberculosis, neoplasm, pyogenic infections
- Abdomen and pelvis: tuberculosis, inflammatory bowel disease, hidradenitis suppurativa, neoplasm

Consider

- Face: lupus panniculitis, granuloma inguinale
- Pelvis: granuloma inguinale

Prognosis and Therapy

There is general agreement that the treatment of actinomycosis requires high-dose antibiotics to be given for a long period. The treatment of choice is penicillin G, 18 to 24 million units intravenously for 2 to 6 weeks, followed by oral penicillin or amoxicillin, to be given for 6 to 12 months. Cervico-facial disease or any more limited disease can receive a shorter course of therapy. A good rule to follow is to give therapy until full resolution of clinically evident disease. Alternative treatment for those allergic to penicillin includes tetracycline, doxycycline, erythromycin, and clindamycin. Imipenem has been used successfully as short-term therapy. Chloramphenicol is the alternative to penicillin in cases of CNS involvement. Risk factors for death or relapse include duration of disease longer than 2 months, lack of antibiotic therapy or surgical therapy, and needle aspiration rather than open drainage or excision.

With early diagnosis and more limited disease, as compared to the bulky disease of the past, treatment can be shorter: 30 days for cervico-facial disease and 3 months for pelvic or thoracic disease.[5] Periapical actinomycosis can be successfully treated with curettage and 10 days of antibiotic therapy.

Surgery is indicated for bulky disease involving the chest, abdomen, pelvis, and CNS. It should be directed to resection of necrotic tissue, excision of sinus tracts, draining of empyemas and abscesses, and curettage of bone, always accompanied by antibiotic therapy.

Antibiotics that are effective against synergistic microbes that accompany the *Actinomyces* can reasonably be included in the initial therapy.

Prevention

Good oral hygiene and prevention of periodontal disease may decrease colonization by *Actinomyces*. Physicians dealing with patients using an IUD should be aware of the risk of developing the disease.

NOCARDIOSIS AT A GLANCE

- Aerobic Gram-positive filamentous bacteria.
- Worldwide distribution, environmentally acquired infection, due to primary traumatic inoculation.
- Pulmonary infections mostly in immunocompromised patients and skin infections mostly in immunocompetent patients.
- Skin disease mostly caused by *Nocardia brasiliensis*; less commonly *N. asteroides*, *N. otidiscaviarum*, and *N. farcinica*.
- Cutaneous nocardiosis can take the form of either cellulitis or more characteristic lymphocutaneous nodules in a sporotrichoid pattern; skin lesions also occur in disseminated disease.
- Diagnosis is based on Gram stain of clinical specimen showing thin, gram-positive branching bacteria, weakly positive with acid-fast staining; microbiologic isolation of *Nocardia* sp. is diagnostic, but requires keeping cultures under observation 5 to 7 days.
- Treatment: sulfonamides.

NOCARDIOSIS

Epidemiology

The *Nocardia* sp. are aerobic, Gram-positive, filamentous, higher bacteria found worldwide in soil and decaying organic plant matter. They can be found in house dust, beach sand, garden soil, and swimming pools. They are able to cause disease in many organs, including the skin. Approximately 1000 cases of nocardiosis occur annually in the United States.[6] Cutaneous disease comprises 5 percent to 22 percent of all cases.[6] A higher incidence of primary cutaneous nocardiosis in Europe may be explained on the basis of more frequent isolation of *N. brasiliensis* in the environment. Patients have also been described in India and Argentina.[4] Disease occurs most commonly in males.

Immunocompromised patients account for 50 percent of cases, mostly pulmonary,

systemic, and CNS infections. They are commonly seen in transplant patients, patients with acquired immunodeficiency syndrome (AIDS)[4] or malignancy, or those receiving steroids. Primary cutaneous disease is most commonly seen in immunocompetent patients and has been reported rarely in children in United States, mostly in the south and southwestern part of the country.[7]

Etiology and Pathogenesis

The *Nocardia* sp. of medical importance include *N. asteroides*, most commonly associated with lung and systemic disease, and *N. brasiliensis*, most commonly associated with skin infection. Other species include *N. farcinica*, *N. otidiscaviarum*, *N. nova*, *N. pseudobrasilensis*, *N. transvalensis*, and *N. abscessus*. It is only recently that many of this species have been completely separated, especially those of the *N. asteroides* group, including *N. farcinica* and *N. nova*. It is interesting to note that *Nocardia* sp. belong to a subgroup of bacteria called the *aerobic nocardioform actinomycetes* that also include *Mycobacterium*, *Corynebacterium*, *Rhodococcus*, and *Gordona*. All these microorganisms have mycolic acid as constituent of their cell wall, which explains the varying acid fastness on appropriate staining. The proposed etiologic agent for Whipple disease, *Tropheryma whippelii*, also belongs to this group.

The usual inflammatory response in infected tissue is neutrophilic, with branching, beading filamentous bacteria within abscesses. Sulfur granules are uncommon in primary cutaneous nocardiosis; they have been described in disseminated disease. They are more commonly seen when the clinical picture is that of mycetoma (see Actinomycetoma).

Clinical Findings

Cutaneous involvement by *Nocardia* can manifest either as cellulitis or more characteristically, as lymphocutaneous nodules in a sporotrichoid pattern. Disseminated disease can also present in the skin as a consequence of hematogenous spread. In most series, skin disease is second only to pulmonary involvement in frequency. Mycetoma due to *Nocardia* is discussed in Clinical Findings under Actinomycetoma.

Predisposing factors for primary cutaneous nocardiosis include soil or sand exposure while gardening or farming; or superficial injury from domestic shrubbery, outdoor falls, or accidents. The frequent history of thorn injury or gardening may suggest incorrectly a diagnosis of sporotrichosis. Cat scratches or insect bites may be also the portal of entry, especially in children.[7]

The most common cause of primary cutaneous nocardiosis is *N. brasiliensis*, but *N. asteroides*, *N. otidiscaviarum*, *N. nova*, and *N. farcinica* have also been implicated. Most patients are immunocompetent, but *Nocardia* cutaneous infection may also occur in the context of immunosuppression. A recent series of nocardial infection in AIDS patients showed skin lesions in 11 percent of cases, most commonly cutaneous abscesses and suppurative adenitis.[4]

The disease has been also described in ulcerative bullous, linear/keloid, and nodulo-pustular forms (Fig. 185-4A) that may evolve into the more specific sporotrichoid pattern (see Fig. 185-4B). Patients may also present acutely with eccrine hidradenitis, or chronically with hyperkeratotic plaques. Cutaneous nocardiosis may begin suddenly, reactivate after months to years, or follow a chronic course for up to 10 years. A case of simultaneous infection in a husband and wife has also been described. Very rarely, pure cutaneous disease may lead to systemic illness. The cellulitic form most commonly affects the lower extremities, as compared to sporotrichoid form, in which the upper extremities are most commonly involved. Children frequently present with cellulitis, abscesses, and lymphadenitis affecting lower extremities and trunk; 20 percent of cases will have lesions at multiple sites.[7]

Lymphocutaneous forms may account for 24 percent of all *Nocardia* cutaneous infections (see Fig. 185-4). The first case proven to be due to *N. brasiliensis* was described by Alarcon[9]; the patient developed acute nodular suppurative lymphadenitis after injuring the finger with a rose thorn. Although the upper extremity is the most common location, disease of lower extremity and cervico-facial region have also been reported. A common history is appearance of a solitary papule or nodule on the upper limbs, 2 to 4 weeks after cutaneous inoculation. Then, proximal nodules develop along lymphatic drainage. The primary lesion is initially warm and tender, then becomes fluctuant and later ulcerates. Macroscopic grains may be seen, but draining sinuses are rare. Systemic symptoms are mild. Regional lymphadenitis is common but lymphangitis is unusual.

Sternal wound infections usually develop 1 month after thoracic surgery.

▲ **FIGURE 185-4** **A.** Early lesions of lymphocutaneous nocardiosis. **B.** Lymphocutaneous nocardiosis: typical sporotrichoid pattern. (Used with permission from Marcia Karam, Daniel Asz, and Roberto Arenas, Hospital Manuel Gea González, Mexico City.)

The symptoms include erythema, clear-to-purulent drainage, wound dehiscence, and/or fever. Diabetes mellitus seems to be the only identifiable risk factor. At least in one outbreak, the hands of an anesthesiologist were culture positive for *N. farcinica*. In another case of sternal osteomyelitis and mediastinal abscess, the patient's occupation (carrying wooden crates loaded with vegetables) may have been the source of infection, in the absence of chest surgery or trauma.

Pulmonary disease is the most common form of clinical infection, but, compared to primary cutaneous diseases, is often due to different species (*N. asteroides* predominates). The disease may take the form of an acute pneumonia or a chronic process with bronchopneumonia, abscesses, and development of cavities. Ten percent of pulmonary infections disseminates to the skin.

Bacteremia due to *Nocardia* is seen in patients with concomitant malignancy, and *N. asteroides* is the agent most commonly isolated. Cutaneous or subcutaneous nodules and abscesses occur in many patients, and the skin may be the portal of entry in some cases. Catheter-associated nocardemia is well documented.

Laboratory tests considered useful include direct examination of clinical specimens, culture, and biopsy. The impor-

tance of direct microscopic examination for the presence of granules cannot be overemphasized. Organisms are detected as Gram-positive, branched filamentous "hyphae," and branching at right angles is diagnostic. Acid-fast stains, including Fite-Faraco and the modified Kinyoun technique, show the filamentous bacteria. For isolation, cultures should be kept for up to 2 to 3 weeks. The microorganisms grow satisfactorily on most of the non-selective media used for isolation of bacteria, mycobacterium, and fungi. Because slow growth of *Nocardia* colonies over 2 days to 2 weeks on routine culture media allows bacterial overgrowth, isolation of this organism from soil and non-sterile sites may be difficult. *Nocardia* do not survive the digestive procedures used routinely in mycobacterial culture. Thayer-Martin and buffered charcoal-yeast extract agar may be used and pre-treatment of specimens with a low pH potassium chloride-hydrochloric acid solution for 4 minutes is required.

Patterns described on histology include monocytic infiltrates, fibrinopurulent exudates, granuloma formation, chronic granuloma formation, chronic nodular dermatitis, microabscess formation, and cocco-bacillary organisms; the presence of granules has been described in disseminated cases.[6]

Differential Diagnosis

In cases of cellulitis, the differential diagnosis is extensive, including both infections and non-infectious etiologies. However, in the lymphocutaneous form, the differential diagnosis can be approached more systematically. The sporotrichoid pattern should be differentiated from the more acute ulceroglandular syndrome, as is seen in tularemia and cat-scratch disease (Box 185-2).

Prognosis and Clinical Course

Primary cutaneous nocardiosis is usually subacute or chronic but has a good prognosis when treated appropriately. However, the disease has the potential to disseminate; sternal wound infections may be complicated with osteomyelitis.[6] Systemic disease, especially sepsis, has a high mortality rate, 44 percent to 85 percent, if the patient is nocardemic.[8]

Treatment

The treatment of *Nocardia* infection is appropriate antimicrobial therapy and surgical drainage and débridement. Factors to consider include site and severity of infection, the immune status of the host, potential for interactions and the species of *Nocardia* involved. Current standard for sensitivity testing is by the broth microdilution method.

Sulfonamides, alone or in combination with trimethoprim (TMP), are the cornerstone of therapy for *Nocardia* infections, but are ineffective against *N. otidiscaviarum*.[8] For primary cutaneous nocardiosis of mild to moderate intensity, sulfonamide (either sulfadiazine or sulfisoxazole) alone has been considered adequate therapy[8] but other authors consider TMP-sulfamethoxazole (SMX) the treatment of choice, despite lack of controlled trials. This is based on synergistic activity of both drugs in vitro against *Nocardia*. The commercially available preparation has a fixed ratio of 1:5, and the dose recommended at the present time is 5 to 10 mg/kg TMP and 25 to 50 mg/kg SMX in two to four divided doses. For primary cutaneous nocardiosis, 5 mg/kg of TMP should be sufficient. Clinical improvement should be seen within 3 to 10 days, and 1 to 4 months of treatment should be curative for sporotrichoid nodules and cutaneous ulcers. Prolonged therapy is required for immunosuppressed patients. Minocycline 100 to 200 mg twice a day is considered the alternative treatment in cases of sulfonamide hypersensitivity or poor tolerance.

In more severe cases or disease involving other organs, a combination of sulfonamide with a second agent is recommended. The second-line drugs most recommended are amikacin, imipenem, and ceftriaxone. Alternative second-line drugs include amoxicillin-clavulanate and linezolid. Immunosuppression is a good indication for a two-drug regimen, including amikacin; 88 percent cure rate has been reported when this drug is used.[6] Sternal infections due to *N. asteroides* have responded to oral ofloxacin therapy.[8] *N. farcinica* has a high degree of resistance to various antibiotics, especially third-generation cephalosporin and imipenem, and combined therapy is highly recommended. Extended treatment for extra-cutaneous nocardiosis, with parenteral therapy followed by an oral regimen is necessary. Surgery is indicated in cases of abscesses (drainage) or extensive necrosis (débridement). Spontaneous resolution or good clinical response despite inappropriate therapy has been seen in children with *Nocardia* cellulitis or lymphadenitis.[7]

Box 185-2

Differential Diagnosis of Lymphocutaneous Nocardiosis

Most Likely
- Sporotrichosis
- *Mycobacterium marinum* infection
- Leishmaniasis
- Pyoderma due to *Staphylococcus aureus*

Consider
- Cryptococcosis
- Tuberculosis
- *M. kansasii chelonae* and *M. fortuitum*
- Cysticercosis

Rule Out
- Epithelioid sarcoma
- Metastatic disease

Prevention

The low incidence of *Nocardia* infections in immunodeficient states does not justify prophylactic use of antibiotics. AIDS patients receiving TMP-SMX for *Pneumocystis* are already protected against *Nocardia*.

ACTINOMYCETOMA (See also Chap. 190)

Epidemiology

Mycetomas are chronic infections of the skin, underlying tissues, sometimes bones, and rarely viscera, caused by both bacteria (actinomycetomas) and fungi (eumycetomas).[10] Only actinomycetoma is discussed further in this chapter (for eumycetomas, see Chap. 190). The disease has a worldwide distribution but it is more frequent in the tropics, especially in India, Sudan, Somalia, Mexico, and Venezuela. *A. pelletieri* and *A. madurae* are common agents in Senegal.[11] Occasional cases are seen in the United States, particularly in the South.[10] Actinomycetoma affect mainly men, and the age ranges from 16 to 40 years old, but frequency before 15 years of age is similar in both sexes.[12]

Etiology and Pathogenesis

Microorganisms reported to cause actinomycetomas include *N. brasiliensis*, *Actinomadura madurae*, *A. pelletieri*, *Streptomyces somaliensis*, and less commonly, *N. asteroides*, *N. otitidiscaviarum*, *Nocardiopsis dassonvillei*, and *N. transvalensis*.[13] *N. pseudobrasiliensis*, *N. veterana* and *N.*

ACTINO-MYCETOMA AT A GLANCE

- Actinomycetoma is caused by bacteria, as opposed to eumycetoma, which is caused by fungi.
- More commonly seen in the tropics.
- Several microorganisms cause the disease. Some species are specific for some geographic areas. In the Americas, *Nocardia brasiliensis* predominates.
- More common in men and in lower extremities.
- Characterized by inflammation, tumefaction, and discharging sinus tracts.
- Macroscopic or microscopic grains are usually white. Gram staining shows filamentous bacteria.

mexicana have been reported recently as agents in human actinomycetoma; and *N. pseudobrasiliensis* has also been associated with invasive or disseminated infections. The infection most commonly affects people living in rural areas in developing countries.

Recent taxonomic studies (using DNA hybridization and ribosomal RNA gene sequencing) have confirmed marked heterogeneity among the genera of aerobic actinomycetes.

In North America (Mexico), South America, and Australia, *N. brasiliensis* is the leading cause of actinomycetomas; in Africa, Saudi Arabia, and India, *S. somaliensis* and *A. madurae* predominate; this species is also identified as the etiologic agent in 10 percent to 15 percent of cases in Mexico and Venezuela.[14]

Clinical Findings

Actinomycetoma is a chronic, localized, slowly progressive, painless disease of the skin and subcutaneous tissue. The pathologic process begins with a minor traumatic injury. Walking barefooted or wearing sandals may be considered a risk factor for these infections in rural communities. The lower limbs are involved in 64 percent of the cases (Fig. 185-5), the foot being the most common site (Fig. 185-6). The lower leg, knee, and thigh, as well as the hand, forearm, (Figs. 185-7 and 185-8), face, neck, and abdominal wall, may also be affected. In Mexico, the upper back (Figs. 185-9 and 185-10) is involved in 17 percent to 25 percent of cases in relation to occupational activity, such as firewood collection. Actinomycetoma caused by *Nocardia* sp. is a very inflammatory process characterized by tumefaction, destructive granuloma with a nodular appearance, deformity, and discharging sinus tracts with communicating channels that exudate pus. Ulceration, crusting, and scarring are also observed.[10] Mycetoma due to *A. madurae*, *A. pelletieri*, and *S. somaliensis* are less inflammatory with smaller sinus tracts; *A. madurae* is mainly seen in women with plantar involvement.[14] With all these agents, the granules may be seen with the naked eye (see Table 185-1), usually in a cream color; the exception will be *A. pelletieri*, in which the granules are red.

▲ **FIGURE 185-5** Actinomycetoma of the lower leg. Multiple, indolent, coalescing nodules.

▲ **FIGURE 185-6** Mycetoma of the foot produced by *Nocardia* sp.: typical location, with multiple draining sites.

The course is chronic and progressive, with potential involvement of bones, lung, and abdominal viscera. In women, mycetomas increase in size during pregnancy and spontaneously improve after delivery. Advanced cases may cause functional disability. Atypical clinical forms include the cryptic mycetoma (without sinus tracts), the so-called *minimycetoma* (single or multiple small lesions observed mainly in children and adolescents), and the occasional inguinal "metastatic" lesions from a primary mycetoma of the foot.[10]

Skin biopsy plays an important role in the diagnosis of actinomycetoma. Typically, in hematoxylin and eosin stained tissue sections, there is a suppurative reaction characterized by the presence of polymorphonuclear cells, fibrosis, neovascularization, and rarely, a granulomatous reaction with a tuberculoid granuloma.[10] *Nocardia* infection is characterized by granules 30 to 200 μm in diameter, partially basophilic to amphophilic, with an amorphous eosinophilic radially arranged material on the periphery (the so-called *Splendore-Hoeppli phenomenon*). Granules of *A. madurae* are soft and bigger (1 to 3 mm diameter), purple with a cartographic shape and an eosinophilic fringe (Fig. 185-11). *A. pelletieri* granules are firm and red with a diameter of 200 to 500 μm. Granules of *S. somaliensis* are rounded, hard, pale, and

▲ **FIGURE 185-7** Mycetoma of the hand and wrist caused by *Nocardia brasiliensis*. Note gross deformity. (Used with permission from Roberto Arenas, MD, Hospital Manuel Gea González, Mexico City.)

▲ **FIGURE 185-8** Radiograph from patient in Fig. 185-6 shows associated marked destruction of bones and underlying soft tissues. (Used with permission from Roberto Arenas, MD, Hospital Manuel Gea González, Mexico City.)

1.5 to 10.0 mm of diameter.[10] These organisms stain in tissue with Gomori methenamine silver, periodic acid-Schiff, and the Brown-Brenn modification of the Gram stain.

Clinical specimens should be sent for direct examination (Gram stain) and culture. On direct examination, *Nocardia* granules are microscopic with a yellowish color. Granules produced by other agents are macroscopic: those of *A. madurae* are white, yellow, or cream whereas grains from *A. pelletieri* are red and those of *S. somaliensis* are cream to brown color. Fine needle aspiration cytology has been reported as a good diagnostic tool.

▲ **FIGURE 185-9** Mycetoma of the shoulder caused by *Nocardia brasiliensis*. (Used with permission from Maria Cecilia Albornoz, MD, Instituto de Biomedicina, Caracas.)

The microorganisms can be cultured on Sabouraud's dextrose agar or Lowenstein-Jensen at room temperature; *Nocardia* strains are white-yellow hard colonies. Microscopically, its very thin filaments are Gram-stain positive and acid fast with the Kinyoun's stain. *A. madurae* produce slowly growing beige or pink colonies; *A. pelletieri* colonies are red. *S. somaliensis* produce beige or tanned colonies. All *Actinomyces* and *Streptomyces* sp. are acid-fast negative.[10]

Biochemistry can be used for identification. *N. brasiliensis* hydrolyzes casein and tyrosine, but not xanthine; *N. otitidiscaviarum* is negative to casein and tyrosine and positive to xanthine testing; *N. asteroides* is negative to all these tests.

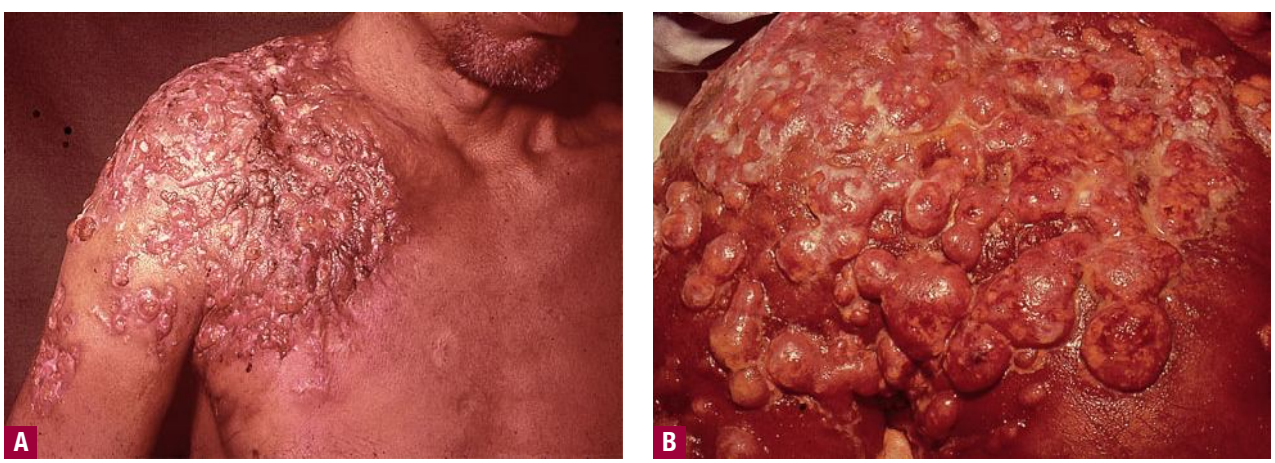
An enzyme-linked immunosorbent assay has been described for the diagnosis of mycetoma due to *N. brasiliensis*; it has been proposed as a method to assess the response to therapy. This test detects antibodies against two immunodominant antigens (24 and 26 kd). An additional advantage of this particular assay might be its demonstrated cross-reactivity with *N. asteroides*.[15]

Differential Diagnosis

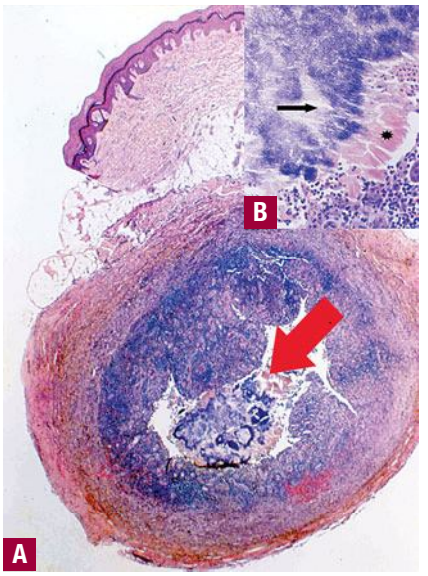
The differential diagnosis includes other infections causing fistulae; for example, eumycotic mycetoma, actinomycosis, botryomycosis, scrofuloderma, and atypical mycobacterial infections (Box 185-3). Botryomycosis is a condition that can mimic actinomycetoma and eumycetoma, both clinically and histologically. The disease can be caused by several organisms, most commonly *S. aureus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Proteus vulgaris*, *Actinobacillus* sp., *Streptococcus* sp., Gram-negative cocco-bacilli, *Propionibacterium* acne, and other anaerobic bacteria. The cutaneous form accounts for 75 percent of the cases; visceral involvement, mainly the lung, is rare. The disease is characterized by localized areas of infiltration, with mass effect and draining sinuses. Extension to the underlying structures, including bone, is not uncommon. Most commonly affected areas are exposed surfaces, such as hands, head, and feet. Patients usually have a predisposing factor such as local trauma, a foreign body, diabetes or human immunodeficiency virus. Botryomycosis is also characterized by the presence of granules, which can be seen macroscopically and microscopically. As in mycetoma, the center of the granule will show agglomeration of the causal agent, most commonly, Gram-positive cocci. Splendore-Hoeppli phenomenon may also be seen around the granules.

Treatment

Therapy for patients with actinomycetoma should be individualized. Eco-



▲ **FIGURE 185-10** **A.** Huge scapulothoracic mycetoma caused by *Nocardia brasiliensis*. Note multiple fistulae. **B.** Close-up. Note doughnut-shaped masses and purulent drainage. (**B,** Used with permission from Maria Cecilia Albornoz, MD, Instituto de Biomedicina, Caracas.)



▲ **FIGURE 185-11** **A.** Skin biopsy of an *Actinomadura* mycetoma shows the granule (*red arrow*) inside the inflammatory reaction (hematoxylin and eosin, 20×). **B.** The contrast between the blue fibrillary material (*black arrow*), representing bacteria, and the eosinophilic proteinaceous material of the Splendore-Hoeppli phenomenon (*star*) (hematoxylin and eosin, 100×).

nomic considerations may influence the choice of therapy, particularly in developing countries. The treatment of choice in actinomycetoma caused by *N. brasiliensis* is diaminodiphenylsulfone (Dapsone) 100 to 200 mg/day (3 to 5 mg/kg) plus TMP-SMX 160/800 mg twice a day for several months in initial cases; the treatment should continue for up to 2 years.[10] Dapsone can also be combined with streptomycin, 1 g/day; clofazimine, 100 mg/day; rifampin, 300 mg twice/day; tetracycline, 1 g/day; or isoniazid, 300 to 600 mg/day; alternative drugs include kanamycin and phosphomycin.

Box 185-3

Differential Diagnosis of Actinomycetoma

- Eumycotic mycetoma
- Actinomycosis
- Botryomycosis
- Scrofuloderma
- Atypical mycobacterial infections

Some resistant cases have been treated with amoxicillin, 500 mg, plus clavulanic acid, 125 mg/day for 5 months.

Amikacin alone or combined with imipenem are powerful antibiotics used as alternative treatments for severe or multi-resistant mycetomas, especially those with bone and visceral involvement. In adults, amikacin is administered 15 mg/kg/day (500 mg intramuscularly twice a day) for 3 weeks; ototoxicity and nephrotoxicity may develop.[16] Patients treated with intravenous imipenem must be hospitalized and treated with a dose of 500 mg three times a day for 3 weeks. It is possible to repeat this cycle several times.[17]

Ramam et al.[18] used a two-step regimen consisting of an intensive phase of therapy with intravenous penicillin (1,000,000 IU every 6 hours) plus intravenous gentamicin (80 mg twice a day), and oral TMP-SMX (80 to 400 mg twice a day) for 5 to 7 weeks. Linezolid, a new oxazolidinone, has shown in vitro antimicrobial activity against *N. brasiliensis*; it also has demonstrated efficacy in patients with nocardiosis. Its main disadvantage of this alternative is the cost. It is available as intravenous and oral preparations.

Patient follow-up is always important, and improvement can be monitored by clinical assessment as well as by laboratory tests: hemoglobin level, white cell count, C-reactive protein, erythrocyte sedimentation rate, enzyme-linked immunosorbent assay (when available), biopsy, and culture.

Amputation is not indicated in actinomycetoma because the very low risk of lymphangitic or hematogenous dissemination. Functional impairment is common with osseous, pulmonary, or abdominal visceral involvement. The disease may be fatal.

CHAPTER 186

Leprosy

Thomas H. Rea
Robert L. Modlin

HISTORICAL ASPECTS

EPIDEMIOLOGY

Now primarily a disease of developing countries, leprosy is endemic in all continents, except Antarctica. In the Americas, only Canada and Chile are not endemic areas, with Texas and Louisiana having endemic foci in the United States. The southernmost nations of Europe have a very low incidence, while leprosy is endemic in many Pacific islands. India has two-thirds of the world's leprosy burden.

During the 1990s, the prevalence of leprosy fell by 90 percent because patients completing a course of multiple-drug therapy have been considered to be cured, but the incidence of the disease, which varies in direct proportion to case-finding efforts, has yet to be reduced convincingly.

In all populations studied, lepromatous disease is more common in men than in women by a 2:1 ratio. If leprosy is common, the "tuberculoid" forms dominate; if leprosy is uncommon, the "lepromatous" forms predominate.[9] Leprosy is said to be a disease of rural incidence, but of urban prevalence. The median age of onset is less in tuberculoid than in lepromatous patients, but in both groups, leprosy is predominantly a young person's disease, the medial age of onset being less than 35 years old. However, old age does not protect. The incubation time for tuberculoid leprosy is up to 5 years and for lepromatous disease may be 20 years or longer.

LEPROSY AT A GLANCE

- Definition: A chronic granulomatous infection and its sequelae, caused by *Mycobacterium leprae.*
- Involvement: Primarily skin and nerves, but also other organs or systems, including eyes, respiratory tract, lymph nodes, testicles, and joints.
- Diagnosis: Requires demonstration of acid-fast bacilli in tissue or a characteristic peripheral nerve abnormality.
- Incidence: Approximately 500,000 new cases yearly, worldwide.
- Long-term morbidity: Despite curative antibacterial treatment, one-fourth to one-third of patients will have a debilitating and permanent neurologic deficit.
- A clinical challenge: Diverse manifestations result from a granulomatous spectrum, and are further increased by superimposed, reactional states.
- An immunologic opportunity: Leprosy is an exemplary model for the understanding of cell-mediated immunity in humans.

The preponderance of opinion supports the traditional view that *Mycobacterium leprae* is transmitted from human-to-human, but *M. leprae* causes lepromatous-like illness in wild armadillos[10]; evidence of armadillo exposure is a risk factor for leprosy in people,[11] and the presence of an *M. leprae*–like organism on sphagnum moss[12] suggest that nonhuman sources for *M. leprae* may be important. The route of infection is unproven, but current evidence favors respiratory transmission; evidence for congenital and percutaneous transmission has been presented, but examples are rare.[13] In leprosy endemic areas, sub-clinical infection is common, as judged by serologic studies identifying *M. leprae*–specific antibodies,[14] but the incidence of overt disease is, by comparison, very small, with most individuals mounting a curative immunologic response.

ETIOLOGY AND PATHOGENESIS

M. leprae, the cause of leprosy, is a non-cultivable, Gram-positive, obligate, intracellular, acid-fast bacillus. The genome of *M. leprae* (3.27 megabases) is notably shorter than that of *M. tuberculosis* (4.41 megabases). The *M. leprae* genome codes for only 1600 genes, *M. tuberculosis* codes for 4000. The two species share 1439 genes in common. In *M. leprae*, only one-half of its genome is coding sequence; this evident gene deletion and decay leaves *M. leprae* with few respiratory enzymes,[6] which explains the failure to cultivate the organism and its obligatory intracellular environment.

In tissues or smears, *M. leprae* is quantified by the biopsy index (BI), a logarithmic scale as to the numbers of bacilli per oil immersion field (OIF): a BI of 6 is 1000 or more bacilli/OIF; a BI of 5 is 100 to 1000/OIF; a BI of 4 is 10 to 100/OIF; a BI of 3 is 1 to 10/OIF; a BI of 2 is 1 bacillus/1 to 10 OIFs; a BI of 1 is 1 bacillus/10 to 100 OIFs; and a BI of 0 is no bacilli in 100 OIFs. Because a BI of 6 indicates 10^9 bacilli per gram of granuloma, tissue with a BI of 0, may have as many as 10^3 organisms per gram.

A patient is considered to be "paucibacillary" if no acid-fast bacilli are found in tissue or smears, and to be "multibacillary" if one or more acid-fast bacilli are found.

M. leprae, like *Treponema pallidum*, is not toxic, the clinical manifestations of leprosy being produced by the host's responses to the *M. leprae*, or, alternatively, by the accumulation of enormous numbers of bacteria, as in signs of diffuse infiltration.

The cell-wall–associated lipoproteins, ligands for the Toll-like receptor 2/1 heterodimer, probably initiates the host's first response to invading *M. leprae*, which is the innate immune response. This response is perhaps important in determining the eventual outcome of the host-parasite interaction.[15] Phenolic glycolipid I is a major species-specific and immunogenic constituent of the highly nonpolar outer layer of the bacillus. Entry into nerves is mediated by the binding of the species-specific trisaccharide in phenolic glycolipid I to laminin-2 in the basal lamina of Schwann cell-axon units,[16] providing a rationale for why *M. leprae* is the only bacterium known to invade peripheral nerves.

A twin study has provided compelling evidence that both genetic and environmental factors are important in determining disease susceptibility and disease expression.[17] A region on chromosome 10p 13, including the PARK2 and PACRG loci for susceptibility to Parkinson disease, has been found to also contain a risk factor for susceptibility to leprosy.[18] This includes both tuberculoid and lepromatous forms, and has been identified in several, but not in all, genetically diverse groups. Major histocompatibility complex class II antigens influence tuberculoid versus lepromatous disease expression, but not disease susceptibility.[19]

CLINICAL FINDINGS

History

For physicians practicing in nonendemic areas, learning that the patient has risk factors for leprosy, (i.e., birth or residence in an endemic area, or a blood relative with leprosy) may lead to a correct diagnosis of leprosy.

Historic data or symptoms that should elicit further suspicion of leprosy include complaints referable to peripheral neuropathy, persistent nasal stuffiness, ocular symptoms, and, in young men, loss of sexual drive or infertility.

Cutaneous and Neural Lesions in the Granulomatous Spectrum

THE GRANULOMATOUS SPECTRUM The in-depth description of the granulomatous spectrum of leprosy was by Ridley and his associates, based on clinical and histologic changes.[3,20] Ridley's construct is a six-member spectrum, ranging from high to low resistance, TT (polar tuberculoid), BT (borderline tuberculoid), BB (borderline), BL (borderline lepromatous), LLs (subpolar lepromatous), and, finally, LLp (polar lepromatous):

TT←BT↔BB↔BL↔LLs LLp

Conceptually, TT and LLp are clinically stable, but, between the poles, the host's granulomatous posture may change, as indicated by the arrows, upgrading (or reversing) to a posture of higher resistance, often with devastating inflammation, or downgrading to a posture of lower resistance, usually silent but occasionally inflammatory. BT patients may upgrade to TT, thus, becoming stable, but LLs patients do not downgrade to LLp nor do LLp patients upgrade. (When the term *LL* is used, it includes both LLs and LLp patients.) The pathogenesis of the granulomatous spectrum is widely accepted as being mediated by a type IV immunologic reaction, cell-mediated immunity (CMI) or delayed-type hypersensitivity (DTH).

The classification is determined primarily by clinical and histologic changes, bacillary numbers being a secondary consideration.

In comparison of pre-Ridley and Ridley terminology, "tuberculoid" corresponds to TT and BT, "borderline" or "dimorphic" to BB and BL, and "lepromatous" to LLs and LLp. In virtually all TT patients, and in most BT cases, acid-fast bacilli cannot be found, whereas in BB, BL, LLs, and LLp, bacilli are demonstrable with ease. Ridley's construct is useful in classifying patients, especially for immunity.

PERIPHERAL NERVE CHANGES Five types of peripheral nerve abnormalities are common in leprosy:

1. Nerve enlargement (usually perceived as asymmetry), particularly in those close to the skin, such as the great auricular, ulnar, radial cutaneous, superficial peroneal, sural, and posterior tibial,
2. Sensory impairment in skin lesions,
3. Nerve trunk palsies either with signs and symptoms of inflammation or without such overt manifestations, that is, silent neuropathy,[21] often with both sensory and motor loss (weakness and/or atrophy) and, if long-standing, also with contracture,
4. Stocking-glove pattern of sensory impairment (S-GPSI), a withering away, so to speak, of the type C fibers, involving heat and cold discrimination before loss of pain or light touch, beginning in acral areas and, over time, extending centrally but sparing the palms, at least for a while, and
5. Anhidrosis on palms or soles, suggesting sympathetic nerve involvement.

Polar Tuberculoid Leprosy. In TT, leprosy immunity is strong, as manifested by spontaneous cure and the absence of downgrading to a posture of less host resistance. The primary skin lesion of TT is a plaque, often assuming an annular configuration secondary to peripheral propagation and central clearing (Fig. 186-1). The border of the plaque or both borders of the annulus are sharply marginated. Typically, the lesion is firmly indurated, elevated, erythematous, scaly, dry, hairless, and hypopigmented, but considerable variation is encountered (see eFigs. 186-1.1 and 186-1.2 in on-line edition).

A nearby sensory nerve may or may not be enlarged, but the lesion itself is characteristically hypesthetic and anhidrotic, with an upper limit of 10 cm in lesion diameter. Skin lesions are often solitary, particularly in those patients who are TT de novo, as contrasted to those who upgrade to TT from BT, where multiple lesions, usually no more than three, may be found. In both groups, immunity is sufficient to affect cure, but antibiotic therapy is recommended.

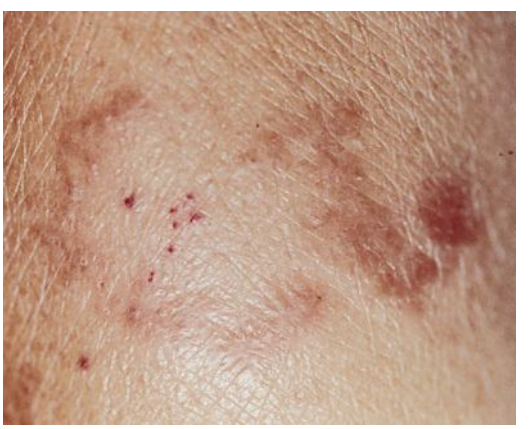
▲ **FIGURE 186-1** A solitary, anesthetic, and annular lesion of polar tuberculoid leprosy, which had been present for 3 months. Its sharp margins, erythema, and scale are more evident than its elevation. The central red dots are the sequelae or "footprints" of testing for pinprick perception when it is absent. (If present, the patient withdraws, preventing overtly purpuric consequences.)

Histologically, the de novo lesions are small tubercles with large lymphocytic mantles. The upgrading lesions have abundant Langhans giant cells, and exocytosis into the epidermis, in addition to lymphocytic mantles.

Borderline Tuberculoid Leprosy. In BT disease, immunologic resistance is strong enough to restrain the infection, in that the disease is limited and bacillary growth retarded, but the host response is insufficient to self-cure (see eFigs. 186-1.3 through 186-1.5 in on-line edition). These patients are somewhat unstable—resistance may increase, upgrading to TT, or decrease, downgrading to BL.

The primary skin lesions of BT are plaques and papules. As in TT, an annular configuration is common, and both borders are sharply marginated, but annular lesions or plaques may have sharply marginated satellite papules (Fig. 186-2). Hypopigmentation may be conspicuous in darkly pigmented patients. In contrast to TT, typically there is little or no scaling, less erythema, less induration, and less elevation, but lesions may become much larger (see eFig. 186-1.3 in on-line edition), that is, well over 10 cm in diameter, a single lesion sometimes involving an entire extremity over time. Multiple, asymmetric lesions are the rule, but solitary lesions are not rare. Impaired sensation in skin lesions is the rule and nerve trunk involvement, enlargement, or palsies, usually asymmetric and affecting no more than two nerves, are common. Nerve abscesses, when they occur, are most often seen in males with BT disease (see eFig. 186-1.5 in on-line edition).

Histologically, lymphocytic mantles are less well developed, Langhans cells are less common or absent, and any exocytosis is focal. Acid-fast bacilli and plasma cells are rare; if present, a DTH reaction [see Delayed-Type Hypersensitivity Reaction (Jopling's Type I Reaction; Upgrading, Reversal, or Downgrading Reactions)] should be suspected.



◀ **FIGURE 186-2** One of several lesions of borderline tuberculoid leprosy, which had an incompletely annular configuration with satellite papules. Compared to the polar tuberculoid lesion in Fig. 186-1, there is less erythema, no evident scales, but sharp margination, and the footprints of absent pinprick perception are also seen.

▲ **FIGURE 186-3** A characteristic borderline or dimorphic lesion, which is an indurated and elevated annular plaque that has a well-defined "tuberculoid" interior margin but a poorly defined "lepromatous" exterior margin. Having both morphologies, it is termed "dimorphic." (From Demis DJ: *Clinical Dermatology*, 23rd revision, vol 3, unit 16–29, 1996, p 14. Used with permission from Lippincott Williams & Wilkins.)

▲ **FIGURE 186-5** Two different host reaction patterns in lepromatous leprosy disease as shown in two ears. In the ear on the left, the diffuse infiltration has become so extensive that the skin of the ear has been thrown into folds, but with no nodule formation. (From Demis DJ: *Clinical Dermatology*, 23rd revision, vol 3, unit 16-16, 1996, page 16. Used with permission from Lippincott Williams & Wilkins.) On the helix of the ear on the right are four nodular lepromatous leprosy lesions, arranged chronologically, so to speak, with the most recent one on top, and the oldest near the bottom. The two top nodules have more poorly defined nodules than do the two older lesions at the bottom. The skin between the nodules is also diffusely infiltrated but has produced no clinically evident changes.

Borderline Leprosy. BB is the immunologic midpoint or mid-zone of the granulomatous spectrum, being its most unstable area, with patients quickly up- or downgrading to a more stable granulomatous posture with or without a clinical reaction. Characteristic skin changes are annular lesions with sharply marginated interior and exterior margins, large plaques with islands of clinically normal skin within the plaque, giving a "Swiss cheese" appearance, or the classic dimorphic lesion. Because of instability, the BB posture is short-lived, and such patients are rarely seen; for example, we have yet to see a nonreactional patient meeting both clinical and histologic criteria.

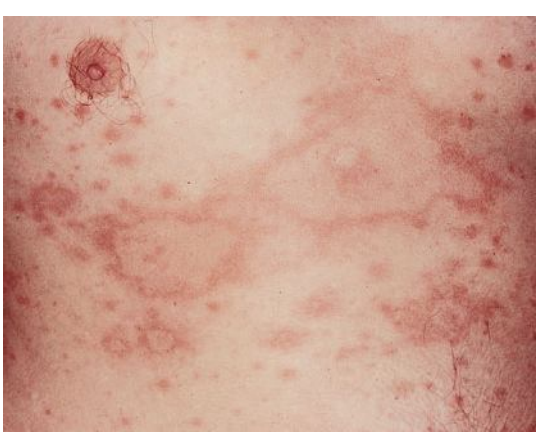
Borderline Lepromatous Leprosy. In BL disease, resistance is too low to significantly restrain bacillary proliferation, but still sufficient to induce tissue-destructive inflammation, especially in nerves. Thus, patients with BL have the worst of both worlds.

The BL category is highly variable in its clinical expression (Fig. 186-3; see eFigs. 186-3.1 through 186-3.3 in on-line edition). Although seen in only one-third of BL patients, the classic dimorphic lesion (one having both morphologies) is the most characteristic, having an annular configuration with a poorly marginated outer border (lepromatous-like) but a sharply marginated inner one (tuberculoid-like; see Fig. 186-3). Poorly or sharply marginated plaques, with "punched out" or "Swiss cheese" sharply marginated areas of normal skin in the interior of the plaque, are also characteristic. Annular lesions with sharply marginated exterior and interior borders are not uncommon. If they occur, lepromatous-like, poorly defined papules and nodules may be numerous, but are usually accompanied by some sharply marginated lesions elsewhere (Fig. 186-4).

Lesions range in number from solitary (something happens first, the tip of an iceberg) to numerous and widespread. Generally speaking, the annular and plaque lesions, however numerous, are asymmetric, but the lepromatous-like nodules, if numerous, are symmetric. Nerve trunk palsies have their highest prevalence in BL disease but are variable in number, ranging from none to serious deficits, both motor and sensory, in all four extremities. Involvement of both median and ulnar nerves, often symmetrical, is characteristic. If disease is extensive, BL patients may have S-GPSI.

Histologically, one classic response is a dense lymphocytic infiltrate confined to the space occupied by the macrophages (see eFig 186-4.1 in on-line edition). Another classic response is lamination of the perineurium with a lymphocytic infiltrate. The pattern may be that of chronic inflammation. Macrophages may be foamy or undifferentiated. Acid-fast bacilli are easily found.

Lepromatous Leprosy. In LL disease, the lack of CMI toward *M. leprae* permits unrestricted bacillary replication and widely disseminated multiorgan disease. Diffuse dermal infiltration is always present subclinically and, in diffuse non-nodular LL, may be overtly manifested by enlargement of ear lobes, widening of the nasal root, and fusiform swelling of the fingers, the latter mimicking a rheumatic illness. Poorly defined nodules are the most common lesions, usually up to 2 cm in diameter, and are symmetrically distributed (Fig. 186-5; see eFig. 186-5.1 in on-line edition). The skin may be thrown into folds, producing leonine facies, often in conjunction with nodular lesions. Dermatofibroma-like (histoid) lesions, usu-



◀ **FIGURE 186-4** Multiple lesions in a patient with borderline lepromatous leprosy. The annular lesions vary in size and are asymmetrically distributed. In contrast, the poorly defined papular and nodular lesions are roughly symmetric. Impairment of sensation was present in most lesions.

▲ **FIGURE 186-6** Multiple dermatofibroma-like (histoid) lesions, which are solitary and confluent, in a patient with subpolar lepromatous leprosy. Their uniformly sharp margins and erythema are in contrast to most of the lesions in Fig. 186-5.

ally multiple, are sharply marginated, erythematous papules or nodules, sometimes confluent into plaques; first identified in relapsing patients as "histoid" leprosy, these are not unusual as presenting lesions in our patients (Fig. 186-6; see eFig. 186-6.1 in on-line edition). Less common presenting skin lesions include digitate, barely indurated patches of erythema (Fig. 186-7), which, in light-skinned patients, are sometimes followed by a mild hyperpigmentation; in dark-skinned patients, multiple hypopigmented macules may arise in such lesions, with melanin concealing the erythema. Also, dermal infiltrate may mimic a shagreen patch (see eFig. 186-7.1 in on-line edition).

Hair loss is common on the eyebrows, where it may progress laterally to medially, or be patchy, but also affects the eyelashes and extremities (see eFig. 186-7.2 in on-line edition). Scalp involvement is rare, likely because of the higher skin temperature. S-GPSI is common and may be so severe as to lead to debilitating trophic changes of the hands or feet.

Histologically, LLs and LLp have many features in common:

1. Nodular lesions have abundant dermal macrophages, foamy or undifferentiated, a sprinkling of lymphocytes, and a thin epidermis above a grenz zone.
2. Clinically, normal skin in usually infiltrated; if scant, in a perivascular distribution.
3. Dense "pseudofollicular" aggregates of lymphocytes may be B cells.[22]
4. Endothelial and Schwann cell acid-fast bacilli are common.
5. Plasma cells and mast cells are inconstantly increased.
6. Foreign-body giant cells may be found in old lesions. In LLs the perineurium in laminated but not infiltrated. In LLp the perineurium is undisturbed.

Indeterminate Leprosy. *Indeterminate leprosy* is a term with nearly as many meanings as it has users. We prefer the definition of Khanolkar,[23] designating an early lesion, appearing before the host makes a definitive immunologic commitment to cure or to an overt granulomatous response. Clinically, the indeterminate lesion is a hypopigmented macule or patch, with or without an associated sensory deficit in or nearby, and acid-fast bacilli, if found, are present in very small numbers. Such lesions are rare in our clinic. The term is inappropriately used to describe lesions rich in bacilli but having neither typical tuberculoid or lepromatous histological patterns, usually BL or LL.

Related Physical Findings

Insensitivity of the cornea is common in all forms of leprosy. In BL and LL disease, numerous changes in the cornea and anterior chamber are possible, iritis being a common serious change, occurring de novo or in association with reactions. Also, in LL, beading of the corneal nerves is common and may be a helpful diagnostic sign.

In all LL patients and in BL patients with extensive disease, wide dissemination of the infection is the rule. In the upper respiratory tract, involvement is from the tip of the nose through the vocal cords, manifesting as rhinitis, septal perforation, nasal collapse, and hoarseness from vocal cord nodules. As judged by elevated follicle-stimulating hormone and luteinizing hormone levels, testicular involvement is common in LL men, less so in BL men, and is clinically manifested by complaints of impotence and infertility, and by atrophy on examination. Involvement of liver, spleen, peripheral lymph nodes, and bone marrow is common, but clinically evident injury is rare.

PREGNANCY AND POSTPARTUM Pregnancy is said to be a precipitating factor for leprosy in 10 percent to 25 percent of women patients, presumably because of altered immunity. When pregnant, LL and BL patients are predisposed to develop erythema nodosum leprosum (ENL, see Erythema Nodosum Leprosum), but postpartum, they are predisposed to develop DTH reactions [see Delayed-Type Hypersensitivity Reaction (Jopling's Type I Reaction; Upgrading, Reversal, or Downgrading Reactions)], putatively due to reduced immunity in the former and restored immunity in the latter.[24] Untreated, lactating BL and LL patients have viable bacilli in their milk, but no risk has been identified in infants ingesting such bacilli.[25] Dapsone in mother's milk may produce hemolysis in the baby.

ACQUIRED IMMUNODEFICIENCY SYNDROME In acquired immunodeficiency syndrome or human immunodeficiency virus pa-

▲ **FIGURE 186-7** These multiple, barely palpable, erythematous, and asymptomatic lesions had been erupting over the previous 2 months in a subpolar lepromatous patient. With treatment, as lesions remitted, they became mildly hyperpigmented. Here, the accentuation of the normal skin markings are in contrast to their effacement in the lesions in Fig. 186-6.

tients, leprosy has not been regarded as an opportunistic infection. For example, in one study, acquired immunodeficiency syndrome or human immunodeficiency virus did not appear to influence disease expression (tuberculoid vs. lepromatous), but was associated with recurrent DTH reactions [see Delayed-Type Hypersensitivity Reaction (Jopling's Type I Reaction; Upgrading, Reversal, or Downgrading Reactions)] (see eFig. 186-7.3 in on-line edition).[26] However, recent reports of leprosy being diagnosed as DTH reactions in the setting of highly active antiretroviral therapy suggests that current views may need revision.[27]

RELAPSING LEPROSY Multibacillary patients who are non-compliant or whose disease develops drug resistance are prone to relapse. Such individuals present in several ways, including (1) a reprise of their initial presentation, (2) florid dermatofibroma-like lesions (histoid lesions), (3) a reactional state, and (4) a posture of higher resistance than their initial presentation, for example, an initially LLs patient having BL or even BT disease.

Reactional States

Generically, the reactional states of leprosy are distinctive, tissue destructive, inflammatory processes, putatively immunologically driven, that greatly increase the morbidity of the disease and, because of the experience required for optimal patient care, justify leprology as a clinical subspecialty. When present, a reactional state is superimposed upon the underlying granuloma, but the reactional state usually dominates the clinical picture. When the immune reaction intensifies, tissue injury may ensue. Too often, the reactional states are dismissed as complications of treatment, but they may occur before treatment is initiated or after it has been completed.

DELAYED-TYPE HYPERSENSITIVITY REACTION (JOPLING'S TYPE I REACTION; UPGRADING, REVERSAL, OR DOWNGRADING REACTIONS) DTH reactions are particularly common in BL patients, but are not rare in LLs, BB, or BT patients.[28,29] Patients may upgrade to a more resistant granulomatous posture, remain unchanged, or downgrade to a less-resistant posture.

Clinically, DTH reactions are characterized by the abrupt conversion of previously torpid plaques to tumid lesions, and by new tumid lesions arising in clinically normal skin with or without an abrupt onset of neuritis. A purplish color is characteristic, but may be subtle (Fig. 186-8). Iritis and lymphedema (elephantiasis graecorum) may be concomitant changes.[29] Morphologic variants include annular, concentric, and eczemaous changes (see eFig. 186-7.3 and eFigs. 186-8.1 through 186-8.5 in on-line edition). Rarely, lesions are solitary, as can happen in BT upgrading to TT, and are often multiple or occasionally myriad, as in BL or LLs upgrading to BT. Neuritis ranges from mild to severe and can be disastrous if multiple nerves are involved. DTH reactions are often a mode of presentation, and DTH reactions occurring soon after presentation may well have been DTH reactions from the beginning. Most common in the first year of treatment, DTH reactions may occur up to 7 years or longer after starting therapy, or well after treatment has stopped. The diagnosis of a DTH reaction is primarily clinical, but histologic confirmation, if available, should be sought, where the most common finding is edema. Other microscopic changes include epithelioid differentiation of macrophages, a mixture of Langhans and foreign-body types of giant cells, and a thickened epidermis.

▲ **FIGURE 186-8** Some of the initial presenting lesions in a patient with a delayed-type hypersensitivity reaction who had borderline lepromatous leprosy. The tumidity, purplish hues, and sharp margination strongly suggest a reversal reaction. The lesions were neither painful nor tender. The differences between these lesions and those shown in Figs. 186-3 and 186-4 emphasize that the delayed-type hypersensitivity reaction, not the underlying borderline lepromatous disease, dominates the clinical picture. The patient also had an irreversible foot drop of recent onset.

ERYTHEMA NODOSUM LEPROSUM (JOPLING'S TYPE II REACTION) ENL occurs most often in LL, in up to 75 percent of cases, but is not rare in BL patients. It is important to appreciate that ENL is not erythema nodosum occurring in leprosy; it is a leprosy-specific response, which has some features in common with erythema nodosum (see Chap. 68). It may occur before, during, or after chemotherapy. The median time of onset is almost 1 year after onset of treatment. Clinically, this reaction is characterized by crops of painful and tender bright-pink, dermal and subcutaneous nodules arising in clinically normal skin, in association with fever, anorexia, and malaise (Fig. 186-9; see eFigs. 186-9.1 through 186-9.5 in on-line edition). Lesions may be targetoid, vesicular, pustular, ulcerative, or necrotic. Of the other organs involved, arthralgias and arthritis are more common in ENL than are neuritis, adenitis, orchitis/epididymitis, or iritis, but each may rarely be the initial presentation. Involvement of both upper and lower extremities is the rule, and facial lesions occur in one-half of the patients. A neutrophilic leukocytosis is often present, occasionally leukemoid in degree. Severe episodes can be associated with an abrupt fall in hematocrit, up to 5 g/dL, easily mistaken for dapsone-induced hemolysis. The improvement in response to thalidomide is dramatic in greater than 90 percent of patients, perhaps qualifying as a diagnostic criterion. When ENL is the presenting mode of leprosy, there may be little or no stigmata of the underlying multibacillary disease. ENL may be precipitated by pregnancy or pyogenic infections.

Although episodes of ENL may be occasional or sporadic, in the more severely involved patients, episodes can be frequent to virtually unremitting. In the latter, brawny induration of the anterior thighs and lateral portion of the arms is characteristic, perhaps a reversible fibrosis. The course of ENL may be

▲ **FIGURE 186-9** Lesions of erythema nodosum leprosum in a patient with lepromatous leprosy. The bright-pink color is characteristic. These lesions are edematous, and pustule formation is suggested. The lesions are painful and tender.

prolonged, and the median required duration of anti-inflammatory treatment is approximately 5 years.

The diagnosis of ENL, if considered, is usually not difficult, as the clinical and histologic features are characteristic and the response to thalidomide is often dramatic.

Histopathologically, the signature cell of ENL is the neutrophil, which may be abundant, scant, or absent, if an old lesion is sampled (see eFigs. 186-9.6 through 186-9.8 in on-line edition). Other common features include an increase in lymphocytes, a thickened epidermis, and a lobular panniculitis. Vasculitis is uncommon. The usual histologic pattern is a "bottom heavy" infiltrate, preferring the deep dermis and subcutis.

LUCIO PHENOMENON Most prevalent in Mexico and the Caribbean region, Lucio phenomenon is restricted to patients with so-called *Latapi lepromatosis* (Lucio leprosy) that consists of diffuse cutaneous infiltration, as well as a purplish suffusion of the hands and feet, telangiectatic mats or eruptive telangiectasias, nasal septum perforation, total alopecia of eyebrows and eyelashes, and, often, S-GPSI.[30] Firm subcutaneous nodules are palpable but not visible. Ocular sparing is the rule.

Lucio phenomenon usually occurs in well-developed, untreated Latapi lepromatosis. Hemorrhagic infarcts arise in crops and have the serrated margins characteristic of septic infarcts (Fig. 186-10; see eFigs. 186-10.1 and 186-10.2 in on-line edition). Lesions are painful but not tender to palpation. Lesions usually crust and may heal with stellate scaring. Ulceration is common, especially below the knees. Lesions vary in size and extent, ranging from a few small lesions on the ankles to many large lesions, placing life in peril. With dapsone alone, lesions may worsen, but in our experience, with one exception, new lesions ceased within 1 week of beginning rifampin.[31] Microscopic changes include ischemic necrosis of the epidermis, deep dermal vessel occlusion by endothelial proliferation, and heavy parasitization of endothelial cells by acid-fast bacilli (see eFig. 186-10.3 in on-line edition).

▲ **FIGURE 186-10** Lesions of the Lucio reaction, which show the characteristic hemorrhagic infarcts and serrated borders. An erythematous halo is characteristic, but is usually gone within 1 week, reflecting microbicidal treatment or aging of the lesion. Lesions are painful but not tender. The patient has Latapi lepromatosis as manifested by diffuse infiltration, total alopecia of the eyelashes and brows, perforation of the nasal septum, no nodular lesions, and severe stocking-glove pattern of sensory impairment. (From Quisimoro FP et al: Lucio's phenomenon: An immune complex deposition syndrome in lepromatous leprosy. *Clin Immunol Immunopathol* **9**:185, 1978.)

HISTOPATHOLOGY

LABORATORY TESTS

Immunopathology and Immunology

Investigation into the immunology of leprosy offers three promises: (1) a better understanding of the disease itself; in particular, the immunopathogenesis of the granulomatous spectrum and the reactional states; (2) eradication or control of the disease by vaccination; and (3) a probe of CMI in humans that, when understood in the model of leprosy, will illuminate other disease processes.

CELLULAR IMMUNITY The great diversity of leprosy is exemplified by comparing its two polar forms. The high-resistance TT form is characterized by few lesions, rare organisms, epithelioid cell granulomas, and a tendency to self-cure. TT leprosy appears to be an entirely different disease than the low-resistance LL form, which manifests wide dissemination, abundant acid-fast bacilli, foamy macrophages, and, if untreated, relentless progression. A sharp margin on a plaque is the inscription of anti–*M. leprae* DTH on the skin; a nerve trunk palsy is its inscription on a peripheral nerve.

The observations of a positive lepromin skin test in tuberculoid subjects and unresponsiveness in lepromatous patients was the first objective and reproducible evidence that host immunity was the mechanism of polar diversity. Lymphocyte transformation tests provided an in vitro correlate of the lepromin skin test[4] and substantial evidence that mediation of polar diversity was through the cellular-immune response. On the contrary, antibody responses to *M. leprae* were found to be stronger in LL patients, indicating the humoral immunity does not lead to resistance to disease.

Immunophenotypic studies established an important difference between the lymphocyte subsets infiltrating skin lesions in tuberculoid versus lepromatous patients, with the former having a predominance of the CD4 subset (CD4/CD8 = 2:1), but the latter having a predominance of the CD8 subset (CD4/CD8 =1:2).[33] The skewing of T-cell subsets in lesions was independent of those in the peripheral blood, because all patients had a normal CD4/CD8 ratio of 2:1. Therefore, it is important to study the immune response of patients at the site of disease activity, that is, in skin lesions.

Reverse transcriptase-polymerase chain reaction studies of messenger RNA (mRNA) cytokine profiles in polar tissues have provided a functional explanation for their immunopathology. Tuberculoid lesions have a type 1 [T helper 1 (Th1) or Th1-like] pro-inflammatory profile, in particular, abundant mRNA coding for interleukin 2 (IL-2), interferon-γ (IFN-γ), and IL-12, but scant mRNA coding for IL-4 or IL-10. In contrast, lepromatous tissues have a type 2 (Th2 or Th2-like) anti-inflammatory profile, in particular, abundant IL-4 mRNA and IL-10 mRNA, but little mRNA coding for the type 1 cytokines.[34] Furthermore, $CD4^+$ T cells in tuberculoid lesions were shown to produce IFN-γ, whereas CD8 T cells in lepromatous lesions accounted for the production of IL-4.[35] The presence of type 1 cytokines likely results in strong T-cell and macrophage activation, the result being CMI to localize the infection. On the other hand, the type 2 cytokines found in lepromatous lesions likely lead to the strong antibody responses, but concomitantly inhibit T-cell and macrophage responses, resulting in progression of the infection. The importance of this paradigm is reflected in experiments designed to

augment CMI in lepromatous patients, where intradermal administration of recombinant IFN-γ to lepromatous patients reduced the number of bacilli-infiltrating tissues.[36] The decision by the host as to which cytokine profile to make, that is, type 1 or type 2, may rest with the response of the innate immune system to *M. leprae*. Cytokines produced by the innate immune system may profoundly affect the adaptive T- or B-cell responses,[37] and, in particular, the Toll-like receptors of the innate system are triggered by mycobacterial lipoproteins, causing the release of IL-12, a key inducer of the type 1 cytokine response.[15]

ANTIBODY IMMUNITY ENL is widely regarded as mediated by immune complexes. There are large amounts of anti–*M. leprae* antibodies in both LL and BL patients, but these antibodies do not confer disease protection. Also, the blood of BL and LL patients contains abundant antigens, including intact bacilli, up to 10^5/mL. Therefore, it is readily conceivable that BL and LL patients should be subject to immune complex–mediated tissue injury. The best direct support for the hypothesis that ENL is immune complex–mediated is the presence of split complement products in serum, which is consistent with extravascular complement activation within tissues.[40] Inferential evidence is that of neutrophil infiltration, suggesting an Arthus phenomenon, and an excess of glomerulonephritis in ENL patients. Also, the cytokine profile in ENL is type 2, despite a preponderance of the $CD4^+$ subset.[39] However, evidence for immune complex mediation is not yet persuasive—it has been difficult to reproduce, and it is confounded by a number of observations, including human leukocyte antigen HLA-DR framework antigen in lesional epidermis,[41] an increase in IFN-γ containing cells as determined by hybridization studies,[42] an excess of IL-2–staining cells as compared with LL tissue,[43] and the precipitation of ENL by the administration of recombinant IFN-γ.[44] Perhaps both immune complexes and cellular immunity are important in the pathogenesis of ENL.

Little is known concerning the immunopathogenesis of the Lucio reaction. Extant evidence favors immune complex mediation.[45] The abundant acid-fast bacilli in endothelial cells could be the optimum location for presentation of antigen to antibody. Its mechanism does appear to differ from that of ENL, in that there is little epidermal expression of HLA-DR framework antigen.[41,45]

Other Laboratory Tests

Most laboratory changes occur in LL or extensive BL disease. Hyperglobulinemia is the most common, giving an elevated sedimentation rate. A biologic false-positive serologic test for syphilis, anemia of chronic disease, and mild lymphopenia are also common. Clinically insignificant anti-phospholipid antibodies are present in 50 percent of LL patients, and may give rise to a lupus anticoagulant or agglutination of sheep erythrocytes (Rubino factor).[46] If examined, the stained smear of the buffy coat shows bacilli up to 10^5/mL. Elevated serum lysozyme and angiotensin-converting enzyme values reflect the extensive accumulation and activation of macrophages synthesizing these proteases. Proteinuria, not uncommon, is associated with a focal glomerulonephritis, seen mostly in patients with ENL. As manifested by high-serum follicle stimulating hormone and luteinizing hormone but low testosterone levels, the testicles are involved in a majority of men with LL, but in a minority of men with BL.

DIFFERENTIAL DIAGNOSIS

As a polymorphous disease, one approach to its differential diagnosis is by emphasizing the types of primary and secondary lesions found in leprosy as well as in the conditions that may mimic leprosy or be mimicked by leprosy.

Primary Lesions

- Macules and patches. The hypopigmentation of pityriasis alba and indeterminate leprosy mimic each other. Faintly indurated BL plaques may mimic patches. Telangiectasias may be eruptive, presenting as mats on the face and upper trunk.
- Papular to nodular lesions. In the dermis, leprosy may mimic or be mimicked by dermatofibromas, eruptive histiocytomas, lymphomas, sarcoidosis, and other granulomas. Eruptive and recurrent inflammatory subcutaneous nodules may be ENL, erythema nodosum, erythema induratum, vasculitis, etc. Palpable but not visible subcutaneous nodules in Latapi lepromatosis may mimic lipomas.
- Plaques. Erythematous plaques may mimic mycosis fungoides. Plaques without pigmentary change may be wheal-like in appearance, causing confusion with urticaria. Hypopigmented plaques may mimic papulosquamous eruptions. Islands of normal skin within a plaque may suggest psoriasis.
- Polymorphous vesiculobullous eruptions. Lesions mimicking autoimmune blistering disease may occur in ENL. Up to 30 percent of LL patients have an antibody directed to desmoglein 1. Immunoglobulin M is not uncommon at the epidermal basement membrane in LL.
- Annular lesions. Leprosy may mimic or be mimicked by annular erythemas, sarcoidosis, syphilis, or tinea.

Secondary Lesions

- Infarcts. Lucio phenomenon lesions and necrotic ENL mimic septic infarcts.
- Ulcers. Ulcers occur in Lucio phenomenon, ENL, neurotrophic ulcers of the plantar surface, and as leg ulcers secondary to venous insufficiency, a consequence of endothelial cell infection.

Clinical Constellations

- Systemic lupus erythematosus–like changes. Fusiform fingers, swan neck deformity, biologic false-positive serologic test for syphilis, anti-phospholipid antibodies, lupus anticoagulant, etc.
- Vasculitis. A true vasculitis may occur in ENL, Lucio phenomenon, and Latapi lepromatosis. Clinically, granulomatous leprosy lesions may mimic vasculitis.

Microscopic Constellations

- Common and uncommon patterns. Granulomatous responses are the common tissue reactions in leprosy, with epithelioid differentiation of macrophages being characteristic of TT, BT, and BB, and undifferentiated or foamy macrophages being the hallmark of BL, LLs, and LLp. Microscopic changes in BB are said to consist of epithelioid differentiation of macrophages, very few lymphocytes, no giant cells, but many acid-fast bacilli. Uncommon patterns can occur, sometimes dominating the histologic picture, and are (1) chronic inflammation, particularly in BL and indeterminate disease; (2) lobular panniculitis in ENL; (3) vasculitis in ENL, Lucio phenomenon, and Latapi

lepromatosis; and (4) normal skin in BL or LL. At the level of the low-power objective, normal skin, a patchy infiltrate involving both the papillary and reticular dermis, or a bizarre "sausage-shaped" infiltrate (following neurovascular bundles) should prompt inclusion of leprosy in the differential diagnosis.

DIAGNOSIS

Criteria for Diagnosis

A firm diagnosis of leprosy requires the satisfaction of one of two criteria: a consistent peripheral nerve abnormality or the demonstration of acid-fast bacilli in tissues. In nonendemic areas, the diagnosis is often difficult, but only because the possibility of leprosy is not considered. There is no test or series of tests that will prove that the patient does not have leprosy.

Because *M. leprae* does not grow in cell-free media, demonstration of mycobacteria by their acid-fast property is used most commonly in diagnosis. Acid-fast bacilli in tissue sections are best shown by carbolfuchsin staining, using modifications of the Ziehl-Neelsen method, collectively called Fite-Faraco stains. *M. leprae*, like *Nocardia* species, is only weakly acid-fast. In smears, either the Ziehl-Neelsen method or auramine-rhodamine staining with fluorescent microscopy is satisfactory. Because of characteristic clinical and histologic changes, positive specification of *M. leprae* is rarely required.

Characteristic histologic changes are extremely helpful in suggesting or corroborating a diagnosis of leprosy, but, excepting the presence of epithelioid cell granulomas within nerves, are not absolutely diagnostic.

False Negatives

False Positives

Alternative Methods

Alternative methods of establishing a diagnosis have been pursued but, at present, are of limited value. *M. leprae*–specific antibodies are most prevalent in multibacillary cases, in which diagnosis is readily made by clinical criteria, and in endemic areas, high antibody titers are far more prevalent than the disease, thus further restricting their use.[14] Reverse transcriptase-polymerase chain reaction may be negative in up to one-half of paucibacillary cases, making a positive signal of value but a negative signal of no help. PCR should be helpful in the diagnosis of patients with lesions having acid-fast bacilli but no stigmata of leprosy and negative cultures.[47] Lepromin skin testing, because of the high rate of positive reactions in unaffected adults, is not useful in diagnosis, but can be of value in classification of patients. All TT and most BT (85 percent in our experience) are positive (3 mm or more of induration at 21 days) and BB through LLp are negative (< 3 mm). Gene expression profiling may provide new tests for the diagnosis and/or classification of leprosy.[22]

COMPLICATIONS

The complications of leprosy, as contrasted to the injury resulting directly from the host's response to *M. leprae*, arise for peripheral nerve injury or venous insufficiency. Approximately one-fourth to one-third of newly diagnosed patients with leprosy have, or will eventually have, some chronic disability secondary to irreversible nerve injury, usually of the hands or feet, or from eye involvement. Collapse of the nose in LL is from the contracture of the scar tissue, which has replaced the bone and cartilage.

Ocular Disability

Exposure keratitis may result from a variety of factors including a dry eye, corneal insensitivity, and lagophthalmos. The keratitis and the anterior chamber lesions, most commonly iritis, may result in blindness.

Disability of Hands and Feet

Weakness from loss of innervation of muscles is a self-evident cause of disability. Loss of protective sensation is less obvious, but no less real. When a sharp or hot object cannot be perceived as such, injury occurs. Because this injury is more severe than if sensation were normal, infection is more apt to occur. Because the infection can produce no painful signal, the part is not rested, allowing the infection to become extensive before help is sought. Repetitive cycles of injury and infection, permitted by loss of protective pain sensation, is the source of severe tissue destruction in leprosy. Contracture secondary to muscle weakness or scar formation may produce further deformity. Charcot's joints are another source of deformity. Dryness of palm or soles from sympathetic involvement further compounds these problems.

Venous insufficiency, secondary to endothelial involvement of deep vein valves, leads to stasis dermatitis and leg ulcers.

Management and prevention of the problems arising from nerve injury require the skills of orthopedic surgeons, ophthalmologists, podiatrists, plastic surgeons, physical therapists, orthotists, and occupational therapists.

PROGNOSIS AND CLINICAL COURSE

In untreated leprosy, the only patients who will self-cure are those with TT, or BT patients who upgrade to TT. Otherwise, the disease will be progressive, with morbidity occasioned by nerve injury and a reactional state. BT, BB, BL, and LLs may upgrade, BT, BB and BL may downgrade, and BL, LLs and LLp may develop ENL.

Treatment arrests much of disease activity, but S-GPSI may progress. Peripheral neuritis of recent onset may improve with corticosteroid treatment. Like the post-polio syndrome, late-arising sensory impairment is sometime seen and is difficult to understand and to manage.

TREATMENT

Medical management is directed at the infection itself, and, if present, at a reactional state[8] (Boxes 186-1 and 186-2). As mentioned in Etiology and Pathogenesis, a patient is considered to be "paucibacillary" if no acid-fast bacilli are found in tissue or smears and to be "multibacillary" if one or more acid-fast bacilli are found. Please see Box 186-1 for the different regimens recommended by the World Health Organization (WHO)[48] and the U. S. Public Health Service (USPHS).[49,50]

The rationale for recommending three drug regimens is that rifampin (bactericidal) will kill all susceptible organisms, including those resistant to dapsone (bacteriostatic), and dapsone will eventually eliminate all susceptible organisms, including those resistant to rifampin. Clofazimine (weakly bactericidal, mainly bacteriostatic) is added to obviate the risk of primary dapsone resistance. The absence of routine follow-up in the WHO recommendations per-

Antibacterial Treatment of Leprosy Recommendations

RECOMMENDING ORGANIZATION	DISEASE TYPE	RIFAMPIN	DAPSONE	CLOFAZIMINE	DURATION	FOLLOW-UP
World Health Organization	PB	600 mg/mo	100 mg/day	—	6 mo	No mandated follow-up. To return prn.
	MB	600 mg/mo	100 mg/day	50 mg/day 300 mg/mo	1 yr	No mandated follow-up. To return prn.
U.S. Public Health Service	PB	600 mg/day	100 mg/day	—	1 yr	At 6 mo intervals for 5 yr.
	MB	600 mg/day	100 mg/day	50 mg/day	2 yr	At 6 mo intervals for 10 yr.

OTHER MICROBICIDAL AGENTS	DOSE
Clarithromycin	500 mg/day
Minocycline	100 mg/day
Levofloxacin	500 mg/day

MB = multibacillary or 1 or more acid-fast bacilli found on smear of biopsy; PB = paucibacillary or no acid-fast bacilli found on smear or biopsy.

haps reflects expectations of a low relapse rate, as well as a low rate of post-treatment reactional states. The presence of semi-annual follow-up visits for up to 10 years in the USPHS recommendations perhaps reflects a differing opinion as to the frequency of non-compliance, bacterial relapse, and post-treatment reactional states.

The rate of relapse after completion of a triple drug regimen is controversial. Most observers concur with the WHO[51] that relapse is rare. A small but growing minority have presented evidence that relapse is a serious problem, approaching 20 percent 10 years after stopping treatment in patients with a BI of 3 or more.[52–55] Shetty et al.[55] have reported on relapses, have reviewed the other reports, and have offered reasons for the controversy. One group reported relapses beginning 6 years after completion of 2 years of triple drug therapy.[54] Two groups reported relapse after smear negativity had occurred.[54,55] Also, a 1-year course of treatment had a higher relapse rate than did a 2-year course.[53] The reported relapses are not considered to be re-infection. Opinion varies as to how to cope with this problem. The WHO plan depends upon the patient's self-referral. The USPHS recommendations would allow resumption of treatment based upon a physician's evaluation. Another approach is to continue dapsone alone indefinitely, after completing multiple drug therapy.

In addition to rifampin, a number of antibiotics have potent bactericidal activity, including minocycline, clarithromycin, and the fluoroquinolones, ofloxacin and levofloxacin. Taking a single dose of three drugs, rifampin, ofloxacin, and minocycline, is being studied as treatment for paucibacillary disease, but the relapse rate has not been determined.[56] Because of their expense, the use of the above agents on a daily basis is prohibitive in the areas where leprosy is common and health care funds scarce. Also, it is not known if some combinations of these potent microbicidal agents, an attractive idea a priori and by analogy to tuberculosis, would have any advantage over the WHO and USPHS recommendations, but they were well tolerated in a small trial.[57]

Because the incidence of primary dapsone resistance is low in our multibacillary patient population,[58] we often use the combination of rifampin, 600 mg daily, and dapsone, 100 mg daily, for 2 to 3 years. Then the choice of continuing dapsone indefinitely or confronting an uncertain relapse rate is discussed with the patient.

In reversal reactions (see Box 186-2), because of the risk of permanent nerve damage, prompt institution of prednisone therapy (0.5 to 1.0 mg/kg/day) is recommended. The dose of prednisone is titrated against overt nerve tender-

Box 186-2

Medical Management of Reaction States

	THALIDOMIDE	PREDNISONE OR PREDNISOLONE	DURATION	OTHER AGENTS OF UNPROVEN VALUE
Reversal reactions (type 1 reactions)	Of no value	0.5–1.0 mg/kg. Rifampin may increase their catabolism. Taper slowly. Alternate-day treatment may be well tolerated.	Usually needed for 6 mo–2 yr. May be longer or shorter.	Nonsteroidal anti-inflammatory agents
Erythema nodosum leprosum (type II reactions)	The most efficacious drug if available and not contraindicated Initially 1 dose of 100–200 mg qd hs Maintainable dose range 50 mg every other day to 500 mg daily	If thalidomide not available, 0.5–1.0 mg/kg/day.	Median duration of treatment is approximately 5 yr. Can persist for 10 yr.	Pentoxifylline
Lucio phenomenon (usually ceases with use of a microbicidal agent)	Of no value	May be helpful.	—	Plasmapheresis reported as helpful in unremitting patients

ness, the patient's symptoms, and careful sensory evaluation of hands and feet, for example with graded Semmes-Weinstein filaments. Therapy should be tapered slowly and the patient cautioned that 6 months or more of prednisone may be needed. If the response of a neuritis to prednisone is not prompt, then rest, enforced with splinting of affected extremities, is advised.

In ENL (see Box 186-2), thalidomide (see Chap. 236) is dramatically effective in a majority of patients if available and not interdicted by its teratogenic effects. The needed dose ranges over one order of magnitude. We usually start with 100 to 200 mg nightly and, if it is only partially effective, we may add prednisone in a 0.5 to 1.0 mg/kg range, tapering the prednisone over the subsequent 6 to 8 weeks. Alternatively, we increase the dose of thalidomide until obtaining a therapeutic or toxic affect, having gone as high as 600 mg at bedtime. Thalidomide is slowly tapered as dictated by abolition of systemic symptoms or morbidity from skin lesions but not the complete disappearance of skin lesions. If thalidomide cannot be used, then corticosteroids may be needed. Management with nonsteroidal anti-inflammatory agents, clofazimine, or pentoxifylline has been found useful by some, but have been disappointing in our hands.

ADVERSE EFFECTS OF DRUGS USED IN LEPROSY

Adverse reactions to dapsone (see Chap. 226) in the short term include the dapsone syndrome, a rare, potentially fatal infectious mononucleosis-like condition, and three kinds of hemolytic anemia, almost universally from a direct membrane effect, uncommonly from a glucose-6-phosphate deficiency, and rarely from an idiosyncratic response. In the long term, dapsone is associated with peripheral neuropathy, usually motor with a sensory component, and, rarely, bone marrow suppression, especially agranulocytosis.

The serious problem with rifampin is hepatotoxicity. Red urine is alarming but banal. As a P_{450} inducer, rifampin may lessen the effect of other drugs, for example, oral contraceptives and corticosteroids. Once-monthly use is rarely associated with severe hemolysis or acute renal failure.

Clofazimine produces skin darkening from the clofazimine itself in the near-term and from a ceroid-lipofuscin pigment in the long-term (see eFig. 186-10.22 in on-line edition).[59] At usual doses of 50 to 100 mg a day, gastrointestinal intolerance, dry skin, and acquired ichthyosis are common. Prolonged administration of large doses may produce a novel enteropathy secondary to mucosal and enteric lymph node drug accumulation. Accumulation in the spleen may predispose to rupture.

Thalidomide (see Chap. 236), infamous for teratogenicity, may produce constipation and dizziness. Neuritis, a common side effect in non-leprosy patients, appears to be rare in ENL patients. An idiosyncratic intolerance is uncommon.

Long-term use of minocycline may be limited by hyperpigmentation, more common in leprosy than in acne, perhaps related to the large accumulation of macrophages in leprosy. We have seen both diffuse hyperpigmentation and intense hyperpigmentation at the site of lesions, usually on the legs or feet (see eFig. 186-10.23 in on-line edition).

Corticosteroids, in addition to their well-known side effects, may also exacerbate co-existing diseases, for example, tuberculosis, hepatitis B, and some parasitic conditions.

PREVENTION

Protocols endeavoring to control leprosy by vaccination usually consist of bacille Calmette-Guérin alone, viable bacille Calmette-Guérin in combination with killed *M. leprae*, or killed *M. leprae* alone.[60] Most studies support a reduction in leprosy incidence, roughly one-third in tuberculoid cases, considerably less in lepromatous. The recent observation that lipid and lipoglycan antigens are presented to T cells ($CD4^-$, $CD8^-$, $CD3^+$) by $CD1^+$ cells opens the door to entirely new vaccination protocols.[61] Other preventive measures, such as isolation of patients or treatment of patient contacts with antimicrobials, have been disappointing.

CHAPTER 187

Lyme Borreliosis

Meera Mahalingam
Jag Bhawan
Anne-Marie Chomat
Linden Hu

Lyme borreliosis, or Lyme disease, is the most commonly reported arthropod-borne illness in both the United States and Europe.[1] It was first recognized in the 1970s after epidemiologic investigations of a clustering of cases of oligoarthritis among children in eastern Connecticut established a probable microbial etiology for the disease.[2] In 1981, Burgdorfer isolated a new spirochetal bacterium, *Borrelia burgdorferi*, from the midgut of the *Ixodes dammini* tick (now *I. scapularis*).[3] Recovery of the organism subsequently from cutaneous lesions, cerebrospinal fluid (CSF), and blood specimens of patients with Lyme disease in both the United States[4,5] and Europe[6–8] definitively linked the disease with *B. burgdorferi*.

EPIDEMIOLOGY

In the United States, the Centers for Disease Control and Prevention (CDC) initiated surveillance for Lyme disease in 1982, and the Council of State and Territorial Epidemiologists made Lyme disease a nationally notifiable disease in 1991. Since 1982, there have been more than 200,000 cases reported to the CDC. In 2003, the number of new cases in the United States was 21,273 (national incidence 7.22 cases per 100,000 people). There is believed to be significant under-reporting of Lyme disease, and the real number of new cases each year in the United States is actually thought to approach 150,000. In 2003, approximately 95 percent of cases occurred in 12 states located in the northeastern, mid-Atlantic, and north central regions: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin. All states except Hawaii, Montana, and Oklahoma reported cases in 2002.[1]

Lyme disease is also widely distributed in Europe, with an estimated 120,000 new cases each year.[9] The highest reported frequencies occur in forested areas of central and Northern Europe (Germany, Austria, Slovenia, and Sweden).[10,11] The infection is also found in eastern Russia, China, Korea, and Japan.[12]

ETIOLOGY

Organism

Borrelia burgdorferi sensu lato, the agent of Lyme borreliosis, belongs to the eubacterial phylum of Spirochaetales, which are vigorously motile, corkscrew-shaped bacteria. The borrelial genome is made up of a linear chromosome and more than 20 circular and linear plasmids, the largest number known for any bacteria.[13] Some of the plasmids can be considered minichromosomes, as they are required for survival of the organism. Among the interesting characteristics of the organism are the large number of lipoproteins (more than 150) encoded by the genome. *B. burgdorferi*'s genome encodes no toxins or other identified virulence factor. *Borrelia* also lack biosynthetic machinery to produce many essential nutrients (e.g., amino acids, fatty acids) suggesting that *B. burgdorferi* is highly dependent on its hosts for obtaining crucial nutrients.[14]

Eleven *Borrelia* sp. have been described worldwide within the *B. burgdorferi sensu lato* complex. Only three—*B. burgdorferi sensu stricto*, *B. afzelii*, and *B. garinii*—have been confirmed to be pathogenic in humans and to cause Lyme borreliosis, although other species are under investigation for their relationship to human diseases (including *B. bissettii*[15,16] and *B. lonestari*[17]).

In the United States, the etiologic agent of Lyme disease is exclusively *B. burgdorferi sensu stricto*. *B. afzelii* and *B. garinii* cause the majority of Lyme disease in Europe, although *B. burgdorferi sensu stricto* is also present.[18] In Asia, only *B. afzelii* and *B. garinii* have been confirmed to exist.

Enzootic Life Cycle of the Agent of Disease

B. burgdorferi is maintained in nature through a cycle involving small rodents, birds, and ticks of the *Ixodes* species.[19,20] Although not important reservoirs for *B. burgdorferi*, deer are an important feeding source for adult ticks and reductions in deer populations can lead to significant decreases in the tick population.[21]

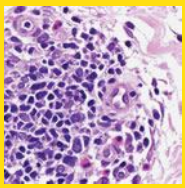
Ixodes ticks have a 2-year, three-stage (larval, nymphal, and adult) life cycle. Larval ticks acquire *B. burgdorferi* organisms by taking a blood meal from an infected animal and maintain the infection during the subsequent molting to the nymphal and adult stages. *B. burgdorferi* remain dormant in the tick's midgut between feedings.[22] Each tick life stage takes one blood meal: larval ticks feed in late summer, nymphal ticks feed the subsequent spring and early summer, and adult ticks feed in the fall and early winter. The major reservoirs for *B. burgdorferi* are small rodents and birds that are fed on by larval and nymphal ticks. Adult ticks feed on larger mammals (e.g., deer) that are not important reservoirs for *B. burgdorferi*. Humans are incidental hosts not important in maintaining *B. burgdorferi* in the wild. Most cases of human illness occur in the late spring and summer months when the nymphs are most active and human outdoor activity is greatest.

Of clinical relevance, certain *Ixodes* ticks are vectors of other tick-borne illnesses in addition to Lyme disease: *I. scapularis* ticks in the United States and *I. ricinus* ticks in Europe may transmit *Babesia microti* (a red blood cell parasite) or *Anaplasma phagocytophilum* (formerly referred to as the agent of human granulocytic ehrlichiosis).[23,24] *I. ricinus* in Europe and *I. persulcatus* in Asia are also vectors of tick-borne encephalitis virus.[25]

Pathogenesis

Once in the host's skin, *B. burgdorferi* begins to spread from the initial inoculation site rapidly into the bloodstream where it disseminates to multiple sites.

LYME DISEASE AT A GLANCE



- Lyme disease is caused by *Borrelia burgdorferi*, a spirochete.
- Clinical course can be prolonged and may involve multiple organ systems.
- Cutaneous hallmarks are erythema migrans and acrodermatitis chronica atrophicans.
- Diagnosis is typically made on clinical grounds and/or serologic testing.
- Early treatment with antibiotics (doxycycline, amoxicillin, or cefuroxime) is highly successful.

Time from inoculation to dissemination varies from as little as 3 days to weeks.[5]

B. burgdorferi has developed strategies to adapt to and survive in markedly different microenvironments.[26] The organism expresses a variety of proteins during its life cycle, facilitating binding to different host proteins, migration within host tissues, transmission, and evasion of the host immune response.[27,28] A well-documented example of host adaptation is the variable expression of outer-surface proteins (Osp) A and C. OspA, primarily expressed while the spirochete is dormant in the tick's midgut,[29] is thought to serve as an anchor by binding the tick midgut protein, TROSPA.[30] When the tick engorges on a host, *B. burgdorferi* down-regulates OspA, releases from the midgut, and begins to multiply and travel to the salivary glands. This process takes between 24 and 48 hours, which explains why removal of the tick before 24 hours of attachment prevents transmission of disease.[31]

As the organism downregulates OspA, it upregulates OspC, which facilitates migration from the tick's gut to its salivary glands. OspC binds to a tick salivary protein, Salp15, which protects the organism from clearance by host immune defenses.[32] Immunosuppressive characteristics of tick saliva also aid in the establishment of early infection. *B. burgdorferi* also bind host factor H to protect itself from complement-mediated killing.[33,34] Specificity of strains of *B. burgdorferi* for factor H from different animal species may, in part, explain differences in host range between the species. *B. burgdorferi* have been shown to upregulate host proteases such as matrix metalloproteinases in the skin and joints which may play a role in pathogenesis by digesting extracellular matrix proteins and allowing dissemination, but this requires further clarification.[35]

Immunology

Both innate and acquired immune defenses have important roles in the control of *B. burgdorferi* infection; however, neither can typically eradicate the disease.[36,37] Phagocytosis, both complement-mediated and non–complement-mediated, is the first line of host defense against *B. burgdorferi*.[38,39] Natural antibodies (polyclonal IgM antibodies) may also function as a first line of defense against *B. burgdorferi*, killing spirochetes in the tick midgut during the blood meal and limiting pathogen burden before the development of a specific adaptive immune response.

Once inside the host, *B. burgdorferi* is a strong inducer of inflammation. Its outer surface lipoproteins are potent inflammatory stimuli.[40–42] Recognition of borrelial lipoproteins occurs through binding to Toll-like receptor 1 and 2 heterodimers, which initiates a cascade of intracellular signaling events culminating in the production of pro-inflammatory cytokines, chemokines, and other molecules important in host defense. Studies using Toll-like receptor–deficient mice have shown that other signaling pathways are also activated by *B. burgdorferi* and result in release of inflammatory mediators. Among the other innate immune receptors recognizing *B. burgdorferi* and mediating inflammation are integrin receptors.[43,44]

Development of a specific humoral immune response generally occurs over weeks to months.[45,46] The IgM response usually peaks between 3 and 6 weeks after disease onset and may remain elevated for months to years; the immunoglobulin G (IgG) response usually follows the IgM response by several weeks so that approximately 90 percent of patients have detectable IgG levels 4 to 6 weeks into the infection. The development of the humoral antibody response typically heralds a significant decrease in the number of organisms and decrease in the level of inflammation. Of note, the acquired humoral response is not typically protective against reinfection, in part due to significant sequence variability in protective antigenic epitopes between *B. burgdorferi* strains and the lack of expression of less variable protective antigens (e.g., OspA) in the mammalian host.[47]

CLINICAL MANIFESTATIONS

The clinical course of Lyme disease is typically described in stages that parallel that of another spirochetal disease, syphilis: early-localized, early-disseminated, and late-disseminated. Localized disease closely follows the bite of an infected tick and is characterized by the erythema migrans (EM) rash with or without constitutional symptoms. Early-disseminated Lyme disease presents days to months after onset of infection as a number of distinct clinical entities affecting the skin, joints, nervous system, and heart. Late-disseminated Lyme disease typically presents in only a subgroup of untreated patients months to years later, and manifests as chronic symptoms localized most often to the skin, joints, and nervous system. A minority of patients go on to develop prolonged post-treatment syndromes. These include a syndrome of antibiotic-resistant arthritis thought possibly to be autoimmune in nature, and, separately, a constellation of symptoms with similarities to fibromyalgia and chronic fatigue syndrome. The relationship of these latter symptoms to infection with *B. burgdorferi* is still debatable.

The disease caused by each species of *B. burgdorferi* is largely the same but certain clinical manifestations are more closely associated with infection due to a particular species.[18,48] For instance, *B. burgdorferi sensu stricto* is the most arthritogenic of the three Borrelia species.[49] For this reason, Lyme arthritis is the most frequent presentation of late Lyme disease in North American patients. Similarly, because *B. afzelii* is the species that has most often been associated with late skin manifestations; some dermatologic conditions [e.g., acrodermatitis chronica atrophicans (ACA) and borrelial lymphocytoma] are nearly exclusively found in Europe. Finally, *B. garinii*, the most neurotropic of the three species, causes a wide range of neurologic abnormalities.

Early Cutaneous Manifestations of Lyme Disease

ERYTHEMA MIGRANS ***Clinical Features.*** In early case reports, EM lesions were reported in 50 percent to 80 percent of patients with Lyme disease. More recent studies have shown lower rates of EM, likely due to improved patient education. Definite history of tick bite at the site of the lesion is obtained in only a small proportion of patients.[53] The lesion itself is believed to be the result of the direct presence of the spirochete, corroborated by reports showing aspiration and cultivation of the organism from the lesion. EM lesions develop within 3 to 30 days of the tick bite (median, 7 days).[54]

EM may be seen anywhere on the body but is most common on the lower extremities, inguinal and axillary regions of adults (Fig. 187-1), and on the face in children ("slapped cheek" appearance) reflecting sites of predilection of the tick.[2] Although no definite sex predilection has been noted in the United States, women are reported to be more commonly affected in European studies.[8]

The skin lesion has a characteristic and pathognomonic appearance (see Fig. 187-1) of an expanding erythema en-

▲ **FIGURE 187-1** Lyme borreliosis. Erythema migrans in the groin with expanding margin at the site of the tick bite of a week's duration. (Reprinted with permission from *Dermatopathology Interactive Atlas*, edited by Bhawan J, Sau P, Byers HR, 2001; http://www.dermpathatlas.com.)

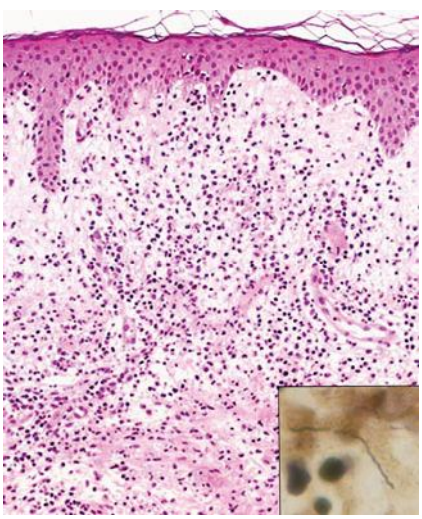
circling the bite site, with the transition between the central zone and periphery being less well demarcated than between that of the periphery and adjacent skin.[53] The border is usually confluent and not patchy. Cases in which the erythema appears stationary or even linear are reported.[5] Typically described as round, the lesion in reality is more oval with the "long line of the oval parallel to the lines of least skin tension" (Langer lines) (see Fig. 187-1).[55] As migration of the lesion proceeds, distortion of this configuration occurs.[56] The center fades after a few weeks leaving only the annular border erythematous (see eFigs. 187-1.1 and 187-1.2 in on-line edition). In very large lesions, only a portion of the erythematous border can be seen (see eFig. 187-1.3 in on-line edition). Uncommon presentations include the entire lesion being homogenously erythematous ("solidly erythematous") (10 percent), forms with marked central necrosis, minimal size EM (size of the ring less than 5 cm at initial presentation) (2 percent), and the vesicular variant (5 percent).[57–59]

The lesion in itself is usually asymptomatic, but 50 percent of patients report mild tingling or itching.[60] Systemic manifestations, reported in approximately 50 percent of patients, may appear before, during, or after the classic rash.[53,56]

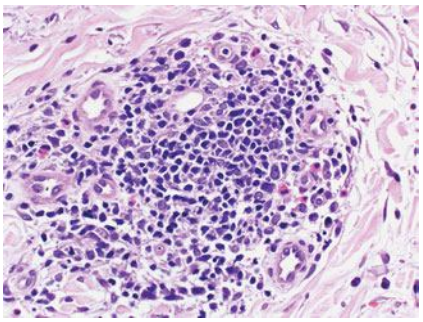
EM has an excellent prognosis, attributable in part to the activation of proinflammatory cytokines such as interferon-γ.[61] EM usually heals spontaneously, but may persist for as long as 6 to 12 months; median duration of the rash in the United States is approximately 4 weeks and in Europe is approximately 10 weeks.[8,18,60]

Multiple EM-like lesions occur in between 1 percent and 17 percent of patients.[53] The reported prevalence of multiple lesions is believed to be higher in the United States (25 percent to 48 percent) than in Europe (8 percent or less).[62] The spatial relationship of multiple lesions to the initial lesion indicates that they may be the consequence of hematogenous dissemination. Secondary EM lesions number from 2 to more than 80, usually occur away from the original lesion, and are usually smaller and less migratory (occur in "crops" of similar size, color, and shape) in comparison to classic EM.[53] Lesions are usually asymptomatic and if untreated spontaneously resolve over weeks to months. Like the primary lesion, secondary EM expands over days to weeks resulting in both solid and annular erythema. Primary EM may still may be present but more often a primary lesion is not found. Constitutional symptoms are usually more severe than those associated with classic EM.[57]

Histopathologic Features. Histopathologic findings vary with the biopsy site[56] and age of the lesion. Biopsies of early lesions show papillary dermal edema and a mixed infiltrate of lymphocytes, neutrophils, a few plasma cells, and a few eosinophils (Fig. 187-2). Biopsies of older lesions display a variably dense perivascular and interstitial infiltrate of lymphocytes and plasma cells (Fig. 187-3). Helpful, albeit non-specific, clues include the



▲ **FIGURE 187-2** Histopathology of erythema migrans. Papillary dermal edema, mixed infiltrate of lymphocytes, neutrophils, few plasma cells, and few eosinophils (hematoxylin and eosin stain). *Inset* shows a spirochete in same biopsy stained with Warthin-Starry stain (oil immersion). (Reprinted with permission from *Dermatopathology Interactive Atlas*, edited by Bhawan J, Sau P, Byers HR, 2001.)



▲ **FIGURE 187-3** Histopathology of erythema migrans. Dense nodular perivascular lymphoid cell infiltrate with many plasma cells and few eosinophils in a biopsy from a later stage of erythema migrans. (Hematoxylin and eosin stain, ×40.)

presence of plasma cells and mast cells in the infiltrate.[63] The presence of plasma cells and eosinophils in the same specimen is reported to be much less common than the presence of either alone.[56]

Immunohistochemical studies indicate the infiltrate to be composed of $CD4^+$ T lymphocytes with the exception of those seen in association with HIV infection in which the infiltrate is mainly $CD8^+$ T lymphocytes, reflective of the CD4 lymphopenia of HIV infection.[64]

Histopathologic features of multiple lesions of EM are identical to primary EM.

Diagnosis. The diagnosis of EM is typically made on clinical appearance in patients in an endemic area. From biopsy specimens, spirochetes are best located in the papillary dermis and may be short or elongate at this stage of the disease (see Fig. 187-2 inset).[56] Direct detection of the spirochete from biopsy specimens by culture or by polymerase chain reaction (PCR) typically has good sensitivity but is usually unnecessary.[65]

Diagnosis and Differential Diagnosis. Atypical lesions exist and broaden the clinical differential diagnosis to include cellulitis, tinea, contact dermatitis, or a fixed drug reaction (Table 187-1). The differential diagnosis of vesicular EM includes poison ivy, contact dermatitis, cellulitis, herpes simplex, and impetigo.

Late Cutaneous Manifestations of Lyme Disease

ACRODERMATITIS CHRONICA ATROPHICANS

Clinical Features. Observed mainly in elderly patients in Europe, ACA has an insidious onset and appears to have predilection for females.[66] Rare cases of ACA have been reported in children.[67] The time interval from the spirochete inocu-

TABLE 187-1
Cutaneous Manifestations of Lyme Disease

	Onset	Diagnosis/Differential Diagnosis
Common Manifestations		
Erythema migrans	Weeks to months (early)	Arthropod bite, erythema multiforme granuloma annulare, urticaria, erysipelas, brown recluse spider bite, fixed drug eruption
Acrodermatitis chronica atrophicans	Months to years (late)	Venous insufficiency, lichen sclerosus, scleroderma, physiologic age-related atrophy, corticosteroid-induced atrophy
Uncommon Manifestations		
Cutaneous scleroborrelioses	Months to years (late)	
Morphea		Primary morphea
Lichen sclerosus et atrophicus		Primary lichen sclerosus et atrophicus
Periarticular fibrous nodules		Rheumatoid nodule, gouty tophi
Progressive facial hemiatrophy		Primary progressive facial hemiatrophy/Parry-Romberg syndrome
Eosinophilic fasciitis		Primary eosinophilic fasciitis/Shulman syndrome
Cutaneous atrophoborrelioses	Months to years (late)	
Anetoderma		Primary anetoderma
Cutaneous lymphoborrelioses	Months to years (late)	
B-cell dominant (including B-cell lymphoma)		Arthropod bite reaction, response to vaccination, granulomas, neoplasm
T-cell dominant		Pityriasis lichenoides, polymorphous light eruption
Other cutaneous lesions	Weeks to months to years (early or late)	
Panniculitis		Erythema nodosum
Granuloma annulare		Insect bite reaction
Erythema multiforme		Drug eruption
Syphilis-like papulo-squamous eruption		Secondary syphilis

lation to the onset of symptoms of ACA is extremely difficult to evaluate. Most patients do not recall the specific tick bite that initiated the disease.[8,68] That the spirochete can survive for decades is favored by reports indicating transmission of the disease from ACA patients even after 20 years.[8]

An inflammatory phase characterizes the early clinical stages of this biphasic disease.[69] The inflammatory phase presents as a bluish-red discoloration on the extensor aspect of fingers, hands, joints, and lower extremities (see eFigs. 187-3.1 and 187-3.2 in on-line edition). Joints usually involved include the elbows and knees. Infiltrated purple bands of varying widths may be observed adjacent to involved joint(s). Associated findings include a cushion-like ("doughy") swelling of the dorsum of the hands and feet (see eFig. 187-3.2 in on-line edition).[69] The extremities are most commonly involved, although extensive lesions on the trunk have also been documented. Lesions typically extend from the distal to the proximal portion of the extremity involved. Although the erythema and swelling initially vary in intensity ("waxes and wanes"), swelling of the posterior aspect of the lower extremities is believed by some to be particularly indicative of Lyme disease.[60]

Cutaneous atrophy (Fig. 187-4) characteristic of the later clinical stage is not an obligatory sequel to the inflammatory phase of ACA.[69] Rarely, coexistence of both kinds of lesions at different sites in the same patient has been documented. The atrophic phase is characterized by lesions with a "cigarette paper-like" appearance and a prominence of superficial veins (see Fig. 187-4).

▲ **FIGURE 187-4** Acrodermatitis chronica atrophicans. Typical end-stage cutaneous atrophy with prominence of superficial veins.

Extracutaneous Features. Central and peripheral nervous system involvement has also been documented in approximately 45 percent of patients with ACA. Thirty percent to 45 percent of patients suffer from a polyneuropathy, often most pronounced in the limb with cutaneous involvement.[62] Chronic joint and bone involvement, attributed to persistence of spirochetes in cutaneous lesions, is most often seen in patients with long-standing ACA or an untreated lesion of EM/ACA and is typically restricted to the extremity involved. The characteristic symptom, exhibited in approximately one-third of patients in one study, was a swollen or painful foot and heel.[62] Other symptoms include subluxation of small joints, bursitis, arthritis, and cortical thickening of bone. Solitary or multiple fibrotic lesions near joints, particularly in the olecranon area, may develop in some patients.[69]

Histologic Features. All three species of *B. burgdorferi* that infect humans have been found in ACA lesions.[71] Histopathologic features of biopsied lesions vary with the clinical phase of ACA. In inflammatory lesions, three layers are typically described: an atrophic epidermis, a zone of uninvolved papillary dermis, and a layer of inflammatory cells composed of lym-

phocytes and plasma cells.[72] The presence of plasma cells in the infiltrate is documented mainly from studies from Europe, as American reports indicate that few or no plasma cells are found.[68,69] The infiltrate may be deep with extension into the subcutis.[60] Occasionally, interface dermatitis has been reported. Unusual findings include the presence of vacuoles, either singly or in groups, at different levels of the dermis.[73] Although some believe these represent mature adipocytes, others believe them to be an expression of lymphedema, given that they are mainly observed from biopsies of markedly edematous sites. In favor of the latter hypothesis is the absence of such vacuoles from the same site post-treatment.

Phenotypic studies indicate the lymphocytes in the infiltrate are mainly of the CD4 phenotype, favoring the concept that ACA is a T cell–mediated immune response.[74] Further in support of this theory is the expression of adhesion molecules, such as intracellular adhesion molecule-1, on endothelial cells, lymphocytes, and basal keratinocytes in the inflammatory infiltrate.[75] Chronicity of the lesions may be partially explained by down-regulation of major histocompatibility complex class II molecules on Langerhans cells.[76]

Diagnosis and Differential Diagnosis. Lesions of ACA are notoriously overlooked or misinterpreted. In those with a relevant clinical history, the onset appears to be related to an untreated lesion of EM and/or neurologic manifestations. In one study, a history of EM months to years earlier on the same side was found in approximately 18 percent of patients.[76] Differential diagnoses are listed in Table 187-1.

Detection of the spirochete substantiates the infective etiology, further supported by positive serologic findings. The latter are of great utility in the diagnosis of ACA. Antibodies to *B. burgdorferi* can be detected in almost all (100 percent) of patients with ACA even years after treatment.

CUTANEOUS SCLEROBORRELIOSES ***Clinical Features.*** Sclerotic skin lesions clinically indistinguishable from primary lichen sclerosus et atrophicus (LSA) or morphea (see eFig. 187-4.1 in on-line edition) develop not only in association with other dermatoborrelioses [approximately 10 percent of patients with ACA and borrellial lymphocytoma (see Uncommon Cutaneous Manifestations of Lyme Disease)] but also in the absence of other cutaneous manifestations of Lyme disease.[57,77,78]

▲ **FIGURE 187-5** Lyme borreliosis. Fibrotic nodules and multiple large, firm subcutaneous nodules on both elbows.

Periarticular ("ulnar") fibrous nodules (Fig. 187-5), described in association ACA, may also occur in the absence of dermatoborrelioses.[79] They usually present as hard nodules on the elbows, knees, and on the lateral aspect of the digits near joints and have been reported to be provoked by trauma, surgery, and electromagnetic radiation.[80]

Uncommon sclerotic disorders associated with Lyme disease include progressive facial hemiatrophy (Parry-Romberg syndrome) and eosinophilic fasciitis (Shulman syndrome) (see Chap. 135).[81] In support of an infectious etiology is the clinical similarity of the cutaneous lesions, positive history of tick bite, and, in rare cases, anti-borrelial serologic evidence and positive culture and PCR from lesions.[82,83] Eosinophilic fasciitis associated with borrelial infection has been termed *borrelial fasciitis*, reflective of the infectious nature of these lesions.[81] However, patients with borrelial fasciitis lack the peripheral blood eosinophilia typical of patients with Shulman disease.

Histologic Features. A unifying feature of LSA- and morphea-like scleroborrelioses is the abundance of plasma cells in the inflammatory infiltrate.[69] Unusual histologic findings include a scleromyxedema-like picture with increased dermal mucin and fibroblast proliferation.[79]

Histopathologic examination of a periarticular fibrous nodule reveals relatively well-circumscribed nodules of broad hyalinized bundles of collagen with macrophages and plasma cells.[80,84] Adjacent capillaries may be occluded by similar deposits.

Progressive facial hemiatrophy and eosinophilic fasciitis show variable dermal sclerosis, loss of appendages, and a perivascular infiltrate composed predominantly of lymphocytes and plasma cells with scattered histiocytes.[60] In borrelial fasciitis, eosinophilic infiltration of the fascial planes is not as impressive as in "idiopathic" Shulman disease.[81]

Diagnosis and Differential Diagnosis. (See Table 187-1) In the absence of other dermatoborrelioses, definitive diagnoses can only be made by positive evidence of infection in the form of identification of the spirochete in tissue sections (identification of the organism in periarticular nodules has been reported to be positive despite the lengthy spatial relationship from the initial tick bite), positive cultures, or positive serology.[85] Conflicting evidence regarding serologic findings in patients with scleroderma or LSA-like lesions exists.[78] Although some reports indicate a high frequency of elevated titers of anti-*Borrelia* antibodies (8 of 15 cases), others suggest that such serologic evidence is minimal.

CUTANEOUS ATROPHOBORRELIOSES ***Clinical Features.*** Atrophic lesions indistinguishable from primary anetoderma (see Chap. 65) may also occur in the absence of other dermatoborrelioses.[69,85] When associated with ACA, these lesions are usually seen at the periphery of an extensive lesion.[86]

Histologic Features. Biopsy specimens from atrophic or anetoderma-like skin lesions show abnormal elastic tissue fibers in association with a perivascular infiltrate of lymphocytes with occasional histiocytes, neutrophils, or eosinophils.[69] Spirochetes are found with difficulty in histologic sections.

Diagnosis. Definitive diagnosis is made by identification of the spirochete in tissue sections, positive cultures, or positive serology in combination with a compatible clinical presentation.[85]

Uncommon Cutaneous Manifestations of Lyme Disease

CUTANEOUS LYMPHOBORRELIOSES (B- AND T-CELL LYMPHOID HYPERPLASIAS) ***Clinical Features.*** Lymphocytic infiltrates associated with *Borrelia* are the least com-

mon of the cutaneous hallmarks of Lyme disease (1 percent) and may present either as single borrelial lymphocytoma (lymphadenosis benigna cutis) or as multiple lesions.[60] The coexistence of lymphocytoma with other dermatoborrelioses led to the suggestion of a unifying causative organism, favored by the development of EM-like lesions following passive inoculation of an infiltrate from a lesion of LABC.[8,87] Lymphocytoma has been reported solely in Europe. However, all three species of *B. burgdorferi sensu lato* have been associated with lymphocytoma so it is unclear whether the lack of U.S. cases is related to strain differences.[71]

More common in children than in adults, lymphocytoma clinically presents as a nodulo-papular lesion in the ear lobes (Fig. 187-6) and scrotum (see eFig. 187-6.1 in on-line edition) in children and the nipple-areolar area in adults.[57] The precise reason for this predilection is not known but is believed to be tissue temperature related.[60] Other locations occur (see eFig. 187-6.2 in online edition). As with the other dermatoborrelioses, most patients are not aware of a preceding tick bite. The incubation period varies anywhere from a few weeks to 10 months. The duration of an untreated solitary lesion can vary from months to years (average, 5 years). Spontaneous resolution may occur, but typically lesions resolve more rapidly with antibiotic therapy.[62] Lesions of multiple lymphocytomas can be entirely subcutaneous, may last for decades, and typically have no specific site predilection or associations with other dermatoborrelioses.

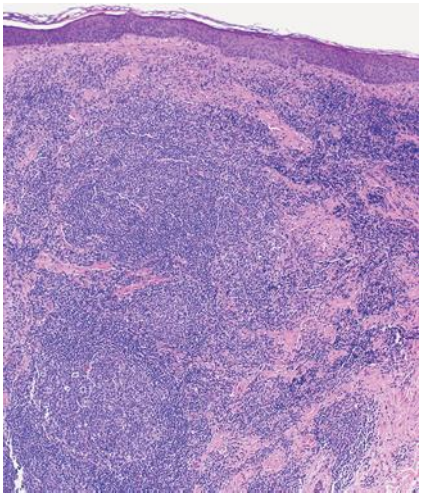
Discoid lesions "starting as small papules and expanding peripherally with central clear" that wax and wane have also been described in association with borrelial infection.[88] The name given for these lesions is *benign lymphocytic infiltrates* of the skin (Jessner-Kanof) (see Chap. 147). More common in men, they tend to be located on the face, neck, and upper trunk. Annular lesions clinically resembling EM have also been described.

▲ **FIGURE 187-6** Borrelial lymphocytoma of ear lobe, 3 months' duration.

Several reports suggest an association of low-grade cutaneous B-cell lymphoma with *B. burgdorferi* infection.[89,90] Clinical presentation of *Borrelia*-associated B-cell lymphoproliferative disease is varied and consists of multiple ill-defined, slowly progressive plaques and nodules presenting on the trunk, extremities, or both, of usually older patients. The highest frequency of infection with *Borrelia* has been found in marginal zone lymphoma (20 percent to 52 percent), followed by follicular center lymphoma (15 percent to 26 percent) and diffuse large B-cell lymphoma (15 percent to 16 percent; see Chaps. 146 and 147).[89,91] That antigenic drive by *Borrelia* may be a pathogenic factor in more than one subtype is supported by the association of *B. burgdorferi* with multiple subtypes of cutaneous B-cell lymphoma. Demonstration of the organism in the skin before development of overt cutaneous B-cell lymphoma serves to confirm the temporal progression of *B. burgdorferi*-associated B-cell lymphoproliferative disease. Clinical regression of marginal zone lymphoma after eradication of *B. burgdorferi* argues in favor of a benign process.[90,92,93]

Histologic Features. Histopathologic findings of benign B- and T-cell dominant hyperplasias are essentially similar to benign lymphoid hyperplasias (Fig. 187-7) secondary to an arthropod bite, vaccination, or other causes (see Chap. 147). Definitive classification of *Borrelia*-associated B-cell lymphoma is confounded by the immunohistochemical profile: expression of CD5 and CD10 (common acute lymphoblastic leukemia antigen), antigens typically associated with centrocytic lymphoma, are absent in *Borrelia*-associated B-cell lymphoma.[89]

Diagnosis and Differential Diagnosis. (See Table 187-1) Positive history of tick bite and presence of other dermatoborrelioses are helpful, given that the histologic findings of cutaneous lymphoborrelioses are not diagnostic. Direct evidence of an infective etiology has been provided from studies demonstrating the presence of fragmented spiral forms suggestive of *B. burgdorferi* in lesions of benign lymphocytic infiltrates[88] and has been confirmed by immunofluorescence using species-specific monoclonal antibodies. Spirochetes may be cultured directly from biopsy specimens or *B. burgdorferi* DNA may be detected by PCR. High titers of anti-borrelial antibodies have been reported in more than 50 percent of patients with LABC solitaria.[87] The common denominator in patients with *Borrelia*-associated lymphoma appears to be a high titer of antibodies, typical of the chronic stage of the infection, against *B. burgdorferi*.[89]



▲ **FIGURE 187-7** Cutaneous borrelial lymphocytoma with definitive history of tick bite. Nodular and diffuse dense lymphohistiocytic infiltrate with prominent germinal center (hematoxylin and eosin stain).

OTHER CUTANEOUS LESIONS Other cutaneous lesions reported in patients with documented Lyme disease include panniculitis, vasculitis, granuloma annulare, erythema multiforme, and a syphilis-like papulo-squamous eruption (see Table 187-1), but *B. burgdorferi* has not been directly recovered from any of these lesions.

Non-Cutaneous Manifestations of Lyme Disease

NERVOUS SYSTEM MANIFESTATIONS *B. burgdorferi* can cause early-disseminated neurologic disease in 10 percent to 15 percent of patients in the United States who have not received antibiotics.[94] Meningitis, cranial neuropathy, and radiculopathy are the most common neurologic manifestations and can manifest as soon as 1 week after EM.[95] Facial palsy is the most characteristic neuropathy of early Lyme disease in the United States, occurring in 40 percent to 50 percent of patients with borrelial neurologic involvement, usually within 4 weeks after onset of EM. Bilateral facial palsy should immediately raise suspicion for Lyme disease, as it is uncommon in most other causes of facial palsy. Involve-

ment of other cranial nerves has been reported, but is relatively rare.[95] The triad of lymphocytic meningitis, cranial palsy (often facial), and radiculoneuritis, known as *Bannwarth syndrome*, is pathognomonic for Lyme disease. It is frequently reported in Europe but is rare in the United States.[96,97] Acute or subacute myelitis leading to spastic paraparesis and CSF pleocytosis, mononeuritis, and a Guillain-Barré-like syndrome may also occur in early disseminated disease.[95,98] Late neurologic manifestations include encephalomyelitis, encephalopathy, and chronic polyneuropathies.[98,99]

CARDIAC MANIFESTATIONS Cardiac involvement occurs in 4 percent to 10 percent of untreated patients in the United States and in 0.3 percent to 4.0 percent of European patients. It usually occurs within several weeks after the onset of infection, although it can occur as early as 1 week and as late as 7 months into the infection.[100,101] Within the heart, *B. burgdorferi* has a predilection for the atrioventricular node, resulting in atrioventricular block. Acute myopericarditis and left ventricular dysfunction can also occur, but are usually self-limited and mild, only sometimes resulting in transient cardiomegaly or pericardial effusion.[102] *B. burgdorferi* has been isolated from endomyocardial biopsy samples from several European patients with chronic dilated cardiomyopathy, a complication observed less frequently in the United States.[103,104]

MUSCULOSKELETAL MANIFESTATIONS Early musculoskeletal manifestations of *B. burgdorferi* infection are typically nonspecific. Inflammatory arthritis is the most frequent clinical sign of late-disseminated Lyme disease in the United States, occurring in 50 percent to 70 percent of patients with untreated or incompletely treated infection. It usually presents 1 or more months after the onset of Lyme disease as asymmetric mono- or oligoarthritis of large joints, most often of the knee.[94] Migratory arthritis is also relatively common.[5,49] Bouts of arthritis are generally frequent and short at first, becoming longer and less frequent with time, each lasting from several days to 1 year.

OTHER MANIFESTATIONS OF LYME DISEASE Ophthalmic complications in the form of conjunctivitis, keratitis, iridocyclitis, retinal vasculitis, chorioiditis, and optic neuropathy are rare manifestations of Lyme disease. They are believed to be the direct result of tissue inflammation by *B. burgdorferi* and are usually associated with other signs and symptoms of disease.[105,106] The eye may also be affected by extraocular manifestations of Lyme disease, such as cranial nerve pareses and orbital myositis. Findings in other organ systems (gastrointestinal, lymphatic, respiratory, urinary, and genital) have been reported, but the associations with borrelial infection are loose.

PERINATAL LYME DISEASE Studies in both human and animal models indicate that *B. burgdorferi* can cross the placenta during the initial spirochetemia, but evidence of a fetal immune response or an adverse neonatal outcome are not definitively established.[107]

LYME DISEASE IN CHILDREN Other than differences in localization of EM lesions (more typically in the head and neck), pediatric Lyme disease is similar to that of adults. Of note, however, in children optic nerve involvement may lead to blindness.[108]

PROGNOSIS AND CLINICAL COURSE

All manifestations of Lyme disease resolve over time, even in the absence of antibiotic therapy. Antibiotic therapy can hasten resolution of some (EM, arthritis), but not all (facial palsy, radiculitis) manifestations, and antibiotic therapy can clearly abort late manifestations.

Dual infection with *B. burgdorferi* and either of *Babesia microti* or *Anaplasma phagocytophilum* occurs at different frequencies depending on the geographic location, and may alter the clinical presentation of Lyme disease in some patients. Some studies suggest more severe disease in patients who are co-infected, but this remains uncertain.[109-111]

COMPLICATIONS

A small number of patients have symptoms that persist for years despite appropriate antibiotic therapy. Up to 10 percent of patients with Lyme arthritis treated with appropriate antibiotics may have continued arthritis that persists for years.[112,113] Arthritis in these patients does typically respond to immunosuppressive agents (methotrexate, antitumor necrosis factor therapies), which has led to suggestions that these patients may have an autoimmune syndrome. Molecular mimicry of borrelial antigens with host proteins has been proposed as one possible mechanism, but this remains unproven.[114]

There have been many reports of patients who develop a fibromyalgia-like syndrome including profound fatigue, depression, myalgias, polyarthralgias without arthritis, and paresthesias, as well as neurocognitive difficulties involving memory, concentration (particularly auditory), and decreased mental flexibility (i.e., impaired verbal fluency) after infection with *B. burgdorferi*.[41,115,116] This syndrome is often referred to as *chronic Lyme disease*. The linkage of these symptoms with *B. burgdorferi* infection remains controversial and several large epidemiologic studies have shown that patients who have contracted Lyme disease are no more likely to suffer from these symptoms than persons in the general population.[117,118]

DIAGNOSIS OF LYME DISEASE

Physical findings, a history of potential exposure, known tick bites, or symptoms consistent with the typical multisystem presentation of Lyme disease can all be helpful in making a diagnosis. In the presence of classic EM or of Bannwarth syndrome, the diagnosis of Lyme disease can be made on clinical grounds alone. Diagnostic conundrums arise in presentations that involve other compatible skin, cardiac, neurologic, or musculoskeletal symptoms in the absence of a history of EM or tick exposure.

Laboratory Tests

DIRECT DETECTION OF *B. BURGDORFERI* The gold standard for diagnosis of Lyme disease is culture of *B. burgdorferi*. However, the need for specialized media and the slow growth of the organism make it impractical in most clinical settings. *B. burgdorferi* can readily be cultured from biopsies of EM and ACA[65] as well as from CSF samples in patients with meningitis.[119,120] Recent studies have also demonstrated that the organism can be recovered from the blood in up to 50 percent of untreated adult patients with EM.[121] However, cultures are generally insensitive in patients with extracutaneous manifestations of Lyme borreliosis, particularly in later stage disease.

PCR assays are very sensitive in detecting *B. burgdorferi* DNA in skin biopsy and synovial fluid specimens from patients with EM and Lyme arthritis, respectively.[122] However, PCR testing for *B. burgdorferi* DNA has not been approved by the U.S. Food and Drug Ad-

ministration (FDA), and its routine use is not recommended.[7]

SEROLOGIC DIAGNOSIS OF LYME DISEASE

Immunologic diagnosis is the main laboratory modality used to support a clinical diagnosis of Lyme disease. In the United States, the FDA has approved more than 70 different immunoassays for Lyme disease[123]—mainly enzyme-linked immunoabsorbent (ELISA) and Western immunoblot assays. ELISA tests use whole-cell lysates of *B. burgdorferi sensu lato* or, less commonly, purified *B. burgdorferi* antigens to capture either anti-*B. burgdorferi* IgG and/or IgM antibodies present in a given sample. Although relatively specific, ELISA tests are associated with a high rate of false-positive results.[124,125] Patients with autoimmune diseases (lupus, rheumatoid arthritis), Epstein-Barr virus, bacterial endocarditis, and other tick-borne diseases appear to be at an increased risk for false-positive IgM serologic testing; syphilis, *H. pylori*, systemic lupus erythematosus, ehrlichiosis, and babesiosis cause false-positive IgG serologic testing.[125–127] A newer ELISA test that uses only a small peptide of the constant region of *B. burgdorferi* VlsE protein appears to have greater specificity than traditional whole cell ELISA testing. This test, also known as the *C6 peptide test*, measures only IgG antibody, but IgG antibody to the C6 peptide develops early in the course of disease and sensitivity of the assay in patients with early disease has been equivalent to that seen with IgM whole cell ELISA tests.[128,129] Western immunoblot assays are more specific because they enable detection of antibodies to individual components of *B. burgdorferi*. Currently, there are no widely accepted standard tests or criteria for serodiagnosis of Lyme disease in either Europe or Asia, in part because of the presence of multiple strains of *B. burgdorferi* that have only partial antigen cross-reactivity.

Other Available Tests for the Diagnosis of Lyme Disease.

Current Recommendations for Use of Serologic Testing for Lyme Disease. Because of its limitations, particularly high false-positive results within the general population, serologic testing should be initiated based on the pre-test probability of disease and serve only to support a clinical diagnosis.[7] It is most helpful in patients with an intermediate pre-test probability of Lyme disease—namely those who reside in endemic areas and who present with signs and symptoms consistent with, but not diagnostic of, Lyme disease (e.g., facial palsy, arthritis, or atrioventricular nodal conduction abnormalities in the absence of an EM lesion). [Patients who reside in areas of high endemicity and have clear EM lesions should be diagnosed on clinical grounds alone without laboratory testing. Testing should be avoided in patients with low suspicion for disease (patients not living in endemic areas, or with non-specific systemic symptoms, or after a tick bite) as the rates of false-positive tests greatly outnumber true positive tests in this setting.] One algorithm for workup of patients presenting with an eruption suspicious for EM is shown in Fig. 187-8.

Once the decision is made to obtain serologic testing, current recommendations are for two-stage testing, starting with a highly sensitive ELISA test first. If the ELISA is negative, the likelihood of Lyme disease is low, and further testing is not generally recommended. However, if the test is positive or indeterminate, a Western immunoblot assay with high specificity should be used to confirm the results. The specificity of this two-step approach is thought to be 99 percent to 100 percent in late-stage Lyme disease.[133] If testing is negative early in the course of disease, the tests can be repeated in 3 to 4 weeks (antibiotic therapy, if given very early, may abort antibody development). It is important to note that in patients with untreated disease for longer than 1 month, IgM testing should not be performed. A positive IgM Western blot with a negative IgG Western blot in this setting is considered a negative result due to the high false positivity rate of IgM testing. Seronegativity in patients suspected of having late Lyme disease practically excludes the diagnosis.[7] Finally, because IgG and IgM antibody titers may persist for years despite antibiotic therapy,[134,135] persistent seropositivity is not in itself an indication of treatment failure, nor is it proof of recent infection or re-infection. Currently, there is no test that allows confirmation of successful clearance of the organism after treatment.

TREATMENT RECOMMENDATIONS

Treatment is indicated for all stages of Lyme disease, even though most manifestations resolve over time without therapy. Patients may not be asymptomatic at the time of completion of the antibiotic course but this is not an indication for extending length of therapy; symptoms generally continue to improve steadily over time. Of note, Jarisch-Herxheimer reactions (fevers, chills, and worsening arthralgias and myalgias) are sometimes reported after the initial dose of antibiotics; the reaction is thought to be caused by host reaction to the dying organisms.

The Infectious Disease Society of America has published guidelines for the treatment of all manifestations of Lyme disease,[136] although many of the recommendations are based on expert opinion and not on rigorously controlled clinical trials. Treatment patterns differ in different countries, but no data suggest differences in either the efficacy of specific antibiotics or in the optimal duration of therapy between patients in North America and Europe.

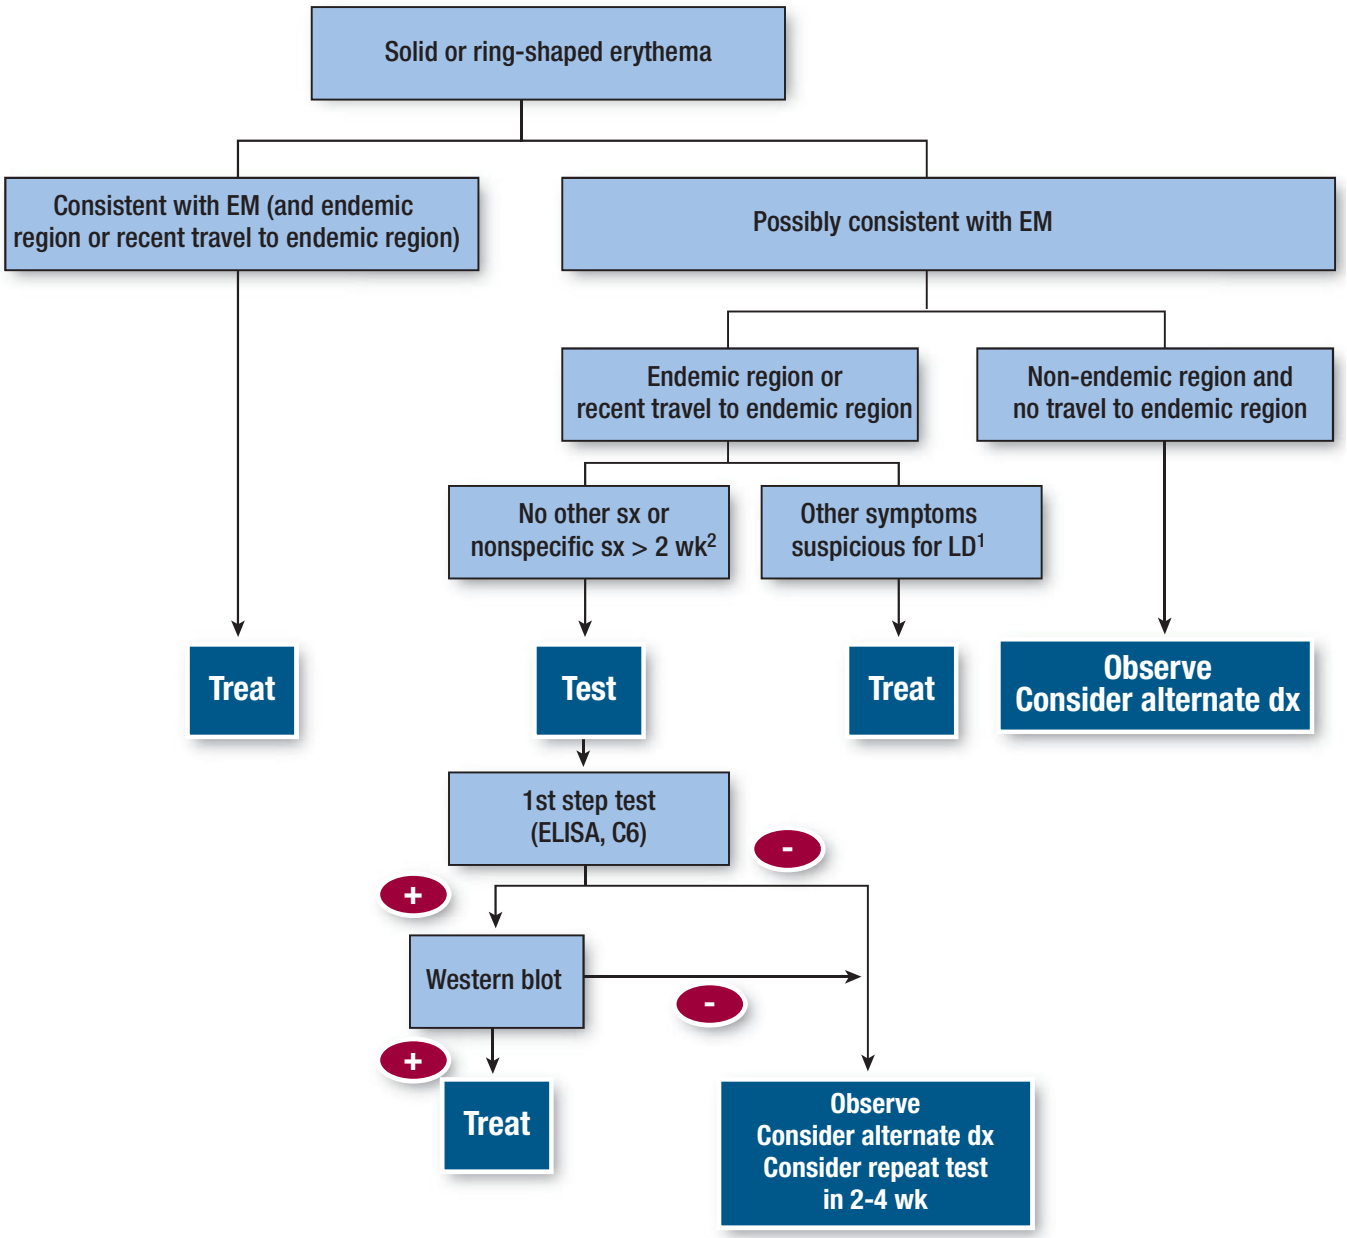
Treatment of all of the cutaneous manifestations of Lyme disease should initially be with oral antibiotics (Table 187-2). Doxycycline is generally considered as first-line therapy, because it has excellent penetration into the central nervous system and is also effective against *A. phagocytophilum,* the agent of human granulocytic ehrlichiosis. Amoxicillin should be used in children and pregnant women. Cefuroxime is a more expensive first-line agent. These three agents have been found to be equally effective.[25,136–138] Macrolides are second-line agents and some evidence suggests that they are less effective than the first-line agents.[136] Duration of therapy is generally recommended to be 14 to 21 days; a recent study showed similar outcomes in patients with EM treated with either a 10- or a 20-day course of oral doxycycline.[139]

Intravenous antibiotics (ceftriaxone, cefotaxime, or penicillin G) may be recommended for patients with cutaneous manifestations that are accompanied by neurologic disease (meningitis, encephalopathy) or high degree heart block. Intravenous antibiotics are also sometimes used for patients with refractory ACA or arthritis.

Treatment of patients with non-specific fibromyalgia-like disease after infection with *B. burgdorferi* is controversial. There are no controlled trials supporting the use of long-term antibiotic therapy.[140]

PREVENTION

Prompt removal of the tick is the most effective measure in preventing disease, as the tick must usually be attached for



▲ **FIGURE 187-8** Approach to patient with erythema migrans (EM). [1]Bell palsy, radiculoneuritis, meningitis, arthritis. [2]Fever, chills, fatigue. dx = diagnosis; ELISA = enzyme-linked immunosorbent assay; LD = Lyme disease; sx = symptoms; dx = diagnosis.

24 to 48 hours for transmission to occur. For adult or nymphal *I. scapularis* ticks that have attached for longer than 36 hours within an endemic area, a single 200-mg dose of doxycycline within 72 hours of tick removal is 87 percent effective in preventing early cutaneous manifestations.[136,141]

In 2002, the only FDA-approved Lyme disease vaccine for humans, a recombinant form of OspA, was withdrawn by the manufacturer despite an 80 percent efficacy in preventing Lyme disease in North America.[142,143] Withdrawal of the vaccine was related to concerns linking the emergence of autoimmune arthritis with host immune responses to OspA.[144] Recently, trials of an OspA vaccine lacking the epitope thought to be linked to autoimmune arthritis have begun in Europe.[145]

Available preventive measures in Lyme disease endemic areas include use of repellents, such as DEET or picaridin, or permethrin treatment of clothing; routine checks for ticks; and landscaping practices to create an inhospitable environment for ticks (removing brush and leaf litter, creating buffer zones of wood chips or gravel between forest and lawn, and application of pesticides to yards). Novel approaches under investigation include biologic agents (fungi) to kill the ticks, the use of devices to target acaricides to rodents and deer without harming them, and the development of vaccines to eradicate disease in the wild reservoirs. The control of infection on a larger scale by the eradication of deer or widespread use of acaricides have had limited public acceptance.[1,146]

TABLE 187-2
Treatment of Lyme Disease

Presentation[a]			Treatment (Alternate)	Treatment Length (Days)	Comments
Early Lyme Disease	Skin	Erythema migrans	A (B)	14 (14–21)	Can consider treating for 10 days if using doxycycline.
		Lymphocytoma	A (B)	14 (14–21)	
	Cardiac	1st and 2nd degree AV block	A (B)	14 (14–21)	Consider IV antibiotics, temporary pacemaker if symptomatic.
		3rd degree AV block	C (D)	14 (14–21)	Consider temporary pacemaker.
	Neuro	Cranial nerve palsy	A (B, C)	14 (14–21)	Consider lumbar puncture to exclude central nervous system involvement.
		Meningitis	C (D)	14 (14–28)	
		Radiculopathy	C[b] (D)	14 (14–28)	Response to treatment usually is slow and may be incomplete; do not repeat antibiotics unless objective relapse.
Late Lyme Disease	Skin	Acrodermatitis	A (B)	21 (14–28)	
	Rheum	Arthritis	A (B, C/D)	28	If persistent or recurrent joint swelling, repeat 28-day course of oral antibiotics or 14–28-day course of IV ceftriaxone. If arthritis persists despite two courses of antibiotics: non-steroidal anti-inflammatory drugs, disease-modifying anti-rheumatic drugs, arthroscopic synovectomy.
	Neuro	Encephalopathy	C (D)	28 (14–60)	Use 14–28 days initially. If no improvement, may consider a second course of similar duration
		Radiculopathy	C (D)	14 (14–28)	

Treatment (doses will need to be adjusted in children):
A: First line oral: Doxycycline[c] (100 mg PO bid), or Amoxicillin[d] (500 mg PO tid), or Cefuroxime (500 mg PO bid)
B: Alternative oral[e]: Azithromycin (500 mg PO qd), or Erythromycin (500 mg PO qid), or Clarithromycin (500 mg PO bid)
C: First line parenteral: Ceftriaxone (2 g IV qd)
D: Alternative parenteral: Penicillin G (18–24 M units/day divided into doses given q4h),[f] or Cefotaxime (2 g IV q8h), or Doxycyline (200–400 mg/day IV in 2 divided doses)

[a]If several manifestations of Lyme disease are present, the route (PO or IV) and length of therapy should be as for the manifestation with the longest and most aggressive (e.g., IV > PO) recommendation.
[b]According to some small studies, oral doxycycline has been found to be effective.
[c]Also effective against *A. phagocytophilum*, the agent of human granulocytic ehrlichiosis. Relatively contraindicated during pregnancy or lactation and for children younger than 8 years.
[d]Preferred choice in children and pregnant women.
[e]Reserved for patients who are intolerant of first-line agents.
[f]Assuming normal renal function.

SECTION 30

FUNGAL DISEASES

CHAPTER 188

Superficial Fungal Infection: Dermatophytosis, Onychomycosis, Tinea Nigra, Piedra

Shannon Verma
Michael P. Heffernan

MYCOLOGY

Fungal infection can be superficial, subcutaneous, or systemic, depending on characteristics of the organisms and of the host. This chapter concentrates on the superficial fungal infections, which are confined to the stratum corneum, hair, and nails. They can be subdivided into infections that induce an inflammatory response, such as those caused by the dermatophytes, and those that result in minimal to no inflammation, such as those caused by the piedras.

DERMATOPHYTES

The dermatophytes are a group of taxonomically related fungi. Their ability to form molecular attachments to keratin and use it as a source of nutrients allows them to colonize keratinized tissues, including the stratum corneum of the epidermis, hair, nails, and the horny tissues of animals.[1] Superficial infection caused by a dermatophyte is termed *dermatophytosis*, whereas *dermatomycosis* refers to a fungal infection by any fungi.

Historical Aspects

Epidemiology

Numerous ways of classifying superficial fungi exist, including habitat and pattern of infection. Geophilic "earth-loving" organisms originate in the soil and only sporadically infect humans, usually by direct contact with the soil. These infections are usually spread by spores, which can live for years in blankets and grooming tools. Infections produced by these organisms are usually inflammatory. Strains of *Microsporum gypseum*, the most common geophilic pathogen cultured from humans, are more virulent than those from the soil, accounting for occasional epidemic spread under appropriate conditions.[2]

Zoophilic ("animal-loving") species are usually found on animals, but are also transmitted to humans. Domestic animals and pets are a common source of these infections in urban areas (e.g., *M. canis* in cats and dogs). Transmission may occur through direct contact with a specific animal species or indirectly when infected animal hair is carried on clothing or present in contaminated buildings or feed. Exposed areas such as the scalp, beard, face, and arms are favored sites of infection. Although human infection with zoophiles is often suppurative, animal infection may be clinically silent, demonstrating the unique adaptation of fungi to their animal hosts.[3] Inflammatory dermatophytoses are most commonly produced by zoophilic dermatophytes.

Anthropophilic ("man-loving") species have adapted to humans as hosts. Unlike the sporadic geophilic and zoophilic infections, anthropophilic infections are often epidemic in nature. They are transmitted from person to person via direct contact or fomites. Infections with these species can vary from asymptomatic to markedly inflammatory due to variability in virulence as well as host susceptibility. Kerion formation, suppuration, or other manifestations of inflammatory tinea facilitate early diagnosis. Noninflammatory disease, in contrast, results in a clinically silent "carrier" state that serves to delay diagnosis and propagate the infection.

Host variability also affects presentation. Immunocompromised individuals

SUPERFICIAL FUNGAL INFECTIONS AT A GLANCE

- Dermatophytes: Fungi capable of colonizing keratinized tissues.
- Dermatophytes can be divided into geophilic, zoophilic, and anthropophilic organisms.
- Dermatophytes come from the genera *Epidermophyton*, *Microsporum*, and *Trichophyton*.
- Tinea capitis, tinea barbae, tinea corporis, tinea manuum, tinea pedis, tinea cruris, and onychomycosis are all caused by dermatophytes.
- Oral antifungals include griseofulvin, itraconazole, fluconazole, and terbinafine.
- Tinea nigra is a superficial dermatophyte infection that may mimic acral lentiginous melanoma.
- Piedra, which consists of white and black forms, is an asymptomatic fungal infection of the hair shaft.

are more susceptible to severe or refractory dermatophytoses, and advances in chemotherapy and transplant medicine have led to an increase in opportunistic infections by previously non-pathogenic dermatophytes.[4] Interestingly, only the severity of dermatophytosis is increased with human immunodeficiency virus disease, not the prevalence.[5] Age, sex, and race are additional important epidemiologic factors, as dermatophyte infections are five times more prevalent in males than females. However, *Trichophyton tonsurans* tinea capitis is more common in female adults than male adults, and most common in African American children. There is no evidence currently to support linkage of dermatophyte susceptibility to any of the ABO groups, nor is there evidence that diabetic patients are especially susceptible. Diabetes may, however, affect the course of established infections.[6]

Patterns of human travel may rapidly influence the distribution of endemic fungi, as illustrated by *T. tonsurans*. Within the past quarter century, it has replaced *M. audouinii* as the predominant cause of tinea capitis in the United States, correlating well with the immigration of Mexican and Caribbean populations. The relative resistance of *T. tonsurans* to griseofulvin has also contributed to its predominance.[3]

Finally, local customs can influence rates of dermatophytoses. For example, the use of macerating occlusive footwear has made tinea pedis and onychomycosis much more common in industrialized nations.[5]

Diagnostic Procedures

A clinical diagnosis of a dermatophyte infection can be confirmed by microscopic evaluation or culture. Although microscopic evaluation can provide evidence of fungal infection within minutes, it does not often allow for speciation or for identification of the susceptibility profile of the infectious agent. Microscopic evaluation may also yield false-negative results, and fungal culture should be performed when a dermatophyte infection is suspected clinically.

MICROSCOPIC EXAMINATION ***Hair.*** Examination of lesions involving the scalp or beard with a Wood's lamp may reveal the fluorescent pteridine of certain pathogens (Table 188-1). If so, hairs that fluoresce should be selected for further examination. However, it is important to note that although the ectothrix organisms *M. canis* and *M. audouinii* will fluoresce on Wood's light examination, the endothrix organism, *T. tonsurans*, will not fluoresce. *T. tonsurans*, which is now the most common cause of tinea capitis in the United States, thus limits the use of Wood's light examination. Hairs must be plucked, not cut, put on a microscopic slide with 10 percent to 20 percent potassium hydroxide (KOH), covered with a coverslip and slightly warmed. Low-power microscopy will reveal two possible patterns of infection (Fig. 188-1):

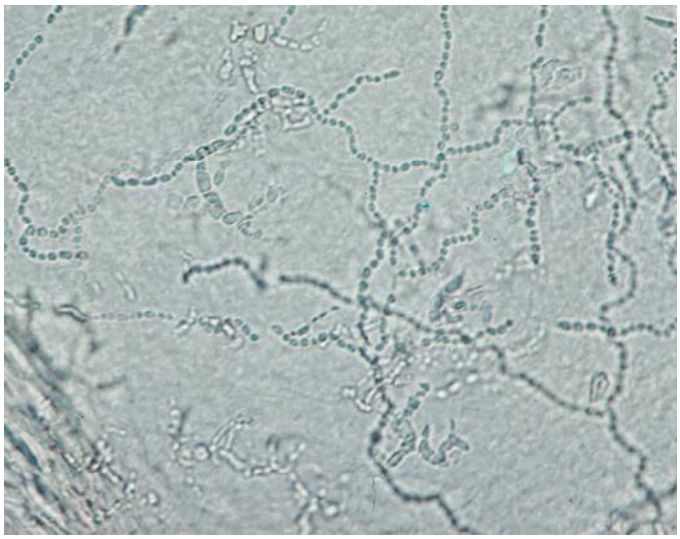
1. Ectothrix—small or large arthroconidia forming a sheath around the hair shaft; or
2. Endothrix—arthroconidia within the hair shaft.

Skin and Nails. Skin samples should be taken by scraping with the dull edge of a scalpel outward from the advancing margins of a lesion. Nail specimens must include clippings of the entire thickness of dystrophic areas of nail, as proximal from the distal edge as possible.

In a 10 percent to 20 percent KOH preparation, dermatophytes have septate and branching hyphae without constriction (Fig. 188-2); however, culture is required for speciation, as all dermatophyte species appear identical.

CULTURE PROCEDURES Speciation of superficial fungi is based on the macroscopic, microscopic, and metabolic characteristics of the organism. Sabouraud's dextrose agar (SDA) is the most commonly used isolation medium and serves as the basis for most morphologic descriptions. However, contaminant saprobes (organisms that feed on dead or decaying matter) grow rapidly on this medium, masking true pathogens. This necessitates the addition of cycloheximide (0.5 g/L) and chloramphenicol (0.05 g/L) to make the medium highly selective for the isolation of dermatophytes. Commercial versions of this agar exist. Dermatophyte test medium contains the pH indicator phenol red; it remains amber with the growth of most saprophytes, but turns red when dermatophyte proteolytic activity increases the pH to 8 or above. Nondermatophytes turn the medium yellow due to their acidic byproducts. Identification of isolated fungi is facilitated by the use of potato dextrose agar, which stimulates the production of conidia and pigment. Finally, species of *Trichophyton* are often differentiated by their nutritional requirements, revealed on *Trichophyton* agar numbers 1 through 7.

It is essential that each laboratory use standardized media, of which several



▲ **FIGURE 188-2** Microscopic examination of skin scrapings (scales) revealing septate, branching hyphae.

commercial variants are available. Cultures are incubated at room temperature (26°C [78.8°F]) for up to 4 weeks before being discarded as no growth. With more than 40 known dermatophytes, proper identification requires a suitable reference source.[7] Table 188-2 lists the characteristics of the most common pathogens.

Pathogenesis

Dermatophytes can survive solely off of human stratum corneum, which provides a source of nutrition for the dermatophytes and for the growing fungal mycelia.[8] Dermatophyte infections involve three main steps: adherence to keratinocytes, penetration through and between cells, and the development of a host response.

TABLE 188-2
Characteristics of the Most Common Dermatophytes

Organism	Colony Morphology		Microscopic Appearance
Epidermophyton floccosum 	Flat feathery colonies with a central fold and yellow to dull gray-green pigment. Yellow to brown reverse pigment.		No microconidia, numerous thin and thick-walled, club-shaped macroconidia.
Microsporum audouinii	Flat and white to gray with widely spaced radial grooves. Tan to salmon reverse pigment. Salmon-pink pigment on PDA. No growth on polished rice.		Terminal chlamydoconidia and pectinate (comb-like) hyphae.
M. canis	Flat, white to light yellow, coarsely hairy, with closely spaced radial grooves. Yellow to orange reverse pigment. Yellow on PDA. Growth on polished rice.		Few microconidia, numerous thick walled and echinulate macroconidia with terminal knobs.
M. gypseum	Flat and granular with tan to buff pigment, no reverse pigment.		Few microconidia, numerous thin-walled macroconidia without knobs.

(continued)

TABLE 188-2
Characteristics of the Most Common Dermatophytes (Continued)

Organism	Colony Morphology	Microscopic Appearance
Trichophyton mentagrophytes	White to creamy with a cottony, mounded surface. None to light brown reverse pigment. No pigment on PDA. Urease positive.	Clustered round microconidia, rare cigar-shaped macroconidia, occasional spiral hyphae. Hair perforation positive.
T. rubrum 	Mounded white center with maroon periphery. Maroon reverse pigment. Cherry red on PDA. Urease negative.	 Few tear-shaped microconidia, rare pencil-shaped macroconidia. Hair perforation negative.
T. schoenleinii	Heaped or folded and whitish. Colorless to yellow-tan reverse pigment.	 Knobby antler-like hyphae (favic chandeliers), numerous chlamydoconidia.
T. tonsurans	Suede-like center with feathery periphery, white to yellow or maroon color. Reverse pigment usually dark maroon, sometimes none to yellow. Partial thiamine requirement.	 Numerous multiform microconidia and rare cigar-shaped macroconidia.
T. verrucosum	Small and heaped, although sometimes flat, white to yellow-gray. Reverse pigment none to yellow. Requires thiamine and usually inositol for growth.	 Chains of chlamydoconidia on SDA. Long and thin "rat-tail" macroconidia with thiamine.
T. violaceum	Waxy and heaped, deep purplish-red. Purple reverse pigment. Partial thiamine requirement.	 Irregular hyphae with intercalary chlamydoconidia. No micro- or macroconidia on SDA, rare micro- and macroconidia with thiamine.

PDA = potato dextrose agar; SDA = Sabouraud's dextrose agar.

ADHERENCE Superficial fungi must overcome several obstacles in order for the arthroconidia, the infectious element, to adhere to keratinized tissue. They must resist the effects of ultraviolet light, variation in temperature and moisture, competition from normal flora, and sphingosines produced by keratinocytes. Fatty acids produced by sebaceous glands are fungistatic, particularly those with chain lengths 7, 9, 11, and 13. The presence of these fatty acids in postpubertal children may account for the dramatic decrease in tinea capitis infections after puberty.

PENETRATION After adherence, spores must germinate and penetrate the stratum corneum at a rate faster than desquamation. Penetration is accomplished by the secretion of proteinases, lipases, and mucinolytic enzymes, which also provide nutrients to the fungi.[8] Trauma and maceration also facilitate penetration and are important factors in the pathogenesis of tinea pedis. Fungal mannans in the cell wall of dermatophytes may also decrease the rate of keratinocyte proliferation. New defenses emerge once the deeper layers of epidermis are reached, including competition for iron by unsaturated *transferrin* and possibly inhibition of fungal growth by progesterone.

DEVELOPMENT OF A HOST RESPONSE The degree of inflammation is influenced both by the patient's immune status and by the organism involved. Immune detection and chemotaxis of inflammatory cells may occur through several mechanisms. Some fungi produce low-molecular-weight chemotactic factors much like those produced by bacteria. Others activate complement via the alternative pathway, creating complement-derived chemotactic factors.

Antibody formation does not appear to be protective in dermatophyte infections, as patients with widespread infections may have elevated antibody titers.[9] Alternatively, type IV, or delayed-type hypersensitivity (DTH), plays a pivotal role in combating dermatophytoses. This arm of cellular immunity is maintained by interferon-γ secretion from type 1 T-helper lymphocytes. In patients without previous exposure to a dermatophyte, primary infection causes minimal inflammation, and a trichophytin skin test is negative.[10] The infection produces mild erythema and scale, the result of increased keratinocyte turnover. It is hypothesized that dermatophyte antigen is then processed by epidermal Langerhans cells and presented in local lymph nodes to T lymphocytes. The T lymphocytes undergo clonal proliferation and migrate to the infected site to attack the fungus. At this time, the lesion becomes abruptly inflammatory, and the epidermal barrier becomes permeable to transferrin and migrating cells. Soon, the fungus is cleared, and the lesion spontaneously resolves. The trichophytin skin test is now positive, and clearing of a second infection will be more rapid.

Dermatophytid reactions, which occur in 4 percent to 5 percent of patients, are inflammatory eczematous allergic skin reactions at sites distant from the primary fungal infection.[11] Unlike the primary lesion, these are KOH examination and culture negative. These reactions may take the form of follicular papules, erythema nodosum, vesicular id of the hands and feet, erysipelas-like, erythema annulare centrifugum, or urticaria (see Chap. 17).[12–16] Although the precise mechanism is unknown, these reactions are associated with a DTH response to the trichophytin test and may involve a local DTH response to systemically absorbed fungal antigen.[11,17]

Genetics

In households afflicted with *T. concentricum* and *T. rubrum*, relatives are more likely to be infected than conjugal partners, even with equal exposure to the fungus. Specific factors facilitating infection are unknown.

DERMATOPHYTOSES

Tinea Capitis

Tinea capitis is a dermatophytosis of the scalp and associated hair. It may be caused by any pathogenic dermatophyte from the genera *Trichophyton* and *Microsporum* excepting *T. concentricum*. The most common cause worldwide is *M. canis*, whereas in the United States *T. tonsurans* is most prevalent followed by *M. canis*.[18]

EPIDEMIOLOGY The incidence of tinea capitis remains unknown, but it is most commonly found in children aged 3 to 14 years old. It is uncommon in adults. For unknown reasons, tinea capitis is more common in children of African descent. Transmission is increased with decreased personal hygiene, overcrowding, and low socioeconomic status. Organisms responsible for tinea capitis have been cultured from fomites such as combs, caps, pillowcases, toys, and theater seats. Even after shedding, hairs may harbor infectious organisms for more than 1 year.[19] Asymptomatic carriers are common, making tinea capitis difficult to eradicate.[20]

PATHOGENESIS Ectothrix dermatophytes (see Table 188-1) typically establish infection in the perifollicular stratum corneum, spreading around and into the hair shaft of mid- to late-anagen hairs before descending into the follicle to penetrate the cortex of the hair. Arthroconidia then reach the cortex of the hair and are transported upward on its surface. Microscopically, only the ectothrix arthroconidia may be visualized on plucked hairs, although intrapilary hyphae are present as well.

The pathogenesis of endothrix infections is the same except that arthroconidia remain within the hair shaft, replacing the intrapilary keratin and leaving the cortex intact. As a result, the hair is very fragile and breaks at the surface of the scalp where support from the follicular wall is lost, leaving behind a tiny black dot. Thus, "black dot" tinea capitis is observed.

CLINICAL FINDINGS The clinical appearance of tinea capitis depends on its etiology (Table 188-3).

TABLE 188-3

[a]Note that a single organism may have more than one presentation.

▲ **FIGURE 188-3** Tinea capitis caused by *Microsporum audouinii*.

Noninflammatory, Human, or Epidemic Type. The noninflammatory pattern of tinea capitis is seen most commonly with the anthropophilic ectothrix organisms such as *M. audouinii* or *M. canis*. This form of tinea capitis is also known as the *seborrheic* form secondary to prominent scaling.[21] Inflammation is minimal. Hairs in the affected area turn gray and lusterless secondary to their sheath of arthroconidia and break off just above the level of the scalp (Fig. 188-3). Often there is no noticeable hair loss. Frequently, however, these lesions appear as well-defined, round hyperkeratotic, scaly areas of alopecia, due to the breaking off of hairs (gray patch type; Fig. 188-4). Appearance is like a "wheat field." Remaining hairs and scales exhibit green fluorescence under Wood's light (see Table 188-1). Lesions usually occur on the occiput.[19]

▲ **FIGURE 188-4** Tinea capitis "gray patch" type. A large, round hyperkeratotic plaque of alopecia due to breaking off of hair shafts close to the surface, giving the appearance of a mowed wheat field on the scalp of a child. Remaining hair shafts and scales exhibit a green fluorescence when examined with a Wood's lamp. *Microsporum canis* was isolated on culture.

Inflammatory Type. The inflammatory type of tinea capitis is usually seen with zoophilic or geophilic pathogens, with common examples being *M. canis* and *M. gypseum*. Inflammatory tinea capitis is the result of a hypersensitivity reaction to the infection. The spectrum of inflammation ranges from a pustular folliculitis to kerion (Fig. 188-5), which is a boggy, inflammatory mass studded with broken hairs and follicular orifices oozing with pus.[22] Such inflammation often results in scarring alopecia. Inflammatory lesions are usually pruritic, and may be associated with pain, posterior cervical lymphadenopathy, fever, and additional lesions on glabrous skin.

"Black Dot" Tinea Capitis. The "black dot" form of tinea capitis is caused by the anthropophilic endothrix organisms *T. tonsurans* and *T. violaceum*. This is the least inflammatory form of tinea capitis. Hair loss may or may not occur. When it does, hairs broken at the level of the scalp leave behind grouped black dots in the areas of alopecia (Fig. 188-6). Diffuse scaling is again typically present, but inflammation varies from minimal to pustular folliculitis or furuncle-like lesions to kerion.[20] Affected areas are usually multiple or polygonal with poorly demarcated, finger-like margins. Normal hairs commonly remain within patches of alopecia.

▲ **FIGURE 188-5** Kerion of the scalp.

▲ **FIGURE 188-6** "Black dot" tinea capitis caused by *Trichophyton tonsurans*.

DIFFERENTIAL DIAGNOSIS (Box 188-1)

HISTOPATHOLOGY In tinea capitis, methenamine silver and periodic acid-Schiff (PAS) stains reveal hyphae around and within the hair shaft. The dermis demonstrates a perifollicular infiltrate of mixed lymphocytes, histiocytes, plasma cells, and eosinophils. Follicular disruption leads to an adjacent foreign-body giant cell reaction.

Markedly inflammatory lesions, such as a kerion, demonstrate a more intense infiltrate of polymorphonuclear leukocyte abscesses within the dermis and follicle.[23] Organisms are difficult to visualize, but fungal antigens are detectable with immunofluorescent techniques.[24]

Tinea Favosa

Tinea favosa or favus (Latin, "honeycomb") is a chronic dermatophyte infection of the scalp, glabrous skin, and/or nails characterized by thick yellow

Box 188-1

Differential Diagnosis of Tinea Capitis

Most Likely

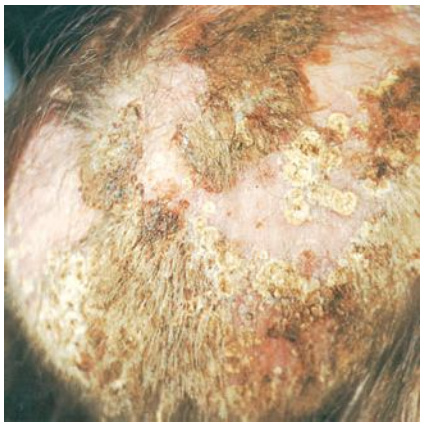
- Seborrheic dermatitis, atopic dermatitis, impetigo and pustular or plaque psoriasis, bacterial pyodermas, folliculitis decalvans, and perifolliculitis capitis abscedens et suffodiens

Consider

- Alopecia areata, trichotillomania, pseudopelade

Rule Out

- Syphilis, lupus erythematosus



▲ **FIGURE 188-7** Favus caused by *Trichophyton schoenleinii*. Note the numerous yellow scutula.

crusts (scutula) within the hair follicles, which lead to scarring alopecia.

EPIDEMIOLOGY Favus is usually acquired before adolescence and extends into adulthood.[25] Associated with malnutrition and poor hygiene, it has become geographically limited in the past century, as it is now seen almost exclusively in Africa, the Middle East, and parts of South America.[26] Even in these regions, its incidence is dramatically declining.

ETIOLOGY *T. schoenleinii* is the most common cause of human favus, with *T. violaceum* and *M. gypseum* occurring as rare isolates.[26] Although favus occurs in poultry, mice, and horses, there are very few reports in the literature of human favus caused by an organism responsible for animal favus.[27]

CLINICAL FINDINGS Early favus (usually the first 3 weeks of infection) is characterized by patchy follicular erythema with slight perifollicular scaling and mild matting of the hair. Progressive hyphal invasion distends the follicle, first producing a yellowish-red papule, then a yellow concave crust often centered about a single dull, dry hair (Fig. 188-7) that is less brittle than that of endothrix infections. The scutulum may reach 1 cm in diameter, engulfing surrounding hairs and coalescing with other scutula to form large adherent mats with an unpleasant cheese-like or musky odor. Over several years, the lesions advance peripherally, leaving central, atrophic clearings of alopecia.[26]

LABORATORY TESTS *T. schoenleinii* exhibits subtle, grayish-green fluorescence along the entire hair with Wood's lamp examination (see Table 188-1). Microscopy with KOH preparation reveals hyphae arranged lengthwise around and within the hair shaft, rare arthroconidia, and vacant air spaces.[26]

Tinea Barbae

EPIDEMIOLOGY Tinea barbae is by definition seen only in males. Largely transmitted by contaminated barbers' razors in the past, improved sanitation has reduced its incidence. Tinea barbae is now more often contracted by direct exposure to cattle, horses, or dogs, and is thus most commonly seen in rural settings among farmers or ranchers.

ETIOLOGY Tinea barbae is most commonly caused by the zoophilic organisms *T. mentagrophytes* and *T. verrucosum*, and, uncommonly, *M. canis*. Among the anthropophilic organisms, *T. megninii*, *T. schoenleinii*, and *T. violaceum* may cause tinea barbae in endemic areas, while *T. rubrum* is an infrequent cause.[26]

CLINICAL FINDINGS Tinea barbae is typically unilateral and more often involves the beard area than the moustache or upper lip. Three forms exist.

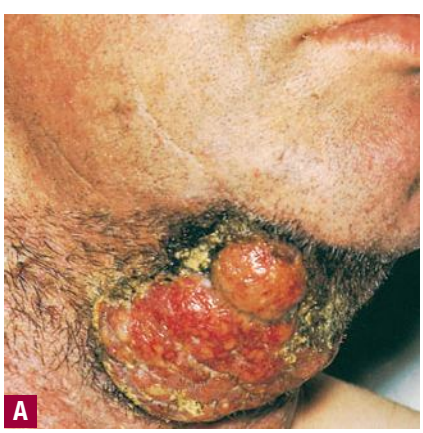
Inflammatory Type. Usually caused by *T. mentagrophytes* and *T. verrucosum*, inflammatory tinea barbae (Fig. 188-8) is analogous to kerion formation in tinea capitis. The lesions are nodular and boggy with a crusting seropurulent discharge.[28] Hairs in this area are lusterless, brittle, and easily epilated to demonstrate a purulent mass about the root. Perifollicular pustulation may coalesce to form sinus tracts and abscess-like collections of pus, eventuating in a scarring alopecia.[26]

▲ **FIGURE 188-9** Circinate tinea barbae has an advancing border of tiny papules, vesicles, and scaling.

Superficial Type. Caused by the less inflammatory anthropophiles, this form of tinea barbae closely resembles bacterial folliculitis, with mild diffuse erythema and perifollicular papules and pustules (see Fig. 188-8B). Hairs that are dull and brittle make endothrix infection with *T. violaceum* a more likely etiology than *T. rubrum*.

Circinate Type. Much like tinea circinata of glabrous skin, circinate tinea barbae exhibits an active, spreading vesiculopustular border with central scaling and relative sparing of the hair (Fig. 188-9).[28]

DIFFERENTIAL DIAGNOSIS (Box 188-2)



◀ **FIGURE 188-8** **A.** Tinea barbae, kerion. Sharply demarcated red nodule studded with multiple yellowish pustules. The surface is edematous and weeping. Note hairs have been lost from this nodule. **B.** Superficial tinea barbae. Scattered follicular papules and pustules easily mistaken for *Staphylococcus aureus* folliculitis.

Box 188-2

Differential Diagnosis of Tinea Barbae

Most Likely

- Bacterial folliculitis (sycosis vulgaris), perioral dermatitis, candidal folliculitis, pseudofolliculitis barbae, acne vulgaris/rosacea, contact dermatitis

Rule Out

- Halogenoderma, herpes simplex

Tinea Corporis (Tinea Circinata)

Tinea corporis refers to all dermatophytoses of glabrous skin except the palms, soles, and groin.

EPIDEMIOLOGY Tinea corporis may be transmitted directly from infected humans or animals, via fomites, or via autoinoculation from reservoirs such as *T. rubrum* colonization of the feet.[1] Children are more likely to contract zoophilic pathogens, especially *M. canis* from dogs or cats. Occlusive clothing and a warm, humid climate are associated with more frequent and severe eruptions.[29]

The occlusive clothing, frequent skin-to-skin contact, and minor trauma (mat burns) of competitive wrestling create an environment in which dermatophytes flourish. Numerous outbreaks of "tinea corporis gladiatorum" have resulted, mostly caused by *T. tonsurans*.[30]

▲ **FIGURE 188-10** Annular tinea corporis on the thigh. Note multiple, confluent annular lesions with a scaly and partially vesicular border. This type of lesion is usually seen with zoophilic dermatophytic infection.

Tinea imbricata, caused by *T. concentricum*, clinically appears as a plaque consisting of concentric erythematous rings. It is largely limited to areas of the Far East, South Pacific, and South and Central America.

ETIOLOGY Although any dermatophyte can cause tinea corporis, the most common cause is *T. rubrum*. *T. mentagrophytes*, *M. canis*, and *T. tonsurans* are also common pathogens.[3] *T. rubrum* and *T. verrucosum* are the most likely candidates in cases with additional follicular involvement.[28] Tinea imbricata is caused by *T. concentricum*.

▲ **FIGURE 188-11** Tinea corporis with typical "ringworm-like" configuration.

CLINICAL FINDINGS Table 188-4 presents the many variants of tinea corporis. The classic presentation is an annular lesion with scale across the entire erythematous border. The border is often vesicular (Fig. 188-10) and advances centrifugally. The center of the lesion is usually scaly but may exhibit clearing. Lesions may be serpiginous and annular ("ringworm"–like; Fig. 188-11). Concentric vesicular rings suggest tinea incognito caused by *T. rubrum*, whereas the concentric rings of tinea imbricata demonstrate little to no vesiculation.[1] *T. rubrum* infections may also present as large,

TABLE 188-4
Variants of Tinea Capitis

Name	Etiology	Clinical Description
Noninflammatory		
Tinea circinata	Any dermatophyte (usually *Trichophyton rubrum, T. mentagrophytes, Microsporum canis*)	Annular lesions with central clearing and an active, spreading border
Bullous tinea corporis	Usually *T. rubrum*	Spongiotic or sub-corneal vesicles/pustules; may be herpetiform
Tinea imbricata	*T. concentricum*	Widespread; multiple concentric, polycyclic scaly lesions with minimal inflammation
Inflammatory		
Kerion of glabrous skin	Zoophilic organisms	Similar to kerion of scalp or beard
Majocchi granuloma	*T. rubrum, T. violaceum, T. tonsurans, T. mentagrophytes*	Perifollicular, granulomatous nodules mostly on the scalps of children; often without pustulation, and associated with underlying disease
Nodular granulomatous perifolliculitis of the legs	*T. rubrum*	Variant of Majocchi granuloma affecting the lower two-thirds of women's legs; unilateral; *T. rubrum* is also present on the nails and feet
Agminate folliculitis	Zoophilic organisms	Well-defined erythematous plaques studded with perifollicular pustules
Subcutaneous abscess (tinea profunda)	*T. mentagrophytes, T. violaceum, T. tonsurans, T. rubrum, M. audouinii*	Deep subcutaneous nodules are present; rarely with lymph node involvement or hematogenous spread
Mycetoma	*M. audouinii, M. canis, M. ferrugineum, T. mentagrophytes, T. tonsurans, T. violaceum, T. verrucosum*	Subcutaneous masses
Tinea faciale	Usually *Trichophyton* species, occasionally *M. canis*	3%–4% of tinea corporis, erythematous, scaly plaques with or without active borders; telangiectasia, atrophy, and photo-exacerbation may mimic lupus erythematosus
Tinea incognito	Any dermatophyte infection modified by glucocorticoids	Atypical with possible absence of inflammation, scaling, or symptoms; dermal nodules or kerion-like lesions may be present

◀ **FIGURE 188-12** Polycyclic pattern of tinea corporis resembling psoriasis.

confluent polycyclic or psoriasiform plaques (Fig. 188-12).

Majocchi granuloma is an infection usually caused by *T. rubrum*, which occurs when fungal hyphae invade hairs and hair follicles. It is classically seen in women who shave their legs and appears as inflamed folliculocentric papules.

DIFFERENTIAL DIAGNOSIS (Box 188-3)

Tinea Cruris

Tinea cruris is a common dermatophytosis of the groin, genitalia, pubic area, perineal, and perianal skin. The designation is a misnomer, because in Latin "cruris" means of the leg. It is the second-most common dermatophytosis worldwide.

EPIDEMIOLOGY Much like tinea corporis, tinea cruris spreads via direct contact or fomites, and is exacerbated by occlusion and warm, moist climates. It is three times more common in men than in women, and adults are affected more commonly than children. Again, autoinfection from distant reservoirs such as tinea pedis caused by *T. rubrum* or *T. mentagrophytes* is common.[1]

Box 188-3

Differential Diagnosis of Tinea Corporis

Most Likely

- Erythema annulare centrifugum, nummular eczema, granuloma annulare

Consider

- Psoriasis, lichen planus, seborrheic dermatitis, pityriasis rosea, pityriasis rubra pilaris, polymorphous light eruption, contact dermatitis, acne rosacea

Rule Out

- Mycosis fungoides, secondary syphilis, lupus erythematosus, dermatomyositis, candidal or deep fungal infections, mycobacterial infections or blastomycosis

ETIOLOGY Most tinea cruris is caused by *T. rubrum* and *Epidermophyton floccosum*, with the latter being most often responsible for epidemics.[26] *T. mentagrophytes* and *T. verrucosum* are also less commonly involved.

CLINICAL FINDINGS Tinea cruris usually appears as multiple erythematous papulovesicles with a well-marginated, raised border. Pruritus is common, as is pain with maceration or secondary infection. *E. floccosum* tinea cruris is more likely to display central clearing, and is most often limited to the genitocrural crease and the medial upper thigh. In contrast, *T. rubrum* infections are often coalescent with extension to the pubic, perianal, buttock, and lower abdominal areas (Fig. 188-13). The genitalia are typically unaffected.[26]

DIFFERENTIAL DIAGNOSIS (Box 188-4)

Tinea Pedis and Tinea Manus

Tinea pedis is a dermatophytosis of the feet, whereas tinea manus affects the palmar and interdigital areas of the hand.

Box 188-4

Differential Diagnosis of Tinea Cruris

Most Likely

- Psoriasis, seborrheic dermatitis, candidiasis, erythrasma, lichen simplex chronicus

Consider

- Familial benign pemphigus, Darier-White disease

EPIDEMIOLOGY Present worldwide, tinea pedis and tinea manus are the most common dermatophytoses. The prevalence of tinea pedis is approximately 10 percent, primarily attributable to modern occlusive footwear, although increased worldwide travel has also been implicated.[26] The incidence of tinea pedis is higher among those using communal baths, showers, or pools.

Tinea manus may be acquired by direct contact with an infected person or animal, the soil, or autoinoculation.[31] However, it is nearly always associated with tinea pedis[26] and occurs most commonly in the hand used to excoriate the feet.

ETIOLOGY Tinea pedis and tinea manus are caused predominantly by *T. rubrum* (most common), *T. mentagrophytes*, and *E. floccosum*.

CLINICAL FINDINGS Tinea pedis may present as any of four forms, or a combination thereof.

Chronic Intertriginous Type (Interdigital Type). The most common presentation of tinea pedis, the chronic intertriginous

▲ **FIGURE 188-13** Tinea cruris. Scaling erythematous plaque with sharp margins in the unguinal and pubic region.

▲ **FIGURE 188-14** Tinea pedis, interdigital. The area is macerated and has opaque white scales and some erosions.

▲ **FIGURE 188-16** "Two feet–one hand" presentation of *Trichophyton rubrum*.

type, begins as scaling, erosion, and erythema of the interdigital and subdigital skin of the feet, particularly between the lateral three toes. Under appropriate conditions, the infection will spread to the adjacent sole or instep, rarely involving the dorsum.[26] Occlusion and bacterial co-infection soon produce the interdigital maceration, pruritus, and malodor of dermatophytosis complex (Fig. 188-14) or "athlete's foot."[32]

Chronic Hyperkeratotic Type. Usually bilateral with patchy or diffuse scaling limited to the thick skin, soles, and the lateral and medial aspects of the feet, this is also known as "moccasin-type" tinea pedis (Fig. 188-15). *T. rubrum*, the most common etiology, produces very few minute vesicles, leaving collarettes of scale less than 2 mm in diameter. Erythema is variable.[1]

Unilateral tinea manuum commonly occurs in association with hyperkeratotic tinea pedis, resulting in the "two feet–one hand syndrome" (Fig. 188-16). When tinea manus extend to the dorsum of a hand, it assumes the clinical pattern of tinea corporis (see eFig. 118-16.1 in online edition). Oral antifungals are often required for treatment due to the high incidence of concomitant onychomycosis and relapse.[33]

Vesiculo-Bullous Type. The vesiculo-bullous type of tinea pedis, typically caused by *T. mentagrophytes*, features tense vesicles larger than 3 mm in diameter, vesiculopustules, or bullae on the thin skin of the sole and periplantar areas (Fig. 188-17). It is rarely reported in childhood, but the most common etiologic agent in childhood is *T. rubrum*.[34]

Acute Ulcerative Type. Rampant bacterial co-infection, most often from Gram negatives in combination with *T. mentagrophytes*, produces vesiculopustules and large areas of purulent ulceration on the plantar surface. Cellulitis, lymphangiitis, lymphadenopathy, and fever are frequently associated.

The vesiculo-bullous and acute ulcerative types commonly produce a vesicular id reaction, either as a dyshidrotic-like distribution on the hands or on the lateral foot or toes.

DIFFERENTIAL DIAGNOSIS (Box 188-5)

LABORATORY TESTS For vesiculo-bullous lesions, examination of the roofs yields the highest rate of positivity on KOH examination.

PATHOLOGY Histologically, hyperkeratotic tinea pedis or tinea manuum is char-

▲ **FIGURE 188-17** Tinea pedis: Bullous type. Ruptured vesicles, bullae, erythema, and erosion on the plantar aspect of the great toe. Hyphae were detected on potassium hydroxide preparation obtained from the roof of the inner aspect of the bulla. In some cases, superficial white onychomycosis may also be seen with this *Trichophyton mentagrophytes* infection.

Box 188-5

Differential Diagnosis of Tinea Manus et Pedis

Most Likely

- Interdigital: Psoriasis, soft corns, bacterial co-infection, candidiasis, erythrasma
- Hyperkeratotic: Psoriasis, hereditary or acquired keratodermas of the palms and soles, dyshydrosis
- Vesiculo-bullous: Pustular psoriasis, palmoplantar pustulosis, bacterial pyodermas

Consider

- Pityriasis rubra pilaris, contact dermatitis, peridigital dermatitis, atopic dermatitis

Rule Out

- Reiter syndrome

acterized by acanthosis, hyperkeratosis, and a sparse, chronic, superficial perivascular infiltrate in the dermis. Vesiculo-bullous forms display spongiosis, parakeratosis, and sub-corneal or spongiotic intraepithelial vesiculation. With both types, foci of neutrophils are occasionally seen in the stratum corneum. PAS or methenamine silver staining demonstrates fungal organisms.

ONYCHOMYCOSIS

Onychomycosis denotes any infection of the nail caused by dermatophyte fungi, nondermatophyte fungi, or yeasts. *Tinea unguium*, however, refers strictly to dermatophyte infection of the nail plate. Onychomycosis is the most prevalent nail disease and accounts for approximately 50 percent of all onychopathies. The four clinical types of onychomycosis are: (1) distal subungual onychomycosis, (2) proximal subungual onychomycosis (PSO), (3) white superficial onychomycosis (WSO), and (4) candidal onychomycosis.

Epidemiology

Onychomycosis is a common infection, with a prevalence estimated in population-based studies at 2 percent to 8 percent, which is likely an underestimate. The Achilles project estimates the prevalence of onychomycosis in Europe at approximately 27 percent,[35] and North American studies show an incidence of 13.8 percent.[36] The increasing prevalence of this disease may be secondary to tight shoes, increasing numbers of immunosuppressed individuals, and increased use of communal locker rooms. Onychomycosis is also increasing in children, accounting for 20 percent of the superficial mycoses diagnosed in children in one study.[37]

The dermatophytosis commonly begins as tinea pedis before extending to the nail bed, where eradication is more difficult. This site then serves as a reservoir for recurrent skin infections, particularly in the setting of a hot and humid environment created by occlusion or tropical climates.[1]

Etiology

The dermatophytes cause the great majority of onychomycosis. *T. rubrum* is responsible for approximately 71 percent of all tinea unguium cases, and *T. mentagrophytes* adds another 20 percent. *T. tonsurans* and *E. floccosum* are also well-known causative agents.[35] Table 188-5 categorizes the most likely causative dermatophytes according to patterns of concurrent infection in other areas.[38]

Yeasts are the source of approximately 5 percent of onychomycosis (see Chap. 189), the majority of which is caused by *Candida albicans* and occurs in conjunction with chronic mucocutaneous candidiasis. The nondermatophyte molds *Acremonium, Aspergillus, Fusarium, Onychocola canadensis, Scopulariopsis brevicaulis,* and *Scytalidium dimidiatum* account for approximately 4 percent of onychomycosis, with *S. brevicaulis* as the most frequently identified mold pathogen.[39] The nondermatophyte molds appear to have a predilection for antecedently diseased or aged nails.[28]

Clinical Findings

The most common form of onychomycosis may be caused by any of the organisms listed above. It begins with invasion of the stratum corneum of the hyponychium and distal nail bed, forming a whitish to brownish-yellow opacification at the distal edge of the nail (Fig. 188-18). The infection then spreads proximally up the nail bed to the ventral nail plate. Hyperproliferation of the nail bed in response to the infection creates subungual hyperkeratosis, and progressive invasion of the nail plate results in an increasingly dystrophic nail.

TABLE 188-5
Causative Organisms According to Anatomic Patterns

- Tinea unguium + tinea pedis and/or tinea corporis
  - *Trichophyton rubrum*
  - *T. mentagrophytes var. interdigitale*
  - *Epidermophyton floccosum*
- Tinea unguium + tinea capitis or favus
  - *T. tonsurans*
  - *T. violaceum*
  - *T. megninii*
  - *T. schoenleinii*
- Tinea unguium + tinea imbricata
  - *T. concentricum*

▲ **FIGURE 188-18** Distal subungual onychomycosis.

PSO (Fig. 188-19) results primarily from *T. rubrum* and *T. megninii* infection of the proximal nail fold, and is evident as a white to beige opacity on the proximal nail plate. This opacity gradually enlarges to affect the entire nail, and subungual hyperkeratosis, leukonychia, proximal onycholysis, and destruction of the entire nail unit may be seen. *T. rubrum* causes PSO almost exclusively in those infected with human immunodeficiency virus.[5] WSO (Fig. 188-20) is a direct invasion of the dorsal nail plate resulting in white to dull yellow sharply bordered patches anywhere on the surface of the toenail. It is usually caused by *T. mentagrophytes*, although nondermatophyte molds such as *Aspergillus*,

▲ **FIGURE 188-19** Proximal subungual onychomycosis in a patient with acquired immunodeficiency syndrome; Kaposi sarcoma is also seen on the fourth toe.

▲ **FIGURE 188-20** White superficial onychomycosis.

Scopulariopsis, and *Fusarium* are also known etiologies. *Candida* species invade via the hyponychial epithelium to affect the entire thickness of the nail plate.[40]

Differential Diagnosis (Box 188-6)

Laboratory Tests

Because onychomycosis is responsible for only 50 percent of dystrophic nails, laboratory diagnostic confirmation is often helpful before treatment with an oral antifungal. KOH examination, nail biopsy, and fungal culture on SDA (with and without antimicrobials) are most useful. However, microscopy is often negative even when there is a high clinical suspicion of onychomycosis, and nails with positive microscopy often yield negative cultures. As most false-negatives are caused by sampling error, the simplest measures to maximize yield are to maximize sample size and perform repeat collections.[41]

Finally, because of the difficulty in discerning pathogens from contaminants, the following guidelines should be followed: (1) if a dermatophyte is isolated on culture, it is a pathogen; (2) if a non-dermatophyte mold or yeast is cultured, it is considered significant only if hyphae, spores, or yeast cells are seen on microscopic examination; and (3) confirmation of an infection by a nondermatophyte requires repeated isolation, classically defined as at least 5 of 20 inocula without concurrent isolation of a dermatophyte.[42] Studies have shown that PAS examination of nail clippings is the most sensitive diagnostic test for onychomycosis, whereas culture is the most specific test.[43]

Treatment of Dermatophytes

DISEASE	TOPICAL TREATMENT	SYSTEMIC TREATMENT
Tinea capitis	Only as adjuvant Selenium sulfide Zinc pyrithione Povidone iodine Ketoconazole	Griseofulvin, 20–25 mg/kg/day Fluconazole, 6 mg/kg/day Itraconazole, 3–5 mg/kg/day Terbinafine, 3–6 mg/kg/day
Tinea barbae	Only as adjuvant Topical antifungals	Griseofulvin, 1 g/day Itraconazole, 200 mg/day Terbinafine, 250 mg/day Fluconazole, 200 mg/day
Tinea corporis/cruris	Allylamines Imidazoles Tolnaftate Butenafine Ciclopirox	Adults: Fluconazole, 150 mg/wk Itraconazole, 100 mg/day Terbinafine, 250 mg/day Griseofulvin, 500 mg/day Children: Griseofulvin, 10–20 mg/kg/day Itraconazole, 5 mg/kg/day Terbinafine, 3–6 mg/kg/day
Tinea pedis/manuum	Allylamine Azole Ciclopirox Benzylamine Tolnaftate Undecenoic acid	Adults: Terbinafine, 250 mg/day Itraconazole, 200 mg twice/day Fluconazole, 150 mg/wk Children: Itraconazole, 5 mg/kg/day
Onychomycosis	Ciclopirox Amorolfine	Terbinafine, 250 mg/day Itraconazole, 200 mg/day Fluconazole, 150–300 mg once/wk

Histopathology

Hyphae are seen lying between the nail laminae parallel to the surface, with a predilection for the ventral nail and nail bed stratum corneum.[44] The epidermis may show spongiosis and focal parakeratosis, and there is a minimal dermal inflammatory response. In WSO, the organisms are present superficially on the dorsal nail and display unique "perforating organs" and "eroding fronds." Candidal onychomycosis displays invasion of pseudohyphae throughout the entire nail plate, adjacent cuticle, granular layer, and stratum spinosum of the nail bed, and the hyponychial stratum corneum.[40]

TREATMENT OF DERMATOPHYTES (Box 188-7)

Tinea Capitis/Favus

Multiple systemic and topical antifungals are available with efficacy against the dermatophytes. Infections involving hair-bearing skin necessitate oral antifungals as the dermatophytes penetrate the hair follicle. The standard treatment of tinea capitis in the United States has been and continues to be griseofulvin. The oral triazole (itraconazole, fluconazole) and allylamine (terbinafine) antifungals also appear to be safe, effective, and have the advantage of shorter treatment durations.

GRISEOFULVIN (See Chap. 233) Griseofulvin is still the only oral treatment approved by the U.S. Food and Drug Administration for tinea capitis. The previously recommended pediatric dosage was 10 to 20 mg/kg/day for 6 to 8 weeks taken with a fatty meal to facili-

tate absorption.[19] However, a reported high failure rate with this treatment has caused most experts to now recommend 20 to 25 mg/kg/day of the microsize form and 15 mg/kg/day of the ultramicrosize form for 8 weeks, although this recommendation is not based on clinical trials.[45]

The disadvantages of griseofulvin include poor compliance because of cost and length of treatment, its bitter taste in liquid form, photosensitivity, headache, and gastrointestinal side effects.[18] It also potently induces cytochrome P_{450} enzymes.[46] No laboratory tests are required for the duration of treatment used for tinea capitis.

FLUCONAZOLE (See Chap. 233) Available as both tablets and a pleasant-tasting liquid, fluconazole at doses of 6 mg/kg/day for 20 days is 89 percent effective in curing *T. tonsurans* tinea capitis.[47] Other effective treatment options include once-weekly dosing of 8 mg/kg fluconazole for 8 to 16 weeks and 6 mg/kg for 2 weeks followed by an additional week of therapy 4 weeks later, if clinically indicated.[48]

Absorption of fluconazole is not affected by meals, and gastrointestinal side effects exist but are uncommon. Hepatitis has been reported but occurs less frequently than with ketoconazole.[46]

ITRACONAZOLE (See Chap. 233) At doses of 3 to 5 mg/kg/day, itraconazole effectively eradicates tinea capitis caused by either *Microsporum* or *Trichophyton* species in 4 to 6 weeks.[49] Pulse therapy at 5 mg/kg/day for 1 week/month for one to three pulses is also effective.

Possible adverse effects of itraconazole include gastrointestinal upset, diarrhea with liquid itraconazole, and peripheral edema, especially when used in conjunction with calcium channel blockers. Like fluconazole, hepatotoxicity occurs at much lower rates than with ketoconazole.[46] However, there are reports of hepatic failure in patients treated with itraconazole. Itraconazole has also rarely been linked to congestive heart failure.

TERBINAFINE (See Chap. 233) Doses of 3 to 6 mg/kg/day of terbinafine can cure *Trichophyton* tinea capitis in 2 to 4 weeks, but 4 to 8 weeks of treatment are required for eradication of *Microsporum*.[18] A randomized comparison of 4 weeks of terbinafine to 8 weeks of griseofulvin showed no statistically significant difference overall. However, a subgroup with *Trichophyton* infection responded better to terbinafine, while *M. audouinii* infections responded better to griseofulvin.[50]

Terbinafine also produces gastrointestinal side effects and, rarely, hepatitis. Although it has fewer cytochrome P_{450} effects than the other oral antifungals, tricyclic antidepressant toxicity has occurred with concomitant terbinafine use as a result of CYP2D6 inhibition.[46] Like itraconazole, there are reports of liver failure in patients using this drug.

ADJUVANT THERAPY (See Chap. 219) A number of shampoos have been shown to help eradicate dermatophytes from the scalp of children, and their use is recommended by most experts. Selenium sulfide (1 percent and 2.5 percent), zinc pyrithione (1 percent and 2 percent), povidone iodine (2.5 percent), and ketoconazole (2 percent) are all commonly used. Common recommendations are to use these shampoos 2 to 4 times weekly for 2 to 4 weeks.[45] With markedly inflammatory tinea capitis, oral glucocorticoids may reduce the incidence of scarring. Although there is no consistent evidence for differences in cure rates, oral glucocorticoids are beneficial in relieving pain and swelling. The usual dose of prednisone is 1 to 2 mg/kg each morning for the first week of therapy.

Household transmission may be prevented through the treatment of infected family members or animals and disinfection of the environment. The use of ketoconazole 2 percent shampoo or selenium sulfide 2.5 percent by all household members three times weekly also reduces transmission by decreasing the shedding of spores.[18]

Tinea Barbae

Like tinea capitis, oral antifungals are essential in the treatment of tinea barbae. Griseofulvin at 1 g daily, itraconazole 200 mg daily for 2 to 4 weeks, terbinafine 250 mg daily for 2 to 4 weeks, or fluconazole 200 mg daily for 4 to 6 weeks are all effective treatment plans. Inflammatory *T. verrucosum*, *T. mentagrophytes*, and *M. canis* infections usually resolve without treatment in 2 to 4 weeks.[26] Systemic glucocorticoids are helpful for severe inflammatory lesions.[28]

Tinea Corporis/Tinea Cruris

For isolated lesions on the glabrous skin, topical agents such as the allylamines, imidazoles, tolnaftate, butenafine, or ciclopirox are effective. Most are applied twice daily for 2 to 4 weeks. Oral antifungals are reserved for widespread or more inflammatory lesions. Comparative studies in adults show fluconazole, 150 mg weekly for 4 to 6 weeks, itraconazole, 100 mg daily for 15 days, and terbinafine, 250 mg daily for 2 weeks, to be as effective as griseofulvin, 500 mg daily for 2 to 6 weeks, with no significant differences in adverse events.[51] Safe and effective regimens for children include ultramicrosize griseofulvin, 10 to 20 mg/kg/day for up to 6 weeks, itraconazole, 5 mg/kg/day for 1 week,[52] and terbinafine, 3 to 6 mg/kg/day for 2 weeks.

Tinea Pedis

Mild interdigital tinea pedis without bacterial involvement can be treated topically with an allylamine, azole, ciclopirox, benzylamine, tolnaftate, or undecenoic acid.[53] Topical terbinafine for 1 week is 66 percent effective.[54]

The newer oral antifungals have replaced griseofulvin as the treatments of choice for severe or refractory tinea pedis when accompanied by onychomycosis. The dosing schedule of terbinafine is 250 mg daily for 2 weeks. Effective regimens of itraconazole for adults are 200 mg twice daily for 1 week, 200 mg daily for 3 weeks, or 100 mg daily for 4 weeks,[51] whereas children should receive 5 mg/kg/day for 2 weeks.[52] Fluconazole, 150 mg weekly for 3 to 4 weeks or 50 mg daily for 30 days, is also effective.[51] Associated onychomycosis is common; if present, treatment of the onychomycosis is necessary to prevent recurrence of tinea pedis.

Maceration, denudation, pruritus, and malodor obligate a search for bacterial co-infection by Gram stain and culture. Antibiotics should be started once bacterial infection is documented and chosen based on sensitivity studies.

Finally, because vesiculo-bullous tinea pedis is the result of a T-cell–mediated immune reaction, symptomatic relief with topical or systemic corticosteroids may be warranted during the beginning of antifungal treatment.[55]

Onychomycosis

Treatment of onychomycosis depends both on the severity of nail involvement and on the causative fungus. Onychomycosis can be divided into cases with and without matrix area involvement. In cases without matrix area involvement, topical treatment alone can be sufficient for treatment, whereas oral and combination treatments are recommended for

cases with matrix involvement. Ciclopirox is sometimes an effective topical agent for tinea unguium (8 percent lacquer) applied daily for 48 weeks. When used for mild to moderate disease, it is 7 percent effective in achieving mycologic cure and clear nails.[56] It also has efficacy against *Candida* sp. and some molds.[57] Despite its much poorer efficacy compared with the newer oral antifungals, topical ciclopirox avoids the risk of drug interactions, an important consideration for chronic therapy in a mostly older population. Amorolfine is another agent specifically prepared for use as a nail lacquer. It is the first member of a new class of antifungal drugs, the morpholine derivatives. It has activity against the yeasts, dermatophytes, and molds that cause onychomycosis and has shown efficacy when applied once weekly.[57]

Oral antifungals may be used for refractory, severe, or nondermatophytic onychomycosis, or when a shorter treatment regimen or higher chance for clearance or cure is desired. Selecting an antifungal should be based primarily on the causative organism, potential adverse effects, and risk of drug interactions.

Terbinafine is fungicidal against dermatophytes, *Aspergillus*, and *Scopulariopsis*, but demonstrates variable activity against *Candida* sp. A course of 250 mg daily for 6 weeks is effective for most fingernail infections, while a minimum 12-week course is required for toenail infections. Most adverse effects are gastrointestinal, and cytochrome P_{450} interactions are insignificant. There is good evidence that a 3-month continuous regimen of terbinafine is the most effective oral treatment for fungally infected toenails available today.[58]

Itraconazole is fungistatic against dermatophytes, nondermatophyte molds, and yeasts. Safe and effective schedules include pulse dosing at 400 mg daily for 1 week per month or a continuous dose of 200 mg daily, both of which require 2 months of treatment for fingernails and at least 3 months for toenails.[39] Children may receive 5 mg/kg/day.[52] Elevated liver enzymes occur in 0.3 percent to 5.0 percent of patients, returning to normal within 12 weeks of discontinuation. Although itraconazole has a broader spectrum of activity than terbinafine, studies have shown a significantly lower rate of cure with itraconazole and higher relapse rates than seen with terbinifine.[59]

Fluconazole is fungistatic against dermatophytes, some nondermatophyte molds, and *Candida*. The usual dosage is 150 to 300 mg once per week for 3 to 12 months, although 450 mg weekly may be used in refractory onychomycosis.

Griseofulvin is no longer considered standard treatment for onychomycosis because of its adverse effects, drug interactions, prolonged treatment course, and low cure rates. Final options for refractory cases include surgical avulsion or chemical removal of the nail with 40 percent urea compounds in combination with topical or oral antifungals.

Combination therapies have been shown to have a more effective clearance rate than either oral or topical treatments alone. Oral terbinafine combined with ciclopirox nail lacquer was shown in one study to increase mycological cure rates from 65 percent with terbinafine alone to 88 percent for the combination.[60] A similar study of terbinafine and amorolfine nail lacquer showed improved cure rates from 37 percent for terbinafine alone to 72 percent for combination therapy.[61]

TINEA NIGRA

Tinea nigra is a superficial dermatomycosis, usually of the palmar stratum corneum, caused by *Hortaea werneckii* (formerly named *Phaeoannellomyces werneckii* and *Exophiala werneckii*).[62]

Epidemiology

Tinea nigra usually occurs in tropical or sub-tropical areas, including Central and South America, Africa, and Asia. It is infrequent in the United States and Europe. Of the approximately 150 cases reported in North America since 1950, the majority were associated with tropical travel.[63] However, endemic foci exist in the coastal southeastern United States and Texas. Person-to-person transmission is rare.[64] Tinea nigra has a female/male predilection of 3:1.

Etiology

Nearly always caused by *H. werneckii*, other dematiaceous fungi such as *Stenella araguata* may produce the same clinical picture. Such dematiaceous fungi are commonly found in soil, sewage, and decaying vegetation.[64] Tinea nigra arises after inoculation subsequent to trauma and has a typical incubation period of 2 to 7 weeks.

Clinical Findings

Tinea nigra is found on otherwise healthy people and presents as an asymptomatic, mottled brown to greenish-black macule with minimal to no scale (Fig. 188-21). It is frequently misdiagnosed as acral lentiginous melanoma. The macule is painless and discrete and is often darkest at the advancing border.

▲ **FIGURE 188-21** Tinea nigra palmaris. An irregular, brownish-black macule on the palm caused by *Hortaea werneckii*. (Used with permission from Stuart Salasche, MD.)

Differential Diagnosis (Box 188-8)

Laboratory Tests

KOH examination of scrapings from the lesion reveals brown to olive-colored thick, branching hyphae and oval to spindle-shaped yeast cells occurring singly or in pairs with a central transverse septum. Cultures may be performed on SDA with cycloheximide and chloramphenicol and grow within 1 week. Growth is initially yeast-like and brown to shiny black, appearing as the typical two-celled yeast forms under microscopic examination. With time, mycelial

Differential Diagnosis of Tinea Nigra

Most Likely

- Junctional nevus, melanoma

Consider

- Chemical exposure

Rule Out

- Addison disease, syphilis, pinta, melanoma

growth predominates as aerial hyphae create a fuzzy grayish-black colony.

Treatment

Tinea nigra responds easily to topical therapy with a keratolytic (Whitfield's ointment, 2 percent salicylic acid), tincture of iodine, or azole antifungal.[63] Treatment should be continued for 2 to 4 weeks after clinical resolution to prevent relapse. Ketoconazole twice daily is curative, as is itraconazole and miconazole or once daily terbinafine; however, systemic therapies are rarely indicated.[62,64]

PIEDRA

Piedra is an asymptomatic fungal infection of the hair shaft also known as *trichomycosis nodularis*. Black piedra is caused by *Piedraia hortae*, whereas white piedra is caused by pathogenic species of the *Trichosporon* genus, namely *Trichosporon asahii*, *T. ovoides*, *T. inkin*, *T. mucoides*, *T. asteroides*, and *T. cutaneum*.[62]

Epidemiology

Black piedra is seen commonly in humans and primates of tropical areas such as South America, the Pacific Islands, and the Far East, and less commonly in Africa and Asia. Scalp hair is most commonly affected. Infestation is encouraged for religious and esthetic reasons by some indigenous cultures.[63] *P. hortae* is present in the soil and in stagnant water and crops.

White piedra is most common in temperate and semi-tropical climates such as South America and Asia, the Middle East, India Africa, and Japan and occurs infrequently in the United States and Europe. It affects facial, axillary, and genital hair more commonly than the scalp.[28] Person-to-person transmission is rare, and infection has not been associated with travel to endemic areas.[65] *T. inkin* is found more commonly on pubic hair and *T. ovoides* on head hair. *T. asahii* can be present in the soil, air, water, vegetation, sputum, and on body surfaces.

Clinical Findings

Black piedra is characterized by firmly attached, hard, brown-black nodules on the hair shaft that vary from microscopic to a few millimeters in size, and are gritty to palpation.[63] Black piedra weakens the hair shaft, often resulting in broken hairs. Scalp hairs are most typically affected, and nodules are most commonly seen on the frontal scalp.

White piedra consists of softer and less adherent whitish to beige nodules that may be discrete or coalesce into sleeve-like structures. Broken hairs are sometimes present but are less common than with black piedra. White piedra can be easily detached from the hair shaft because it affects the outer lipid layers.

Diagnosis

Microscopy immediately differentiates piedra from nits, hair casts, developmental hair shaft defects, and trichomycosis axillaris. In addition, the nodules of trichomycosis axillaris are usually smaller and may fluoresce under a Wood's lamp.

Laboratory Tests

Nodules of black piedra examined with KOH display a periphery of aligned hyphae and a well-organized center of thick-walled cells packed closely together, sometimes termed *pseudoparenchyma*. These nodules are mostly outside of the hair shaft. *P. hortae* grows well, albeit slowly, on most laboratory media and is uninhibited by cycloheximide.

The nodules of white piedra have a less organized and more intrapilar appearance than do the nodules of black piedra, with hyphae arranged perpendicularly to the hair shaft.[63] *T. asahii* thrives on SDA and is inhibited by cycloheximide.

Treatment

Shaving the infected hair is often curative and is the best treatment for both black and white piedra. Shaving may be augmented by the use of a topical azole antifungal. Because of the high rate of relapse and evidence for intrafollicular organisms in white piedra, some authors suggest using an additional systemic antifungal in this disease such as oral itraconazole.[65]

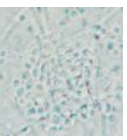
CHAPTER 189

Yeast Infections: Candidiasis and Tinea (Pityriasis) Versicolor

Matthew P. Janik
Michael P. Heffernan

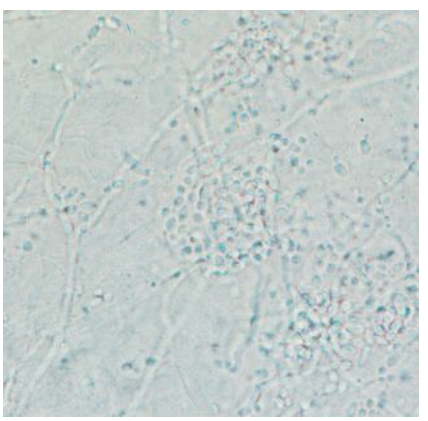


CANDIDIASIS

Candidiasis (or *candidosis*) refers to a diverse group of infections caused by *Candida albicans* or by other members of the genus *Candida*. These organisms typically infect the skin, nails, mucous membranes, and gastrointestinal tract, but they also may cause systemic disease.

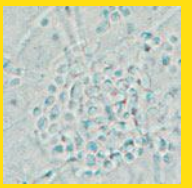
Etiology

The genus *Candida* is a heterogeneous group of approximately 200 yeast species.[1] Many species of *Candida* are opportunistic human pathogens, although the majority do not infect humans. All species within the genus *Candida* share the ability to produce pseudomycelia (Fig. 189-1), with the exception of *C. glabrata*. *Candida* do not possess morphologic or biochemical characteristics that would classify them in the genera of imperfect yeast, which are unicellular for the majority of their life cycle, nor do they produce ascospores or teliospores. Other species of *Candida* cause clinical disease under certain circumstances, such as immunosuppression, prolonged hospitalization, and previous antibiotic use.[2,3] These infections may be systemic or localized. *C. albicans* is a dimorphic yeast that is responsible for 70 percent to 80 percent of all candidal infections, which makes it the most common cause of superficial and systemic candidiasis.[2] Epidemiologic studies indicate that the relative prevalence of *C. albicans* in clinical isolates is declining, and other species such as *C. glabrata, C. tropicalis, C. krusei,*[1,4] *C. dubliniensis,*[5] and *C. parapsilosis*[1,6] are increasingly encountered as pathogens. The different species of *Candida* can be identified in the laboratory by microscopic examination of yeast morphology. Polymerase chain reaction assays and enzyme-linked immunosorbent assays for species differentiation are now becoming more readily available.[1,7]



▲ **FIGURE 189-1** *Candida* in potassium hydroxide preparation. Pseudomycelia in clusters of grape-like yeast cells.

YEAST AT A GLANCE



- *Candida albicans* accounts for 70 percent to 80 percent of all candidal infections.
- Clinically lesions are erythematous, macerated patches with satellite vesicopustules.
- *Candida* sp. are seen as typical budding yeasts with hyphae or pseudohyphae.
- *Malassezia furfur* and *M. globosa* most frequently cause tinea versicolor, hypopigmented or hyperpigmented macules with fine scales on the chest, back, abdomen, and proximal extremities.
- *Malassezia* sp. are long and have short, septate, and occasionally branching hyphae with a "spaghetti and meatballs" appearance.

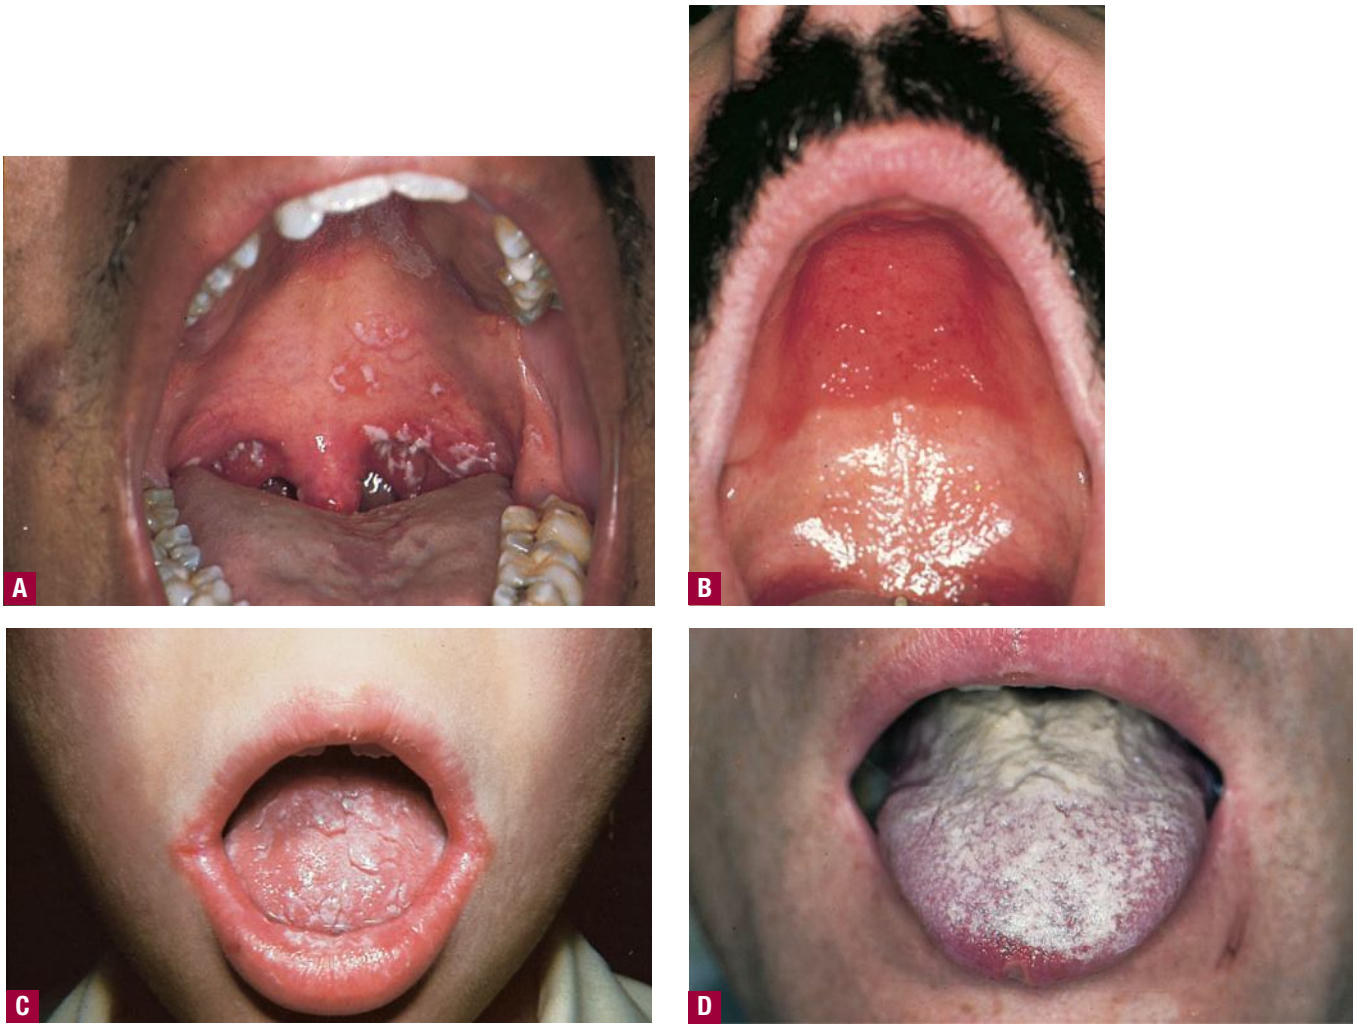
Pathogenesis

C. albicans is often found as a saprophyte and colonizes the mucous membranes of warm-blooded animals. In up to 50 percent of normal individuals, the oropharynx is colonized.[3] In addition, *C. albicans* exists as a commensal organism in the vaginal mucosa of 20 percent to 25 percent of asymptomatic, healthy women[8] and up to 30 percent of pregnant women.[9] The yeast is rarely isolated from normal human skin except occasionally from intertriginous areas. Likewise, the organism is infrequently found in soil, vegetation, and air samples.

Factors predisposing to *Candida* infection are outlined in Table 189-1.

TABLE 189-1
Factors Predisposing to *Candida* Infections

- Mechanical factors
  - Trauma (burns, abrasions)
  - Local occlusion, moisture, and/or maceration
  - Dentures
  - Occlusive dressings or garments
  - Obesity
- Nutritional factors
  - Avitaminosis
  - Iron deficiency (chronic mucocutaneous candidiasis)
  - Generalized malnutrition
- Physiologic alterations
  - Extremes of age
  - Pregnancy
  - Menses
- Systemic illnesses
  - Down syndrome
  - Acrodermatitis enteropathica
  - Endocrine disease
    - Diabetes mellitus
    - Cushing disease
    - Hypoadrenalism
    - Hypothyroidism
    - Hypoparathyroidism
  - Uremia
  - Malignancy (especially hematologic, thymoma)
  - Immunodeficiency
    - Acquired immunodeficiency syndrome
    - Severe combined immunodeficiency syndrome
    - Myeloperoxidase deficiency
    - Chédiak-Higashi syndrome
    - Hyperimmunoglobulinemia E syndrome
    - Chronic granulomatous disease
    - DiGeorge syndrome
    - Nezelof syndrome
- Iatrogenic causes
  - Indwelling catheters and intravenous lines
  - X-ray irradiation
  - Medications
    - Glucocorticoids
    - Other immunosuppressive agents
    - Antibiotics (especially broad spectrum, metronidazole)
    - Tranquilizers
    - Oral contraceptives (especially estrogen dominant)
    - Colchicine
    - Phenylbutazone



▲ **FIGURE 189-2** **A.** Pseudomembranous candidiasis or thrush. Note the characteristic white patches on the palate. **B.** Atrophic candidiasis under dentures. Edema and erythema at the site of contact with dentures. **C.** *Candida* perlèche with erythema and fissuring at the corners of the mouth. **D.** Hyperplastic candidiasis of the tongue.

Clinical Manifestations

The cutaneous and mucosal manifestations of candidiasis can be divided into several distinct clinical syndromes.

ORAL CANDIDIASIS Acute pseudomembranous candidiasis or thrush is the most common form of oral candidiasis. Predisposing factors include diabetes mellitus, systemic steroid use, antibiotic use, pernicious anemia, malignancies, radiotherapy to head and neck, and cell-mediated immunodeficiency[3,10,11] (see Table 189-1). Up to one-third of patients infected with human immunodeficiency virus develop oral candidiasis, and over 90 percent of patients with acquired immunodeficiency syndrome develop oral candidiasis over the course of their disease.[12] Oral candidiasis appears as discrete white patches that may become confluent on the buccal mucosa, tongue, palate, and gingivae (Fig. 189-2A). This friable pseudomembrane resembles milk curds and consists of desquamated epithelial cells, fungal elements, inflammatory cells, fibrin, and food debris (see Figs. 189-2A, C, and D). Scraping the patches exposes a brightly erythematous surface underneath. Microscopic examination of this material reveals masses of tangled pseudohyphae and blastospores (see Fig. 189-1). In severe cases, the mucosal surface may ulcerate.

Acute atrophic candidiasis (erythematous candidiasis) commonly occurs after sloughing of the thrush pseudomembrane.[10] This condition is associated with broad-spectrum antibiotic therapy, glucocorticoid use, and human immunodeficiency virus infection[3] (see Chap. 198). The most common location is on the dorsal surface of the tongue, where there are patchy depapillated areas with minimal pseudomembrane formation. There is both an asymptomatic and symptomatic variant, the later of which is characterized by burning or pain.[13]

Chronic atrophic candidiasis (denture stomatitis) (see Fig. 189-2B) is a common form of oral candidiasis seen in 24 percent to 60 percent of those wearing dentures.[14] Female patients are affected more commonly than males. Clinical findings of chronic erythema and edema of the palatal mucosa that contacts the dentures as well as angular cheilitis are present. Presumably, the chronic low-grade trauma and occlusion provided by dentures predispose to candidal colonization and subsequent infection.[15]

Candidal cheilosis (angular cheilitis), so-called *perlèche*, is characterized by erythema, fissuring, maceration, and soreness at the angles of the mouth (see Fig. 189-2C). This condition is commonly encountered in habitual lip lickers, usually in the young, and in elderly patients with sagging skin at the oral commissures. Loss of dentition, poorly fitting dentures, malocclusion, and riboflavin deficiency may be predisposing factors.

Box 189-1

Differential Diagnosis of Oral Candidiasis

Most Likely

- Lichen planus
- Herpetic infection
- Erythema multiforme
- Pernicious anemia

Consider

- Mucositis due to chemotherapy
- Lupus erythematosus
- Histoplasmosis
- Salicylate toxicity

Rule Out

- Glucagonoma
- Zink deficiency
- Pemphigus vulgaris

Cheilosis is often associated with chronic atrophic candidiasis due to denture wear.[10]

The differential diagnosis of oral candidiasis is summarized in Box 189-1.

VAGINAL AND VULVOVAGINAL CANDIDIASIS (See also Chap. 76) Approximately three-fourths of all women will experience an episode of vulvovaginal candidiasis (VVC) in their lifetime. *C. albicans* causes 80 percent to 90 percent of cases of VVC, and *C. glabrata* is the next most common species involved.[16] Risk factors for VVC include diabetes mellitus, steroid use, presence of an intrauterine device, wearing of tight-fitting and synthetic clothing, and immunosuppression.[17] A retrospective study conducted by MacDonald et al.[18] also showed a clear relationship between the use of oral antibiotics and subsequent VVC. These factors disrupt the vaginal lactobacilli that normally inhibit overgrowth of *Candida*.[16]

Patients generally present with a thick vaginal discharge associated with burning, itching, and occasional dysuria. Examination shows whitish plaques on the vaginal wall with underlying erythema and surrounding edema that can extend to the labia and perineum.

Recurrent VVC is defined as four or more episodes per year. Recurrent VVC occurs in up to 5 percent of women.[16] Changes in the hormonal environment, such as pregnancy and the luteal phase of the menstrual cycle, can induce a relapse of VVC. Use of a genital cleansing solution or douche is also associated with recurrent candidiasis. The mechanism may be an allergy or hypersensitivity response that increases susceptibility to *Candida*. If none of these factors is involved, one must suspect use of antibiotics, immunosuppression, or diabetes.[19] Frequent sexual intercourse may predispose women to recurrent VVC. This is assumed to be due to both vaginal abrasions sustained during intercourse and semen allergy.[20]

***CANDIDA* OF MALE GENITALIA: BALANITIS AND BALANOPOSTHITIS** *Candida* sp. cause 30 percent to 35 percent of infectious balanitis. Factors predisposing to balanitis include candidal vaginal infection in sexual partners, diabetes mellitus, and an uncircumcised state. *C. albicans* balanitis presents as small papules or fragile papulopustules on the glans or in the coronal sulcus (Fig. 189-3).These break to leave superficial erythematous erosions with a collarette of whitish scale. Infection may spread to the scrotum and inguinal areas. In diabetic or immunosuppressed patients, a severe edematous, ulcerative balanitis may occur. Occasionally, patients complain of a transient erythema and burning occurring shortly after intercourse.

CUTANEOUS CANDIDIASIS *C. albicans* has a predilection for colonizing moist, macerated folds of skin. Intertrigo is the most common clinical presentation on glabrous skin. Usual locations for intertrigo include the genitocrural, axillary, gluteal, interdigital, and inframammary (Fig. 189-4) areas and between folds of skin on the abdominal wall. Predisposing conditions include obesity, wearing of occlusive clothing, diabetes mellitus, and occupational factors.[21] Cutaneous candidiasis appears as pruritic, erythematous, macerated skin in intertriginous areas with satellite vesicopustules. These pustules break open, leaving an erythematous base with a collarette of easily detachable necrotic epidermis.

▲ **FIGURE 189-3** Candidiasis: balanoposthitis. Multiple discrete pustules on the glans penis and inner aspect of the foreskin.

Cutaneous candidal infection is diagnosed by the typical appearance of skin lesions and the presence of satellite vesicopustules. The clinical diagnosis should be confirmed by KOH examination and culture of skin scrapings. See Box 189-2 for the differential diagnosis of intertriginous candidiasis.

Several clinical variants of *Candida* intertrigo deserve special mention. Candidal diaper dermatitis is caused by yeast colonization from patients' gastrointestinal tracts. Chronic occlusion by wet diapers furthers the infection. Lesions appear first in the perianal area and spread to the perineum and inguinal creases, which show pronounced erythema[22] (see Fig. 189-4C). *Erosio interdigitalis blastomycetica* refers to interdigital candidal or polymicrobial infection of the hands or feet; because of anatomic considerations, it usually affects the third or fourth interspace (see Fig. 189-4D). *Candida* miliaria often affects the back in bedridden patients. Lesions start as isolated vesicopustules that contain yeast. *Candida* also can colonize and infect the skin around wounds covered by occlusive dressings (Fig. 189-5). Broad-spectrum topical antibiotics also contribute to *Candida* wound infections.[23]

Candidal paronychia is common in individuals whose hands are habitually involved in wet work (e.g., housekeepers, bakers, fishermen, bartenders). Typically there is redness, swelling, and tenderness of the paronychial area with prominent retraction of the cuticle toward the proximal nail fold (Fig. 189-6). Occasionally, pus can be expressed. Secondary nail changes include onycholysis and transverse depressions of the nail plate (Beau's lines) with a brownish or green discoloration along the lateral borders.[24,25] Candidal paronychia should be differentiated from bacterial paronychia or paronychia associated with hypoparathyroidism, celiac disease, acrodermatitis enteropathica (see Chap. 130), reactive arthritis syndrome (see Chap. 20), acrokeratosis paraneoplastica, and retinoid therapy.

DISSEMINATED CANDIDIASIS The incidence of disseminated candidiasis is steadily rising as more immunosuppressed patients are living longer. The organisms responsible include *C. albicans, C. tropicalis, C. glabrata,* and *C. parapsilosis.*[26] These organisms may gain hematogenous access from the oropharynx or gas-

▲ **FIGURE 189-4** Candidal intertrigo. **A.** Erythematous, eroded, pustular papules coalescing to plaques involving the scrotum and inguinal area with satellite lesions. Collarette-like scales where pustules have eroded. **B.** Confluent and discrete erythematous, eroded areas with pustular and erosive satellite lesions. **C.** Red, partially eroded plaques on the vulva surrounded by a delicate collar in an infant. Outside the main lesions are a few pustular satellite lesions. **D.** Erosio interdigitalis blastomycetica. Erythematous eroded areas between the fingers occurring in a waitress.

Box 189-2

Differential Diagnosis of Intertriginous Candidiasis

Most Likely

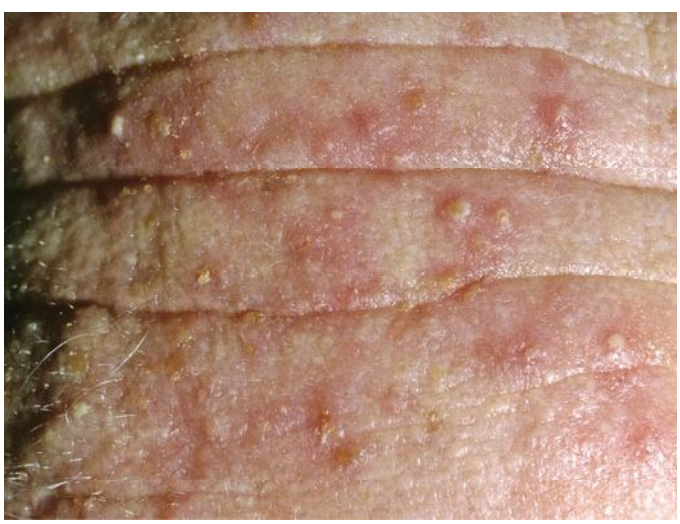
- Bacterial intertrigo
- Dermatophytosis (e.g., tinea cruris)
- Psoriasis
- Contact dermatitis
- Erythrasma
- Seborrheic dermatitis

Consider

- Familial benign pemphigus
- Flexural Darier disease
- Leiner disease

Rule Out

- Glucagonoma
- Extramammary Paget disease
- Secondary syphilis
- Zinc deficiency



▲ **FIGURE 189-5** *Candida* miliaria on the forehead of a diabetic patient that arose after use of a semi-occlusive dressing for headache.

◀ **FIGURE 189-6** Chronic onychia and paronychia caused by *Candida albicans*. **A.** Note the warm but not hot, slightly tender, edematous nail fold with some onycholysis. This is very often misdiagnosed as staphylococcal paronychia. **B.** This is a chronic inflammatory condition with pustulation of the nail fold that also can involve the nail plate.

trointestinal tract when the function of the mucosal barrier is compromised (e.g., by mucositis secondary to chemotherapy) or through contaminated intravenous catheters. Multiple organs are involved.[27] Skin lesions occur in some patients with disseminated infection. The recognition of such lesions may be important in early diagnosis, because antemortem blood culture results are negative in a high percentage of patients with autopsy-proven systemic candidiasis.[27]

The characteristic skin lesions are 0.5- to 1.0-cm erythematous papules with a hemorrhagic or pustular center (Fig. 189-7). The eruption is located on the trunk and extremities and has a varying number of lesions. Associated findings include fever and myalgias.[28] Necrotic cutaneous lesions also have been encountered in these patients.

▲ **FIGURE 189-7** Invasive candidiasis with candidemia. Multiple erythematous papules on the hand of a febrile patient with granulocytopenia associated with treatment of acute myelogenous leukemia. The usual source of the infection is the gastrointestinal tract. *Candida tropicalis* was isolated on blood culture. Candidal forms were seen in lesional skin biopsy specimens.

The differential diagnosis of disseminated candidiasis is provided in Box 189-3.

CHRONIC MUCOCUTANEOUS CANDIDIASIS

Chronic mucocutaneous candidiasis (CMC) consists of several clinical syndromes characterized by chronic, treatment-resistant, superficial candidal infections of the skin, nails, and oropharynx. There is virtually no propensity for disseminated visceral candidiasis. In many cases there are specific abnormalities in cell-mediated immunity; in others, the defects are more global. The clinical findings of CMC can be exhibited in a unique spectrum of disease.

There are multiple more or less distinct clinical syndromes of CMC (Table 189-2).[29–31] In general, the various syndromes may be familial or sporadic. When they present in childhood, lesions are detected before the age of 3 years. Oral lesions or diaper dermatitis appear first, followed by angular cheilitis (perlèche), lip fissures, nail and paronychial involvement, vulvovaginitis, and cutaneous involvement. Cutaneous lesions may appear with an erythematous, serpiginous border or areas of brownish desquamation on a background of mild erythema (Fig. 189-8).

Nail involvement is characterized by markedly thickened and dystrophic nail plates whose entire thickness is invaded by *Candida*. The paronychial areas are red and edematous, there may be pus, and the fingertips are often bulbous (see Fig. 189-6B).

There are multiple conditions that have been associated with CMC. Most notably these include candidal esophagitis or laryngitis, endocrinopathies (usually hypoparathyroidism, hypoadrenalism, and hypothyroidism), diabetes mellitus, vitiligo, and iron deficiency. Recurrent pyogenic, viral, or other fungal infections also may occur. When CMC first appears in adulthood, it is often associated with a thymoma.[32]

Box 189-3

Differential Diagnosis of Disseminated Candidiasis

Most Likely

- Bacterial sepsis (e.g., gonococcal, meningococcal, staphylococcal)

Consider

- Pityrosporum folliculitis
- Deep fungal infections (e.g., cryptococcosis, torulopsosis, or sporotrichosis)

Always Rule Out

- Disseminated fungal infections (e.g., aspergillosis)
- Disseminated herpes infection

Laboratory Findings

Direct microscopic examination of specimens for the presence of yeast and isolation of yeast in culture are needed to diagnose infection definitively. In superficial candidal infections, the diagnosis can be made by examining skin scrapings and observing typical budding yeasts with hyphae or pseudohyphae (see Fig. 189-1). *C. albicans* grows readily on Sabouraud's agar with added antibiotics and is usually recommended for isolation. Whitish mucoid colonies grow within 2 to 5 days.

In systemic candidiasis with skin lesions, the diagnosis usually can be made from histopathologic examination and culture of appropriate skin biopsy specimens. Blood culture results often are negative in this setting.[26] Serologic studies using immunodiffusion, counterim-

TABLE 189-2
Classification of Chronic Mucocutaneous Candidiasis

Clinical Syndrome	Inheritance	Age at Onset	Distribution of Lesions	Endocrinologic Abnormality	Associated Findings	Notes
Chronic oral candidiasis	Sporadic	Any	Mucosa of tongue, lips, buccal cavity; perlèche; no skin or nail involvement	None	Esophagitis	Denture stomatitis is a variant.
Chronic candidiasis with endocrinopathy	Autosomal recessive	Childhood	Mucous membranes, skin, and/or nails	Frequent (hypoadrenalism, hypothyroidism, hypoparathyroidism, or polyendocrinopathy)	Alopecia totalis, thyroiditis, vitiligo, chronic hepatitis, pernicious anemia, gonadal failure, malabsorption, diabetes mellitus	Endocrinopathy may be delayed in onset.
Chronic candidiasis without endocrinopathy	Autosomal recessive	Childhood	Mucous membranes, perlèche, and nail involvement; less common skin involvement	None	Blepharitis, esophagitis, laryngitis	—
	Autosomal dominant	Childhood		None	Dermatophytosis, loss of teeth, recurrent viral infections	—
Chronic localized mucocutaneous candidiasis	Sporadic	Childhood	Mucous membranes, skin, and/or nails	Occasionally	Pulmonary infections, esophagitis	Hyperkeratotic lesions (*Candida*), granuloma.
Chronic diffuse candidiasis	Autosomal recessive	Childhood	Widespread on mucous membranes, skin and nail involvement	None	—	Erythematous, serpiginous skin lesions.
		Adolescence	Widespread on mucous membranes, skin and nail involvement	None	History of frequent course of antibiotics	—
Chronic candidiasis with thymoma	Sporadic	Adulthood (after third decade)	Mucous membranes, nails, and skin	None	Thymoma, myasthenia gravis, aplastic anemia, neutropenia, hypogammaglobulinemia	Chronic mucocutaneous candidiasis often precedes diagnosis of thymoma.

munoelectrophoresis, and latex agglutination methods may be somewhat helpful in the diagnosis; however, false-negative and false-positive reactions are common. More promising are techniques to detect circulating candidal antigens (e.g., mannan or enolase) or metabolic products (e.g., arabinitol), which show encouraging sensitivities and specificities in serial testing.[33]

Microscopic Studies

Because *Candida* sp. may infect virtually any organ system, specimens for laboratory examination will vary from body fluids to surgical biopsy samples. Direct microscopic examination for the presence of yeast provides rapid evidence to support the clinical diagnosis. Body fluids such as urine and cerebrospinal fluid should be centrifuged and the sediment examined directly to increase the probability of finding yeast. Sputum, surgical biopsy specimens, and tissue scrapings must be treated with a clearing agent such as 10 percent KOH and ink before the material is examined. *Candida* appears as oval budding cells, elongated filamentous cells connected end to end (pseudohyphae), or septate hyphae (see Fig. 189-1).

Pathology

Superficial candidiasis is characterized by sub-corneal pustules. Organisms are seldom seen within the pustule but can be visualized in the stratum corneum with the aid of a periodic acid-Schiff (PAS) stain. The histologic examination of a candidal granuloma shows marked papillomatosis and hyperkeratosis and a dense dermal infiltrate consisting of lymphocytes, granulocytes, plasma cells, and multinucleated giant cells. In systemic candidal infections with skin involvement, biopsy specimens show focal areas of yeast in the dermis and within blood vessels. Organisms can be identified using PAS or methenamine silver stains. There may be a surrounding mononuclear cell infiltrate, leukocytoclastic vasculitis, or microabscess formation.

Treatment

Treatment options are available and effective for each of the candidal infections.

ORAL CANDIDIASIS In cases of uncomplicated oral candidiasis, nystatin suspension (400,000 to 600,000 units four times per day) or clotrimazole troches (10 mg dissolved in the mouth five times per day) are effective. However, in recurrent cases, oral azoles (see Chap. 233) are proven to be more effective.

CANDIDAL VULVOVAGINITIS AND BALANITIS Two therapeutic options exist when dealing with candidal vaginitis. There are many topical imidazoles that are effective, such as butoconazole, miconazole, and clotrimazole, available over the counter, and tioconazole, econazole,

▲ **FIGURE 189-8** Mucocutaneous candidiasis. Well-demarcated serpiginous lesions with massive scaling. Lesions look like psoriasis.

and terconazole available by prescription (see Chap. 219). They may be used for 3 or 7 days.[34] All these topical agents are safe to use during pregnancy.[35] Oral fluconazole, itraconazole, and ketoconazole offer efficacy similar to that of topical therapy (see Chap. 233). Prophylactic regimens can be used to prevent recurrent cases. A weekly clotrimazole 500-mg tablet intravaginally or fluconazole 150 mg/week orally has been shown to prevent recurrences.[34] The recommended treatment for candidal balanitis is topical clotrimazole cream or a single 150-mg dose of fluconazole.

INTERTRIGO Intertrigo has been treated successfully with topical antifungals including nystatin and topical imidazole creams. Miconazole powder can be use to dry moist intertriginous areas.

CANDIDAL PARONYCHIA Chronic paronychia due to *Candida* is resistant to therapy. All wet work should be minimized, and a topical imidazole in solution form is the ideal treatment.[36] Four percent thymol in chloroform or absolute alcohol is drying and may be a suitable alternative. Oral ketoconazole also may be used.[37]

DISSEMINATED CANDIDIASIS Amphotericin B is available in newer lipid-based formulations. Also, caspofungin is available for treating disseminated candidiasis (see Chap. 233).[38]

PITYROSPORUM INFECTIONS OF THE SKIN: PAPULOSQUAMOUS TINEA VERSICOLOR, *PITYROSPORUM* FOLLICULITIS, AND INVERSE TINEA VERSICOLOR

The genus *Malassezia* currently includes nine species of lipophilic basidiomycetous yeast: *M. furfur, M. pachydermatis, M. sympodialis, M. globosa, M. restricta, M. slooffiae, M. obtusa, M. dermatis,* and *M. equi*.[39] Previously, *M. furfur, M. pachydermatis,* and *M. sympodialis* were the only members of the genus. In 1996, a new taxonomic classification based on morphology, ultrastructure, and molecular biology was proposed[40] that added four new species. More recently, it was projected that the possible identification of new species *M. japonica, M. nana,* and *M. yamatoensis* may bring the total to 12.[41] These yeasts cause a wide spectrum of superficial cutaneous disease, including tinea (pityriasis) versicolor, *Pityrosporum* folliculitis, and seborrheic dermatitis, while contributing to atopic dermatitis and psoriasis.[39]

Etiology and Pathogenesis

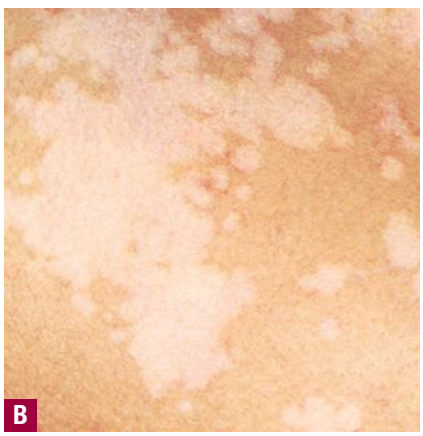
M. furfur can be cultured from diseased and normal skin and is considered part of the normal flora, particularly in sebum-rich areas of the skin.[42] *M. furfur* is a dimorphic, lipophilic organism that grows in vitro only with the addition of C12 to C14 fatty acids such as olive oil and lanolin. Under appropriate conditions, it converts from the saprophytic yeast to the predominantly parasitic mycelial morphologic form associated with clinical disease. Factors responsible for mycelial transition include a warm, humid environment, oral contraceptive use, heredity, systemic corticosteroid use, Cushing disease, immunosuppression, hyperhidrosis, and a malnourished state.[42,43]

The species of *Malassezia* can be differentiated by their nutritional requirements, morphology, and molecular biology.[39,40] *M. pachydermatis* is the one member of the genus *Malassezia* without an absolute requirement for exogenous lipids. This is due to its ability to produce phospholipase, which directly correlates with skin infection.[44] Although previously recognized as a zoophilic organism, it has been identified only recently as a human pathogen. In one study, *M. pachydermatis* caused a series of infections in a neonatal care nursery, where it was presumably spread to patients from health care workers whose pet dogs were colonized with the fungus.[45] It was later proven that the vast majority of dog owners tested positive for *M. pachydermatis* on their hands.[46] Other members of the genus, including *M. sympodialis* and *M. slooffiae*, are part of the normal skin flora.[47] A few studies also linked *M. sympodialis* with neonatal cephalic pustulosis, a skin disorder also known as *neonatal acne*.[48,49]

M. furfur has long been identified as the fungus causing tinea versicolor. However, studies now indicate that *M. globosa* may be involved in the pathogenesis of this disease. In patients with tinea versicolor, when the organism was identified, the vast majority of lesions were associated with *M. globosa*.[39]

Tinea versicolor is an opportunistic infection of the skin. Experimental inoculation of *Malassezia* under occlusion can cause infection.[42] The resulting increase in humidity, temperature, and CO_2 tension appear to be important factors that make the skin susceptible to infection.[50] When the occlusion is terminated, healing occurs, although the organism is not eradicated from the skin and can be cultured from clinically uninvolved areas.[51] It also may colonize follicular structures, and a high recurrence rate is expected.

The yeast may filter the rays of the sun and interfere with normal tanning.[51]



▲ **FIGURE 189-9** Tinea versicolor. **A.** These lesions are darker because of hyperemia secondary to inflammatory response and increased melanin. **B.** There are sharply marginated, uniformly hypopigmented macules with fine, sometimes barely perceptible scales, which are easily scraped off with a glass slide. When the lesions are very large, as on the left, they can be confused with vitiligo.

Mayser et al.[52] discussed a specific compound synthesized by *Malassezia* called *pityriacitrin* that absorbs ultraviolet light.[52] Other metabolites of *M. furfur* such as azaleic acid, a dicarboxylic acid, can cause hypopigmentation by inhibiting tyrosinase and injuring melanocytes.[51,53] The long-standing damage to melanocytes due to these by-products may explain why most hypopigmented lesions persist for months and some persist for years.[53]

Clinical Features

Cutaneous infections with *Malassezia* may take three forms: (1) papulosquamous tinea versicolor, (2) folliculitis, and (3) inverse tinea versicolor. The most common presentation is scaly hypopigmented or hyperpigmented macules observed in characteristic areas of the body, including the chest, back, abdomen, and proximal extremities (Fig. 189-9). Less common areas of involvement include the face, scalp, and genitalia. The characteristic scale is described as dust-like or furfuraceous. This characteristic feature of the disease can be produced by lightly scraping a scalpel blade over the involved skin.[53] The color of the lesions varies from almost white to reddish brown or fawn colored. The presenting complaint is usually a cosmetic one, because lesions often fail to tan with sun exposure. Pruritus is mild or absent.

The differential diagnosis of papulosquamous tinea versicolor is presented in Box 189-4.

In *Malassezia (Pityrosporum)* folliculitis, lesions typically appear on the back, chest, and sometimes the extremities in adolescents (Fig. 189-10A). Pruritus is more common than with typical tinea versicolor. The primary lesion is a perifollicular, erythematous, 2- to 3-mm papule or pustule. Only appropriate culture and KOH examination can distinguish this infection from a bacterial folliculitis. Frequently, biopsy with special stains for fungus is necessary, but *Malassezia* can often be recognized in follicles even in hematoxylin and eosin–stained sections (see Fig. 189-10B). Diabetes mellitus, glucocorticoid use, antibiotic therapy, and use of immunosuppressive medications can predispose to this disorder.[39] There have also been cases of recalcitrant acne vulgaris and concurrent *Pityrosporum* folliculitis.[54] See Box 189-5 for the differential diagnosis of *Pityrosporum* folliculitis.

Box 189-4

Differential Diagnosis of Papulosquamous Tinea Versicolor

Most Likely
- Pityriasis alba
- Pityriasis rosea
- Seborrheic dermatitis
- Dermatophyte infections

Consider
- Vitiligo
- Psoriasis
- Pityriasis rubra pilaris
- Confluent and reticulated:
  - Papillomatosis of Gougerot and Carteaud

Always Rule Out
- Secondary syphilis

▲ **FIGURE 189-10** **A.** *Pityrosporum* folliculitis on the anterior chest. **B.** Histopathology. Note the organisms in the follicular ostia on staining with hematoxylin and eosin.

The lesions of *inverse tinea versicolor* are encountered predominantly in flexural areas.[55] These lesions are sharply demarcated confluent erythematous patches that can be confused with inverse psoriasis, seborrheic dermatitis, erythrasma, candidiasis, and dermatophytic infections.

Box 189-5

Differential Diagnosis of *Pityrosporum* Folliculitis

Most Likely
- Bacterial folliculitis
- Acne vulgaris

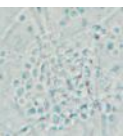
Consider
- Candidal folliculitis
- Eosinophilic folliculitis

Always Rule Out
- Disseminated candidiasis
- Pustular drug eruption

Each of the cutaneous variants has an equal sex distribution and tends to flare during the summer months, presumably due to increased heat and humidity. These infections are also more common in tropical climates. Although the disease can occur at any age, it favors late adolescence and early adulthood when sebaceous glands are most active.[39,42]

Laboratory Findings

To identify the *Malassezia* yeast forms, scale from involved skin should be scraped onto a glass slide and treated with 10 percent KOH. Alternatively, cellophane tape can be used to pick up skin scales from the lesion. The tape is mounted on a glass slide with methylene blue, and the organism is selectively stained.[56] The microscopic appearance of the yeast is classically described as "spaghetti and meatballs" (Fig. 189-11).



Pathology

In tinea versicolor, the organisms inhabit the stratum corneum. There is usually no dermal infiltrate. Yeast may be observed with hematoxylin and eosin staining alone. PAS staining is confirmatory. Microscopic examination reveals clusters of oval budding yeast cells 3.5 × 4.5 μm long with short, septate, and occasionally branching hyphae (see Fig. 189-11). In *Pityrosporum* folliculitis, organisms are noted in widened follicular ostia mixed with keratinous material (see Fig. 189-10B). Rupture of the follicular wall can occur with a resulting mixed inflammatory and foreign-body giant cell response.

Diagnosis

The clinical appearance of tinea versicolor is usually characteristic, and KOH examination is confirmatory. A Wood's lamp examination may show yellowish fluorescence of involved skin.

Treatment and Prognosis

TINEA VERSICOLOR Multiple topical products are useful in treating tinea versicolor. The most widely used has been 2.5 percent selenium sulfide shampoo, which is applied daily for 2 weeks and left on for at least 10 minutes, then washed off. Subsequently, applying the drug once or twice per month will usually prevent recurrence. All the topical azole antifungals have been effective in the treatment of tinea versicolor. Ketoconazole 2 percent shampoo is lathered on affected areas and left for 5 minutes; this treatment is repeated for 3 consecutive days.[57] Topical terbinafine 1 percent solution applied twice daily to lesions for 7 days has yielded cure rates of more than 80 percent.[58]

Although topical therapy is ideal for localized lesions, systemic treatment may be necessary for patients with extensive disease or frequent recurrences, or for whom topical agents have failed.[59] Oral ketoconazole (200 mg daily for 7 days) or oral itraconazole (200 to 400 mg daily for 3 to 7 days) is almost universally effective. Even one dose of itraconazole 400 mg by mouth has been shown to be more than 75 percent effective and in one study was just as effective as itraconazole given for 1 week.[60] Fluconazole is also effective and can be administered as a single dose of 400 mg.[57]

***PITYROSPORUM* FOLLICULITIS** *Pityrosporum* folliculitis also can be treated successfully with systemic therapy. Although there are few controlled trials, oral ketoconazole (200 mg daily for 4 weeks), fluconazole (150 mg weekly for 2 to 4 weeks), and itraconazole (200 mg daily for 2 weeks) are useful systemic agents in the treatment of this condition.[39,56]

CHAPTER 190

Deep Fungal Infections

Roderick J. Hay

Deep fungal infections comprise two distinct groups of conditions, the subcutaneous and systemic mycoses. Neither are common, and the subcutaneous mycoses, with some exceptions, are largely confined to the tropics and sub-tropics. In recent years, the systemic mycoses have become important opportunistic infectious complications in immunocompromised patients, including those with acquired immunodeficiency syndrome (AIDS) and patients receiving treatment for malignancies. They also include a group of primary respiratory infections, such as histoplasmosis and coccidioidomycosis, which may affect otherwise healthy individuals and those with underlying illness. The fungi that cause these respiratory infections are usually dimorphic or exist in a different morphologic phase (e.g., yeast or mold) at different stages of their life cycle.

Patients with subcutaneous fungal infections often present to a physician with signs of skin involvement. By contrast, patients with systemic mycoses only occasionally have skin lesions, either following direct involvement of the skin as a portal of entry or after dissemination from a deep focus of infection. There are a number of excellent texts about fungi and the diseases they cause.[1–4]

Treatment of these conditions remains difficult in many cases, although there is now a wide range of antifungal drugs with different modes of action (see eFig. 190-0.1 in on-line edition.)

SUBCUTANEOUS MYCOSES

The subcutaneous mycoses, or mycoses of implantation, are infections caused by fungi that have been introduced directly into the dermis or subcutaneous tissue through a penetrating injury, such as a thorn prick. Although many are tropical infections, some, such as sporotrichosis, are also prevalent in temperate climates; any of these infections may present as an imported disease in a patient who has originated from an endemic area, sometimes after a lapse of many years. The most common subcutaneous mycoses are sporotrichosis, mycetoma, and chromoblastomycosis. Rarer infections include lobomycosis and subcutaneous zygomycosis.

Sporotrichosis

Sporotrichosis is a subcutaneous or systemic fungal infection caused by the dimorphic fungus *Sporothrix schenckii*.[5,6] The fungus occurs in the natural environment, presumably in mold form, but develops as a yeast in infections. The most frequent site of this infection is the dermis or subcutis. There is also a systemic form of sporotrichosis whose clinical features range from pulmonary infection to arthritis or meningitis. One important characteristic of the diagnosis of cutaneous lesions is the scarcity of organisms in tissue, making confirmation of the diagnosis by microscopy potentially difficult.[6] Sometimes in tissue, fungal cells are surrounded by an eosinophilic refractile fringe, the asteroid body, that is a characteristic of the organism, although a similar phenomenon may occur with other infectious organisms (e.g., Schistosome eggs).

EPIDEMIOLOGY Infections occur in both temperate and tropical countries. They are seen in North, South, and Central America, including the southern United States and Mexico, as well as in Africa, Egypt, Japan, and Australia (see eFig. 190-0.2 in on-line edition).[6] The countries where the highest rates of infection occur are Mexico, Brazil, and South Africa. However, sometimes hyperendemic areas are found where large numbers of cases occur.[7] In the United States, infections are most common in the midwestern river valleys. Infections are now rare in much of Europe. In nature, the fungus grows on decaying vegetable matter such as plant debris, leaves, and wood. Although it is usually a cause of sporadic infection, *S. schenckii* also may affect groups of workers exposed to the organism, such as those using straw as a packing material, gardeners, forestry workers, and those whose recreational activities bring them into contact with plant debris. The organism is thought to be introduced into the skin through a local injury.

CLINICAL FINDINGS One important feature of the infection is the development of clusters of cases in defined geographic areas. For instance, there was a major outbreak of sporotrichosis in the South African gold mines from 1941 to 1944.

The two clinical varieties of sporotrichosis are the subcutaneous and systemic forms of disease.[5,8,9] Subcutaneous sporotrichosis is by far the more common and includes two main forms: lymphangitic and fixed infections. The lymphangitic form is the more common and usually develops on exposed skin sites such as hands or feet. The first sign of infection is the appearance of a dermal nodule that breaks down into a small ulcer. Draining lymphatics become inflamed and swollen, and a chain of secondary nodules develops along the course of the lymphatic (Fig. 190-1); these also may break down and ulcerate. In the fixed variety, which accounts for about 15 percent of cases, the infection remains localized to one site, such as the face, and a granuloma develops that subsequently may ulcerate. Satellite nodules may form around the rim of the primary lesion. Other clinical variants of subcutaneous sporotrichosis may mimic mycetoma, lupus vulgaris, and chronic venous ulceration. In some cases, deep extension of the infection may affect joints or tendon sheaths. Patients with AIDS who develop sporotrichosis often have multiple cutaneous lesions[9] without prominent lymphatic involvement, but deep infections, such as arthritis, are also reported.

In the much rarer systemic form of sporotrichosis, lesions can develop almost anywhere, although chronic lung nodules, with cavitation, arthritis, and meningitis have been described most frequently. These may co-exist with cutaneous lesions of sporotrichosis.

DIFFERENTIAL DIAGNOSIS Conditions commonly confused with sporotrichosis are

SUBCUTANEOUS MYCOSES AT A GLANCE

- Are usually sporadic
- Are contracted in the tropics and sub-tropics
- May cause chronic disability
- Are best diagnosed by histopathology, except for sporotrichosis
- Often require months of successful antifungal treatment

▲ **FIGURE 190-1** Sporotrichosis. An ulcerated nodule is seen on the thumb, with proximal lymphangitic spread represented by subcutaneous nodules. (Used with permission from Takeji Nishikawa, MD.)

mycobacterial (see Chap. 184) and primary cutaneous *Nocardia* infections (see Chap. 185) and leishmaniasis (see Chap. 206). The nontuberculous mycobacterial infection due to *Mycobacterium marinum* (fish-tank granuloma), in particular, closely resembles lymphangitic sporotrichosis.

LABORATORY TESTS The best sources of diagnostic material are smears, exudates, and biopsies. *S. schenckii* is seen very rarely in direct microscopic examination because yeasts are usually present only in small numbers; the organism can be isolated readily on Sabouraud's agar. In primary culture, the fungus grows as a mold, with compact, white colonies that darken with age. Microscopically, the hyphae produce small oval or triangular conidia either on specialized hyphae or elsewhere on the mycelium. Ideally, the organism should be converted to yeast phase on enriched media such as brain-heart infusion agar at 37°C (98.6°F) to complete the identification.

Pathologically, sporotrichosis causes a mixed granulomatous reaction with neutrophil microabscesses. The fungus, if present, is usually in the form of small (3 to 5 μm) cigar-shaped or oval yeasts that may, on occasion, be surrounded by a thick, radiating eosinophilic fringe forming the distinctive asteroid body. Organisms are usually sparsely distributed in lesions, and it may be necessary to scan several sections to identify one yeast. An intradermal sporotrichin skin test is available in some countries and may have a role to play in allowing the physician to identify the most appropriate laboratory investigations to instigate.

TREATMENT Although spontaneous remissions may occur, most patients are treated with antifungal chemotherapy.[10] Potassium iodide (saturated solution), 4 to 6 mL tid, is effective in the cutaneous types of sporotrichosis and should be continued for 3 to 4 weeks after clinical cure. The daily dose is built up slowly from 1 mL tid over 2 to 3 weeks to avoid side effects such as hypersalivation and nausea. This is an inexpensive form of therapy, but it is unpalatable. Alternative treatments include itraconazole, 200 mg daily, and terbinafine, 250 mg daily, which are better tolerated, and intravenous amphotericin B for deep infection. In all cases, treatment is continued for at least 1 week after clinical resolution.

Mycetoma (Maduromycosis, Madura Foot)

Mycetoma is a chronic localized infection caused by different species of fungi or actinomycetes. It is characterized by the formation of aggregates of the causative organisms, known as *grains*, that are found within abscesses. These either drain via sinuses onto the skin surface or involve adjacent bone, causing a form of osteomyelitis. Grains are discharged onto the skin surface via these sinuses. The disease advances by direct spread, and distant metastatic sites of infection are very rare. Mycetomas caused by species of fungi are known as *eumycetomas*, and those caused by aerobic actinomycetes or filamentous bacteria are known as *actinomycetomas* (see Chap. 185). The organisms are usually soil or plant saprophytes[11] that are only incidental human pathogens.

EPIDEMIOLOGY Mycetomas are mainly, but not exclusively, found in the dry tropics where there is low annual rainfall (see eFig. 190-1.1 in on-line edition).[11,12] They are sporadic infections that are seldom common, even in endemic areas.[13] Occasionally, nonimported cases are reported from temperate climates, although in these cases, the most common organism is *Scedosporium apiospermum*. Actinomycetomas due to *Nocardia* sp. are most common in Central America and Mexico. In other parts of the world, the most common organism is a fungus, *Madurella mycetomatis*. The actinomycete *Streptomyces somaliensis* is isolated most often from patients originating from Sudan and the Middle East. The causative organisms of mycetoma have been isolated from either soil or plant material, including Acacia thorns, in endemic areas.

The organisms are implanted subcutaneously, usually after a penetrating injury. It is unusual to find any underlying predisposition in patients with mycetoma, and the persistence of the organism after the initial inoculation appears to be related to its ability to evade host defenses through a variety of adaptations such as cell wall thickening and melanin deposition.[14]

CLINICAL FINDINGS The clinical features of both fungal and actinomycete mycetomas are very similar.[12] They are most common on the foot, lower leg, or hand, although head or back involvement also may occur. Infection of the chest wall is most characteristic of *Nocardia* infections (see Chap. 185). The earliest stage of infection is a firm, painless nodule that spreads slowly with the development of papules and draining sinus tracts over the surface (Fig. 190-2). Local tissue swelling, chronic sinus formation, and later bone involvement distort and deform the original site of infection (Figs. 190-3 and 190-4). Lesions are seldom painful except in the late stages and where sinus tracts are about to emerge onto the skin surface. Dissemination from the initial site is exceptionally rare, although local lymphadenopathy may occur.

X-ray changes include periosteal erosion and proliferation, as well as the development of lytic lesions in the bone. Bone scans or magnetic resonance imaging may identify bone lesions at an earlier stage.

DIFFERENTIAL DIAGNOSIS Chronic bacterial or tuberculous osteomyelitis may re-

▲ **FIGURE 190-2** Mycetoma. Brawny edema and crusted papules on the plantar surface.

▲ **FIGURE 190-4** Mycetoma. Chronic fibrotic involvement of the foot with lymphatic spread to the popliteal fossa.

semble mycetoma. Actinomycosis (see Chap. 185) is also similar but usually develops close to certain sites, such as the mouth or the cecum, where the causative organisms are sometimes commensal.

LABORATORY TESTS Finding the mycetoma grains is the key to establishing the diagnosis, and these are generally discharged from the openings of sinus tracts. However, they also may be obtained by removing the surface crust from a pustule or sinus tract with a sterile needle and gently squeezing the edges. Grains are 250- to 1000-μm white, black, or red particles that can be picked out with the naked eye (Table 190-1). Direct microscopy of grains is important because it will show whether the grain is composed of the small actinomycete or broader fungal filaments. In general, it is not possible to distinguish the fine actinomycete filaments in potassium hydroxide (KOH) mounts or, for that matter, in hematoxylin and eosin–stained material. In addition, black grains are always caused by fungi; red grains, by actinomycetes (see Table 190-1).

Final identification requires isolation of the causal agent in culture. In view of the number of possible species, a series of different culture media and conditions of incubation should be used. Morphologic and physiologic characteristics are used to distinguish between the genera and species. There are now a few examples where the organism has been identified using specific primers through use of the polymerase chain reaction. Serology is diagnostically helpful only in some cases (e.g., in *S. somaliensis)*, and even then, more as a guide to therapeutic response.

Histologically, there is a chronic inflammatory reaction with neutrophil abscesses and scattered giant cells and fibrosis.[11] Grains (50 to 250 μm) are found in the center of the inflammation. Their size and shape may help in the identification, although with nonpigmented eumycetomas, this is seldom sufficient (Fig. 190-5).

TREATMENT Of the fungal causes of mycetoma, some cases of *M. mycetomatis* infection respond to ketoconazole, 200 mg daily, over several months. For the others, a trial of therapy with griseofulvin, terbinafine, or itraconazole is worth attempting. However, responses to chemotherapy are unpredictable, although antifungals may slow the course of infection. Surgery, usually amputation, is the definitive procedure and may have to be used in advanced cases. However, the value of major surgery in a disfiguring but nonlife-threatening infection has to be weighed against the availability of appropriate prosthetic limbs.

Actinomycetomas (see Chap. 185) generally respond to antibiotics such as a combination of dapsone with streptomycin or sulfamethoxazole-trimethoprim plus rifampin or streptomycin. Amikacin also may be used in recalcitrant *Nocardia* infections. The responses in all but a few cases are good.[15]

▲ **FIGURE 190-3** Eumycetoma caused by *Scedosporium* leading to significant distortion of the forefoot.

Chromoblastomycosis (Chromomycosis)

Chromoblastomycosis is a chronic fungal infection of the skin and subcutaneous tissues caused by pigmented or dematiaceous fungi that are implanted into the dermis from the environment. In the ensuing inflammation, they form thick-walled single cells or cell clusters (sclerotic or muriform bodies), and these may elicit a marked form of pseudoepitheliomatous hyperplasia often accompanied by trans-epidermal elimination of organisms. The infection can be caused by a number of different pigmented fungi, the most common being *Phialophora verrucosa, Fonsecaea pedrosoi, F. compactum, Wangiella dermatitidis,* and *Cladophialophora carrionii*.[16]

EPIDEMIOLOGY The fungi that cause chromoblastomycosis can be isolated in the environment from wood, plant debris, or soil.[17] The vast majority of infections are caused by *F. pedrosoi* and *C. carrionii*. As with other subcutaneous mycoses, infection follows implantation through a tissue injury. The infection is

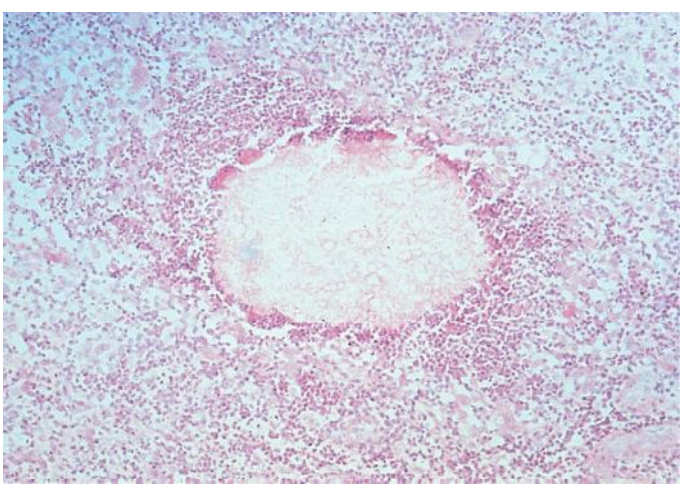
TABLE 190-1
Macroscopic and Histopathologic Features of Mycetoma Grains

Organisms	Hematoxylin and Eosin Section Appearances
Eumycetoma	
Dark grains	
Madurella mycetomatis	Cement present, vesicles sometimes prominent
M. grisea	Cement absent, compact outer layer
Leptosphaeria senegalensis	Cement in outer zone, dark periphery with vesicular center
Exophilia jeanselmei	Cement absent, often hollow
Pyrenochaeta romeroi	Cement lacking, compact outer layer
Pale grains	
Fusarium sp., *Acremonium, Scedosporium apiospermum, Aspergillus nidulans, Neotestudina rosati*	Compact, pigment lacking, interwoven fungal filaments (*S. apiospermum* may have prominent vesicles)
Actinomycetoma	
Pale (white to yellow) grains	
Actinomadura madura	Basophilic-stained fringe in layers
Nocardia brasiliensis	Small, pale blue, eosinophilic fringe
Yellow to brown grains	
Streptomyces somaliensis	Grains fractured, basophilic or pink
Red to pink grains	
A. pelletieri	Small, basophilic layers

found as a sporadic condition in Central and South America, although rarely in North America. It occurs in the Caribbean region, Africa (particularly Madagascar), Australia, and Japan (see eFig. 190-5.1 in on-line edition). It also may occur as an imported infection outside the usual endemic areas. The disease is most frequent in male rural workers.

CLINICAL FINDINGS The initial site of the infection is usually on the feet, legs, arms, or upper trunk. The clinical features vary.[17] The initial lesion is often a warty papule that expands slowly over months or years (Figs. 190-6 and 190-7). Alternatively, lesions may be plaque-like with an atrophic center. The more common verrucous form spreads slowly and locally. Individual lesions may be very thick and often develop secondary bacterial infection. Satellite lesions around the initial site of infection are local extensions of the infection and usually are produced by scratching. Complications of chromoblastomycosis include local lymphedema, leading to elephantiasis and squamous carcinomas in some chronic lesions.

DIFFERENTIAL DIAGNOSIS The disease must be differentiated from chronic tropical lymphedema with hyperplasia (mossy foot). Other chronic verrucous lesions, such as tuberculosis and blastomycosis, are often more extensive. The identification of organisms in the lesions of chromoblastomycosis is essential.



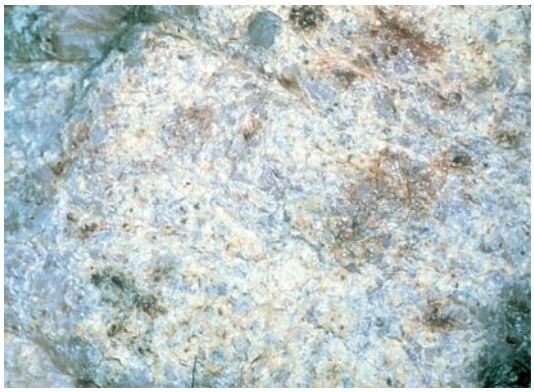
▲ **FIGURE 190-5** Pale eumycetoma grain (hematoxylin and eosin stain).

▲ **FIGURE 190-6** Chromoblastomycosis. A solitary, large, verrucous plaque surrounded by a halo of erythema is seen on the calf. (Used with permission from Ted Rosen, MD, and Howard Rubin, MD.)

LABORATORY TESTS The typical sclerotic or muriform fungal cells can be seen in skin scrapings taken from the surface of lesions, particularly areas where there is a small dark spot on the skin surface, using KOH mounts. The lesions also should be biopsied because the pathologic changes and presence of muriform cells are typical. The histology shows a mixed granulomatous response, with small neutrophil abscesses and often exuberant epidermal hyperplasia.[18] The organisms, which are often seen either in giant cells or in neutrophil abscesses, appear singly or in small groups of brown pigmented cells, often with a single or double septum and thick cell wall.

In culture, these fungi are very similar in gross macroscopic appearance, producing black colonies with a downy surface. Their cultural identification depends on demonstrating the presence of different but specific types of sporulation, and either single or multiple sporulation mechanisms may be seen in each organism. Accurate differentiation between the different fungi may be difficult. At this stage, the choice of treatment does not depend critically on correct identification of the organisms, although there may be differences in the speed of response to azole drugs (see following section Treatment).

TREATMENT The main treatments for chromoblastomycosis are itraconazole, 200 mg daily, with or without flucytosine, 30 mg/kg qid (in a patient with normal renal function)[19]; terbinafine, 250 mg daily[20]; and, in extensive cases, intravenous amphotericin B (up to 1



◀ **FIGURE 190-7** Close-up view of chromoblastomycosis. Note hyperkeratosis with pigmentation.

mg/kg daily). Lesions can be spread by surgery, which should be used only as an adjunctive therapy after drug treatment. The local application of heat may be helpful in some instances. The responses of these fungi to different antifungal agents do not appear to differ significantly, although there is some evidence that *C. carrionii* responds more rapidly to terbinafine and itraconazole. In any event, treatment is continued until there is clinical resolution of lesions, which usually takes several months. Extensive lesions often respond poorly to treatment.

Pheohyphomycosis (Phaeomycotic Cyst, Cystic Chromomycosis)

Phaeohyphomycosis is a rare infection characterized by the formation of subcutaneous inflammatory cysts. It is caused by dematiaceous fungi, the most common of which are *Exophiala jeanselmei* and *W. dermatitidis*, but some 103 species have been described as causal agents.[21] However, unlike in chromoblastomycosis, these organisms form short, irregular, pigmented hyphae in tissue. The infection may occur in any climatic area, although it is more common in the tropics. It also may appear in immunosuppressed patients, particularly those receiving long-term glucocorticoid therapy. The lesions present as cysts and may be mistaken for other similar structures such as Baker's cysts. The diagnosis is usually made after surgical excision. Histologically, the cyst wall consists of palisades of macrophages and other inflammatory cells surrounded by a fibrous capsule, and the fungal hyphae are found in the macrophage zone. Although the fungi in tissue lesions are usually pigmented, this is not always the case; cystic lesions caused by non-pigmented fungi being called hyalohyphomycotic cysts. The treatment is surgical excision, although relapse can occur, particularly in immunocompromised patients.

Lobomycosis (Keloidal Blastomycosis, Lobo Disease)

Lobomycosis is an uncommon infection seen in Central and South America, often in remote rural areas. The source of the organism is unknown, although similar lesions have been found on freshwater dolphins. Lobomycosis is characterized by the appearance of keloid-like skin lesions on exposed sites.[22] Although it cannot be cultured in vitro, it is caused by a fungus, *Lacazia loboi*, that forms chains of rounded cells in tissue, each joined by a small tubule. Lesions may occur anywhere on the body but usually are found on exposed parts such as the legs, arms, and face. They can spread from site to site by autoinoculation. Antifungal drugs are not effective, and surgical removal is the main treatment.

Subcutaneous Zygomycosis [Basidiobolomycosis, Subcutaneous Phycomycosis and Conidiobolomycosis, (Rhino)-Entomophthoromycosis]

Subcutaneous zygomycosis is a rare tropical subcutaneous mycosis characterized by the development and spread of a chronic, firm swelling involving subcutaneous tissue. There are two main varieties caused by different organisms.[23] The first, most often caused by *Basidiobolus ranarum* (*B. haptosporus*), is more common in children. It occurs in a wide variety of countries and environments from South America to Africa and Indonesia. The organism can be found in plant debris and in the intestinal tracts of reptiles and amphibians. Lesions usually develop around limb girdle sites and present with a firm, slowly spreading, woody cellulitis. The second form, caused by *Conidiobolus coronatus*, is seen in adults. The organism can be isolated from soil, plant debris, and some insects. The early infection starts in the region of the inferior turbinates of the nose. Spread involves the central part of the face, and once again, the swelling is hard and painless. It may cause very severe deformity of the nose, lips, and cheeks. These infections are distinct to those caused by other zygomycete fungi.

Histopathologically, a chronic granulomatous response with large numbers of eosinophils can be seen. The fungi are present as large, strap-like hyphae without cross walls or septa. They are also often surrounded by refractile eosinophilic material (Splendore-Hoeppli phenomenon). The organisms can be cultured readily on Sabouraud's agar. Lesions usually respond to oral treatment with potassium iodide, given in similar doses to those used in sporotrichosis (see Treatment under Sporotrichosis). Ketoconazole (400 mg daily) and itraconazole (100 to 200 mg daily) also may be useful in this condition, although experience to date is limited to a few cases.

Rhinosporidiosis

Rhinosporidiosis is a chronic infection caused by the organism *Rhinosporidium seeberi*, which causes the development of polyps affecting the mucous membranes. The organism has never been cultured, and it is now thought to be an aquatic protist and a member of the Mesomycetozoa. Rhinosporidiosis is seen most often in southern India and Sri Lanka. Cases also have been described in South America, the Caribbean, and South Africa. Exposure to water (lakes, pools) has been associated with the infection. The main site affected is the nasal mucosa, but the conjunctival mucosa also may be affected.[24] The infection causes the development of large polyps that are studded with white flecks; these are small cysts or sporangia containing small spores. These are best seen in histopathologic sections, where the large sporangia or spore sacs in different phases of development are readily seen. The only treatment is surgical excision.

SYSTEMIC MYCOSES

The systemic mycoses are fungal infections whose initial portal of entry into the body is usually a deep site such as the lung, gastrointestinal tract, or paranasal sinuses. They have the capacity to spread via the bloodstream to produce a generalized infection. In practice, there

ENDEMIC AND OPPORTUNISTIC SYSTEMIC MYCOSES

AT A GLANCE

- Where the patient has lived or visited is important for correct diagnosis.
- A careful history relevant of underlying disease states and their treatment is critical.
- Erythema nodosum may be caused by some endemic mycoses (e.g., coccidioidomycosis).
- Skin biopsy is important in making the diagnosis.
- Positive fungal culture must be interpreted with caution, as the organism identified may simply be colonizing the site.
- Warn the laboratory if you are sending material from a suspected endemic mycosis case for culture, as these are dangerous pathogens and require containment facilities.
- Treatment usually requires prolonged therapy often with intravenous drugs such as amphotericin B, voriconazole, or caspofungin.

TABLE 190-2
Underlying Predisposition and Opportunistic Systemic Mycoses

PREDISPOSITION	INFECTION
Neutropenia (whatever cause) functional neutrophil defects	Aspergillosis, oropharyngeal, and/or systemic candidiasis, zygomycosis, infections due to rare organisms
CD4 lymphopenia (e.g., acquired immunodeficiency syndrome)	Oropharyngeal candidiasis, cryptococcosis, and endemic respiratory mycoses such as histoplasmosis, nocardiosis
Diabetes mellitus	Zygomycosis
Heart valve surgery	Various but mainly *Candida albicans* and non-*albicans Candida* sp.
Abdominal surgery	Candidiasis

are two main varieties of systemic mycosis: the opportunistic mycoses and the endemic respiratory mycoses.

The chief opportunistic systemic mycoses seen in humans are systemic or deep candidiasis, aspergillosis, and systemic zygomycosis. These affect patients with severe underlying disease states, such as AIDS, or with neutropenia associated with malignancy, solid-organ transplants, or extensive surgery. Where combination antiretroviral therapy is used, the incidence of systemic mycoses in patients infected with human immunodeficiency virus (HIV) has dropped considerably. In the neutropenic patient in particular, other fungi also may cause infection occasionally. Different underlying conditions predispose to different mycoses, and a scheme for this is shown in Table 190-2. Generally, skin involvement is not common with most of these opportunistic infections, which can occur in any climate and environment. The clinical manifestations of the opportunistic mycoses are also variable because they depend on the site of entry of organism and the underlying disease.

The endemic respiratory mycoses are histoplasmosis (classic and African types), blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and infections due to *Penicillium marneffei*. The clinical manifestations of these infections are affected by the underlying state of the patient, and many develop in the presence of particular immunodeficiency states, notably AIDS. However, they follow similar clinical patterns in all infections. These infections also may affect otherwise healthy individuals. They have well-defined endemic areas determined by factors that favor the survival of the causative organisms in the environment, such as climate. The usual route of infection is via the lung (Fig. 190-8).

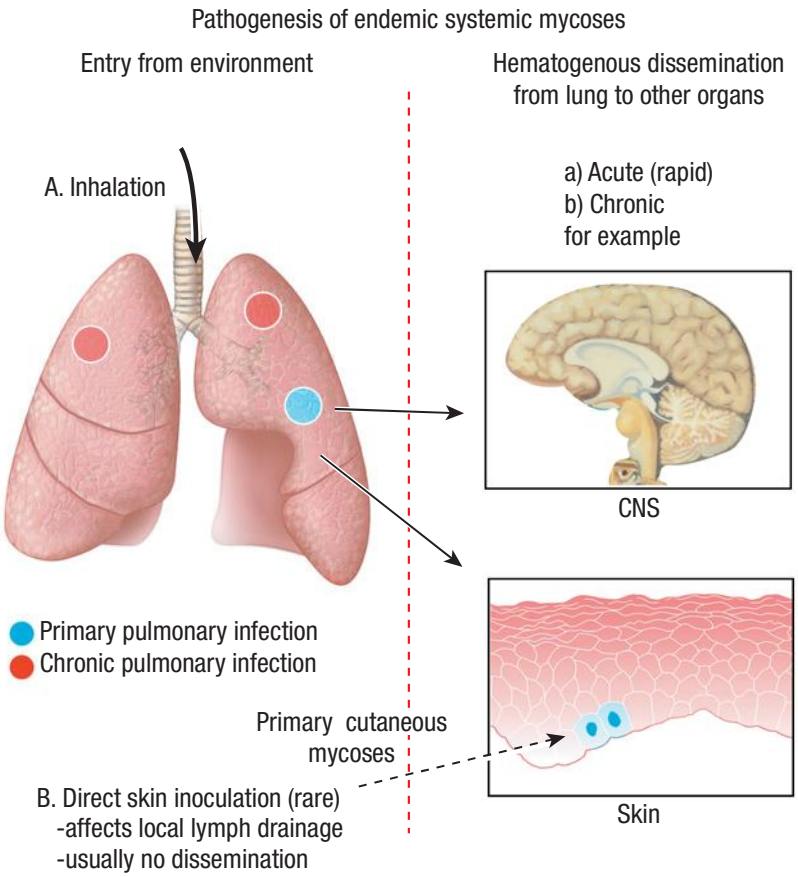
In practice, because of the tendency for both groups of infections to develop in predisposed patients, the distinction between opportunistic and endemic mycoses is blurred. This is particularly the case with cryptococcosis, which shares clinical and pathologic features of the two main types of respiratory systemic mycoses but is mainly seen now in AIDS patients.

Histoplasmosis

Fungi of the dimorphic genus *Histoplasma* cause a number of different infections in animals and humans. These range from equine farcy, or equine histoplasmosis, a disseminated infection of horses caused by *Histoplasma farciminosum* to two human infections known as *classic* or *small-form histoplasmosis* and *African histoplasmosis*. These are caused, respectively, by two variants of *H. capsulatum*: *H. capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii*. They can be distinguished because their respective yeast phases differ in size, the *capsulatum* variety producing cells from 2 to 5 μm in diameter and the *duboisii* form producing cells of 10 to 15 μm in diameter. The other important differences are in their epidemiology and clinical manifestations. They also show minor antigenic differences that are apparent in serodiagnosis but their mycelial phases are identical. The two types of human infections will be referred to as *histoplasmosis* and *African histoplasmosis* because this nomenclature is used most widely.

SMALL-FORM OR CLASSIC HISTOPLASMOSIS OR HISTOPLASMOSIS CAPSULATI Histoplasmosis results from infection with the dimorphic fungus *H. capsulatum* var. *capsulatum*. A sexual state of this fungus, *Ajellomyces capsulatus*, also has been described. The infection starts as a pulmonary infection that, in most individuals, is asymptomatic and heals spontaneously, the only evidence of exposure being the development of a positive intradermal skin test reaction to a fungal antigenic extract, histoplasmin.[25] However, in addition, there is a symptomatic disease that includes respiratory infections and acute or chronic pulmonary histoplasmosis, as well as a disseminated infection that may spread to affect the skin or mucous membranes. Direct inoculation into the skin may occur as a result of a laboratory accident.

Epidemiology. Histoplasmosis occurs in many countries from the Americas to Africa, India, and the Far East (see eFig. 190-8.1 in on-line edition). In the United States, it is endemic in the Mississippi and Ohio River valleys, where often more than 80 percent of the population may have acquired the infection asymptomatically. Exposure rates are usually lower in all other endemic areas, although high rates are also found in northern South America and some Caribbean islands. Histoplasmosis is not found in Europe. *H. capsulatum* is an envi-



▲ **FIGURE 190-8** The route of infection and dissemination to the skin of the endemic (respiratory) mycoses. CNS = central nervous system.

ronmental saprophyte that can be isolated from soil, particularly when it is contaminated with bird or bat excreta. The disease is acquired by inhalation of spores, and epidemics of respiratory infection may occur in persons exposed to a spore-laden environment when exploring caves or cleaning sites heavily contaminated with bird droppings, such as bird roosts or barns. Although any person can acquire histoplasmosis through inhalation, it causes a distinctive disseminated infection in patients with disease affecting cellular immune capacity, such as AIDS or lymphoma.[26,27]

Clinical Findings. The spectrum of histoplasmosis includes asymptomatic as well as benign symptomatic infections and a progressive disseminated variety with bloodstream spread to multiple organs.[25] Skin lesions may develop as a result of immune-complex formation in the primary infection (erythema multiforme) or from direct spread after dissemination from the lungs; rarely, infections may develop at a point of inoculation into the skin.

Asymptomatic forms of histoplasmosis are, by definition, without signs or symptoms, but those exposed usually have a positive histoplasmin skin test. The percentage of skin test reactors in the community indicates the chances of exposure, and, in endemic areas, this may range from 5 percent to 90 percent. Occasionally, asymptomatic pulmonary nodules removed at surgical exploration or autopsy are found to contain *Histoplasma*.

ACUTE PULMONARY HISTOPLASMOSIS. In acute pulmonary histoplasmosis, patients are often exposed to large quantities of spores such as may be encountered in a cave or after cleaning a bird-infested area. Patients present with cough, chest pain, and fever, often with accompanying joint pains and rash—toxic erythema, erythema multiforme, or erythema nodosum. These skin rashes are not common, occurring in fewer than 15 percent of patients, but they may be precipitated by treatment of the acute infection. On chest x-ray, there is often diffuse mottling, which may calcify with time.

CHRONIC PULMONARY HISTOPLASMOSIS. Chronic pulmonary histoplasmosis usually occurs in adults and presents with pulmonary consolidation and cavitation, closely resembling tuberculosis. Skin involvement is not seen.

▲ **FIGURE 190-9** Histoplasmosis, disseminated. Multiple erythematous keratotic papules and small plaques resembling guttate pattern psoriasis are seen on the chest and arm of a man with advanced human immunodeficiency virus disease. (Used with permission from J. D. Fallon, MD.)

ACUTE DISSEMINATED HISTOPLASMOSIS. In patients with acute disseminated histoplasmosis, there is widespread dissemination to other organs such as the liver and spleen, lymphoreticular system, and bone marrow. Patients present with progressive weight loss and fever. This form is the type that is most likely to occur in untreated AIDS patients, who often develop skin lesions as a manifestation of disseminated infection (Fig. 190-9).[28] There are papules, small nodules, or small molluscum-like lesions that subsequently may develop into shallow ulcers. These skin lesions are more common in HIV positive patients than in others with disseminated histoplasmosis. Diffuse micronodular pulmonary infiltrates also may develop. Patients have progressive and severe weight loss, fever, anemia, and hepatosplenomegaly.

The distinction between acute and chronic dissemination in histoplasmosis is somewhat artificial because these merely represent extremes of behavior, with progression occurring over a few months, on the one hand, and over several years, on the other. Intermediate forms occur, and other organs such as the meninges and heart may be affected.

CHRONIC DISSEMINATED HISTOPLASMOSIS. Chronic disseminated histoplasmosis may appear months or years after a patient has left an endemic area. The most common clinical presenting features are oral or pharyngeal ulcer-

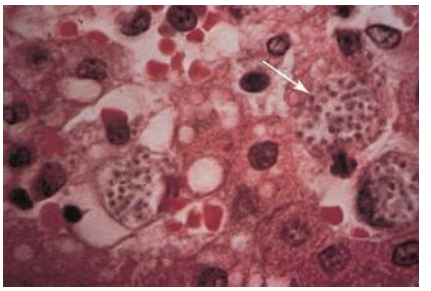
ation or adrenal insufficiency (Addison disease) due to adrenal infiltration. The mouth ulcers are often large, irregular, and persistent and may affect the tongue as well as the buccal mucosa. The patients otherwise may appear well, but it is important to investigate them for evidence of infection elsewhere (e.g., by abdominal computed tomography scan). Adrenal infection in particular should be excluded.

PRIMARY CUTANEOUS HISTOPLASMOSIS. Primary cutaneous histoplasmosis is rare and follows inoculation of the organism into the skin, for instance, after accidental laboratory- or postmortem room–acquired infection. The primary lesion is a nodule or indurated ulcer, and there is often local lymphadenopathy.

Differential Diagnosis. The organism is the same size as a number of others causing deep mycoses such as *P. marneffei* and small forms of *Blastomyces* and *Cryptococcus* (see Laboratory Tests). It is also similar in size to *Leishmania* sp., and in the tropics, kala-azar is an important part of the differential diagnosis. These observations emphasize the importance of carrying out appropriate laboratory tests to confirm the diagnosis.

Laboratory Tests. The diagnosis of histoplasmosis is established by identifying the small intracellular yeast-like cells of *Histoplasma* in sputum, peripheral blood, bone marrow, or biopsy specimens. *Histoplasma* must be separated from *P. marneffei* because the two organisms are of a similar size, although the latter shows characteristic septa formation. The identity of the organism should be confirmed by culture; it grows as a mold at room temperature. The white, cottony colonies develop at room temperature on Sabouraud's glucose agar to produce two types of spores, the larger (8 to 15 μm), rounded, tuberculate macroconidia being typical; the smaller microconidia are infectious. Confirmation of the identity should be obtained by demonstrating the production of diffusing exoantigen by an immunodiffusion assay (exoantigen test). Mycelial-phase cultures of *H. capsulatum* are very infectious, and laboratories receiving specimens should be warned about the suspected diagnosis.

The intradermal histoplasmin skin test is an epidemiologic tool that is of no help in diagnosis. In patients with disseminated histoplasmosis, it is often negative. By contrast, serology is often useful in diagnosis. A rising complement-fixation titer indicates dissemination. Precipitins detected by immunodiffusion are also valuable because the presence of antibodies to specific H and M antigens correlates well with active or recent infection.[28] A new development, particularly helpful in AIDS patients, has been serologic tests for the detection of circulating *Histoplasma* antigens.[29] In histopathologic sections, *H. capsulatum* is an intracellular parasite often seen in macrophages. The cells are small (2 to 4 μm in diameter) and oval in shape with small buds (Fig. 190-10). Mycelial forms are seen rarely in tissue.



▲ **FIGURE 190-10** Histoplasmosis, disseminated. Lesional biopsy specimen shows dermal macrophages packed with dozens of tiny yeast forms of *Histoplasma capsulatum* (*arrow*).

AFRICAN HISTOPLASMOSIS (LARGE-FORM HISTOPLASMOSIS OR HISTOPLASMOSIS DUBOISII) African histoplasmosis is sporadic and uncommon even in AIDS patients.[30] It is seen in patients from areas south of the Sahara and north of the Zambezi River in Africa. Infections seen outside Africa are all imported. The most common clinically involved sites are the skin and bone, although lymph nodes and other organs, including the lungs, may be affected. Skin lesions range from small papules resembling molluscum contagiosum to cold abscesses, draining sinuses, or ulcers. It is not clear if there is an asymptomatic form of African histoplasmosis as in classic histoplasmosis. The diagnosis is confirmed by culture and microscopy (direct microscopy or histopathology). The organisms of *H. capsulatum* var. *duboisii* are different from the smaller *capsulatum* forms. They are usually 10 to 15 μm in diameter, slightly pear-shaped, and clustered in giant cells. *Histoplasma* serology, using conventional tests, is often negative in African histoplasmosis.

Treatment. The choice of therapy for histoplasmosis depends on the severity of the illness. For patients with some disseminated or localized forms of the disease, oral itraconazole (200 to 400 mg daily) is highly effective. It also has been used for long-term suppressive treatment of the disease in AIDS patients after primary therapy either with itraconazole or amphotericin B.[31] However, there is now evidence that provided CD4 counts do not fall in patients on highly active antiretroviral therapy (HAART) therapy (see Chap. 198), suppressive treatment can be discontinued. In AIDS, some patients receiving treatment for histoplasmosis, an immune reconstitution syndrome has been reported after commencing HAART therapy with intestinal obstruction, uveitis, and arthralgia. Intravenous amphotericin B (up to 1 mg/kg daily) is given to patients with widespread and severe infections and is the main alternative used. Ketoconazole and fluconazole are also effective in many cases. In African histoplasmosis, itraconazole is also the treatment of choice, but once again, in severe cases amphotericin B may be used.[30]

Blastomycosis (North American Blastomycosis, Gilchrist Disease)

Blastomycosis is a chronic mycosis caused by the dimorphic pathogen *B. dermatitidis*.[32] Its chief sites of involvement are the lungs, but disseminated forms of the infection may affect skin, bones, central nervous system, and other sites.

EPIDEMIOLOGY Blastomycosis is found in North America and Canada.[33] Most cases, though, come from the Great Lakes region and southern states of the United States. It also occurs sporadically in Africa, with the largest numbers of cases coming from Zimbabwe,[34] and cases also have been reported from the Middle East and India (see eFig. 190-10.1 in on-line edition).

It is thought that the natural habitat of *Blastomyces* is in some way related to wood debris and is close to rivers or lakes or in areas subjected to periodic flooding. However, it is difficult to isolate *Blastomyces* from the natural environment.[35] Blastomycosis also may affect domestic animals such as dogs.

CLINICAL FINDINGS As with histoplasmosis, there is a sub-clinical form of the infection; its prevalence has not been defined in detail because of lack of a commercial *Blastomyces* skin test antigen and the extent of antigenic cross-reactivity with fungi such as *Histoplasma*. Primary cutaneous blastomycosis is also very rare and follows trauma to the skin and the subsequent

introduction of fungus, for instance, in laboratory workers or pathologists.[36] After inoculation, an erythematous, indurated area with a chancre appears in 1 to 2 weeks with associated lymphangitis and lymphadenopathy.

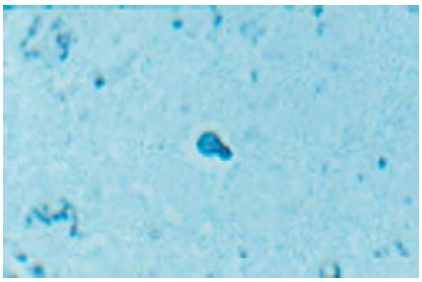
Pulmonary blastomycosis is very similar in clinical presentation to pulmonary tuberculosis.[33,36,37] There may be no symptoms, or there may be low-grade fever, chest pain, cough, and hemoptysis, and unlike histoplasmosis, it often co-exists with disseminated disease. Skin lesions are a common presenting feature of disseminated blastomycosis.[36,38] They are often symmetric and usually affect the face and extremities. The early lesion is a papule or nodule, which may ulcerate and discharge pus. With time, this enlarges to form a hyperkeratotic lesion, often with central ulceration and/or scarring (Figs. 190-11 and 190-12). Oral lesions are less common. Multiple skin lesions are often found in disseminated infection. Other patients may present with nodules and abscesses, and in many patients lesions of different morphologies are present. African patients with blastomycosis have a higher frequency of skin and bone involvement.[34] Although blastomycosis can affect almost any organ, other common sites for dissemination include the bone, the epididymis, and the adrenal gland. Less commonly, there is widespread rapid dissemination with multiple organ involvement, and *B. dermatitidis* can produce a form of adult respiratory distress syndrome. Skin lesions in widespread disseminated disease are usually papules, abscesses, or small ulcers. Widespread blastomycosis has been described in AIDS patients, but it is not common.[39]

▲ **FIGURE 190-11** Blastomycosis. Inflammatory plaque with ulceration resembling pyoderma gangrenosum on the calf. (Used with permission from Elizabeth M. Spiers, MD.)

▲ **FIGURE 190-12** Blastomycosis. Chronic verrucous plaque on the cheek.

DIFFERENTIAL DIAGNOSIS The chronic skin granulomas must be differentiated from those due to tuberculosis, other deep mycoses, non-melanoma skin cancers, pyoderma gangrenosum, and drug reactions due to bromides and iodides.

LABORATORY FINDINGS The fungus can be found in KOH mounts of pus, skin scrapings, or sputum as thick-walled, rounded refractile spherical cells with broad-based buds (Fig. 190-13). In culture, the fungus grows as a mycelial fungus at room temperature. It produces small, rounded, or pear-shaped conidia. At higher temperature [37°C (98.6°F)] and on enriched media, it produces yeast forms with the characteristic buds. In tissue sections, the typical organisms with broad buds may be found although it may be necessary to search several fields to find the characteristic cells. These are often found in giant cells or surrounded by neutrophils (Fig. 190-14). Precipitating antibodies to *B. dermatitidis* are often present in the sera of infected patients, and a characteristic precipitin line, the E band, has been described in a high proportion of proven cases; there is also an enzyme-linked immunosorbent assay for blastomycosis. However, one of the problems with serodiagnosis in blastomycosis is the presence of a high number of false-positive reactions in uninfected persons and cross-reactivity with other fungi.

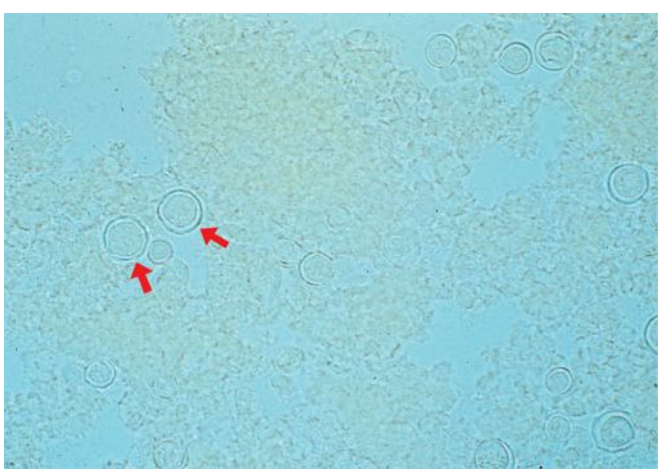


▲ **FIGURE 190-14** Blastomycosis. Lesional biopsy specimen shows a budding yeast form (Gomori methenamine silver stain).

TREATMENT Treatment is similar to that used for histoplasmosis; itraconazole (200 to 400 mg daily) is used in the less severe forms of the infection or when there is only localized spread. Treatment is usually given for at least 6 months. Follow-up surveillance is necessary because relapse can occur, particularly where there are deep sites of infection or the patient is immunosuppressed. Amphotericin B (up to 1 mg/kg daily) is generally used for the treatment of widespread disseminated forms of blastomycosis.

Coccidioidomycosis (Coccidioidal Granuloma, Valley Fever, San Joaquin Valley Fever, Desert Rheumatism)

Coccidioidomycosis is the infection caused by the fungus *Coccidioides immitis*.



▲ **FIGURE 190-13** Direct preparation (potassium hydroxide) of *Blastomyces* (*arrows*).

It shows an unusual form of dimorphism, with a mold form at room temperature and the development of large, spore-containing structures, spherules, in infected tissue. As with other endemic mycoses, there are asymptomatic, acute and chronic pulmonary, and disseminated forms. The disease can affect otherwise healthy individuals or predisposed patients, including those with AIDS.

EPIDEMIOLOGY *C. immitis* is endemic in some semidesert areas of the southwestern states of the United States (e.g., California, Arizona, New Mexico, and Texas) and in parts of Mexico and Central and South America (see eFig. 190-14.1 in online edition). The climate of the endemic areas is marked by very high summer temperatures and low annual rainfall, demonstrated by a characteristic vegetation with cacti and mesquite bushes. Skin tests with coccidioidin show that the incidence of exposure in endemic areas may be as high as 95 percent. The fungus is found in soil and can affect other animals as well as humans. Exposure may result from a brief visit to an endemic area, and local weather can determine exposure rates.[40] For instance, dust storms may cause infection in large numbers of individuals. The usual route of infection is respiratory, although direct implantation into the skin can occur rarely.

CLINICAL FINDINGS As with other systemic mycoses, there is an asymptomatic or sub-clinical form of coccidioidomycosis that is common in endemic areas, judging by the percentages of skin test reactors to coccidioidin in the healthy population. The primary pulmonary form, which is the most common clinical type, presents as a chest infection with fever, cough, and chest pain. Complications such as pleural effusion may occur. Erythema multiforme or erythema nodosum,[40] often accompanied by arthralgia or anterior uveitis, occurs from the third to the seventh week in about 10 percent to 15 percent of patients and is more common in females. Sometimes an early, generalized, macular and erythematous rash is seen in some patients.

The chronic pulmonary form of the disease presents with chronic cough and resembles tuberculosis. Skin lesions normally do not occur in this phase.

In the rare primary skin infection,[41] after inoculation, there is an indurated nodule that develops 1 to 3 weeks after local trauma. This is followed by regional lymphadenopathy. Disseminated coccidioidomycosis develops in fewer than 0.5 percent of infected individuals. It is mainly seen in patients from certain ethnic backgrounds (American blacks, Filipinos, or Mexicans), in pregnant women, and in immunosuppressed patients, including those with AIDS.[42,43] In disseminated disease, lesions may develop in the skin, subcutaneous tissues, bones, joints, and all organs. The skin lesions (Fig. 190-15) are papules, nodules, abscesses, granulomas, ulcers, or discharging sinuses in which there is underlying bone or joint disease. Some lesions appear as flat plaques with central atrophy. Meningitis is an important complication of dissemination and is usually not associated with signs of infection in other sites. In AIDS patients, persistent pneumonia, skin lesions, and widespread dissemination can all occur.

▲ **FIGURE 190-15** Coccidioidomycosis, disseminated. Two intact and ulcerated papules/nodules are seen on the cheek and nose of this comatose patient with coccidioidomycotic meningitis. (Used with permission from Francis Renna, MD.)

DIFFERENTIAL DIAGNOSIS Physicians in endemic areas should be aware of the connection between erythema nodosum and coccidioidomycosis. It also may occur in visitors to endemic areas after only a short stay.

LABORATORY TESTS A characteristic of the laboratory findings is the ability of *C. immitis* to form spore-containing spherules. These are large (up to 250 μm) and can be seen in KOH mounts of sputum, cerebrospinal fluid (CSF), or pus. In culture, colonies of *C. immitis* are mycelial, fast-growing, white, and cottony. On microscopy, there are chains of arthrospores at intervals on the older mycelium. *C. immitis* in the mold phase is highly infectious, and cultures should be handled carefully.

Serologic tests are of value in the diagnosis and prognosis of coccidioidomycosis.[44] Precipitins develop in about 90 percent of infected individuals within 2 to 6 weeks but are short-lived; complement-fixing antibodies are characteristic of more severe infections and, in active infection, increase to a maximum after 6 months. Skin tests with coccidioidin are of little value in diagnosing infections. Spherulin is an antigen obtained from spherules of *C. immitis* and may be better than coccidioidin for detecting sensitization. However, in severe infections, cutaneous anergy to both is common.

Spherules containing large endospores can be seen in tissue sections, although there are a variety of less distinct intermediate stages in spherule formation that also can be seen. Before endospores form, the cytoplasm of the immature spherule is basophilic and subsequently breaks up into spores. Mycelium is seen rarely in histopathologic sections.

TREATMENT No specific therapy apart from rest is necessary in the primary pulmonary infection, and there is little evidence that the symptoms are either improved or shortened by giving an oral azole drug, even though it is widespread practice. For disseminated disease, treatment is still unsatisfactory, but amphotericin B (1 mg/kg daily), itraconazole (200 to 400 mg daily), or fluconazole (200 to 600 mg daily) can all be given.[45] Experience with the newer antifungal agents, such as voriconazole and posaconazole, is limited at present. It is important to follow patients carefully, given the frequency of relapse. Meningitis, arthritis, and progressive disseminated infection involving multiple sites are all particularly refractory to therapy. Generally, soft-tissue coccidioidomycosis (skin and joint) has a better prognosis, and the mortality in patients who present with soft tissue lesions is low.

Paracoccidioidomycosis (South American Blastomycosis, Paracoccidioidal Granuloma)

Paracoccidioides brasiliensis is a dimorphic fungus that causes a respiratory infection with a tendency to disseminate to the mucous membranes and lymph nodes. It is confined to Central and South America.[46]

EPIDEMIOLOGY Paracoccidioidomycosis has been reported from most Latin

American countries, but the infection is found most commonly in parts of Brazil, Colombia, and Argentina. The infection does not occur in the United States, although it has been reported in Mexico (see eFig. 190-15.1 in on-line edition). Exposure rates can be estimated by skin test reactivity and appear to be equal in both males and females, although the prevalence of positive reactors in endemic areas seldom exceeds 25 percent; work with a skin test derived from purified glycoprotein 43 antigen generally demonstrates that exposure rates are higher than previously believed. The active infection is seen predominantly in males. The mechanism is thought to be connected to the presence of a cytoplasmic estrogen receptor on the fungus, and in vitro, estradiol suppresses the conversion of mycelium to yeast.[47] The ecologic niche of the organisms is unknown, but the condition is much more frequent in rural areas; exposure has been associated with proximity to water or areas of high atmospheric humidity.[48]

CLINICAL FINDINGS There are a number of different clinical patterns of paracoccidioidomycosis infection that depend on the predominant site of clinical involvement. These include the lung (pulmonary form), the mucous membranes (mucocutaneous form), and the lymph nodes (lymphatic form). Many patients have a mixed type of infection with involvement of different organ groups.[46]

Patients rarely present with an acute form of pulmonary infection although this has been observed rarely and reported to subside while dissemination occurs. More usually, pulmonary infection tends to be chronic and slowly progressive with weight loss and chronic cough. The lesions may be bilateral and nodular on chest x-ray, and there is often extensive fibrosis. Other sites of involvement include mucocutaneous areas. Oral or circumoral lesions are common in the mucocutaneous forms of paracoccidioidomycosis; lesions also occur in the nose, conjunctivae, or around the anus. These lesions may be small granulomas or ulcers. They heal with scarring, which may cause considerable deformity.

The cervical lymph nodes are sometimes enlarged, tender, and tethered to the overlying skin; they rarely suppurate. Other systemic sites of involvement include the spleen, intestines, lungs, and liver. Paracoccidioidomycosis is uncommon in AIDS patients, although there is a widespread variety that is a more rapidly progressive form of disseminated infection occurring in young adults or older children without recognizable predisposition.[49]

DIFFERENTIAL DIAGNOSIS Differential diagnosis includes tuberculosis, leishmaniasis, and other deep mycoses.

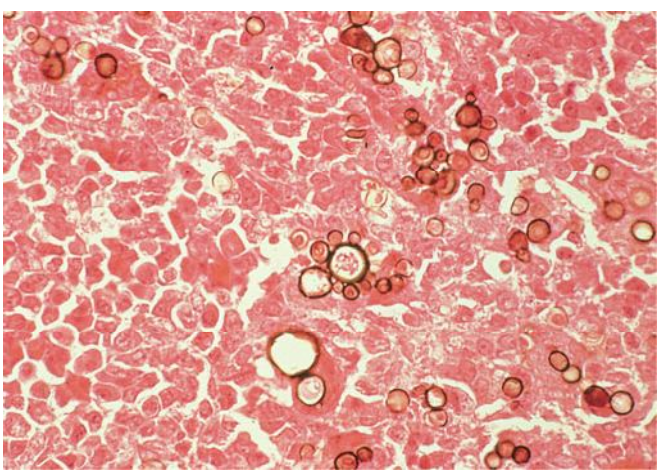
LABORATORY TESTS Sputum, exudates, and scrapings can be screened using KOH. They show numbers of round yeasts with a characteristic form of multiple budding in which a parent cell is surrounded by large numbers of smaller buds. The organism is dimorphic and produces a cottony mycelial-phase growth on primary isolation at room temperature. Once again, the characteristic yeast phase can be induced on enriched media such as brain-heart infusion agar at 37°C (98.6°F). Serology is very helpful in confirming the diagnosis, the main tests being the immunodiffusion assay and a complement-fixation test. Recently, antibodies to a 43-kd antigen have been found to be highly specific for this infection in immunoblotting. There is also an antigen-detection test useful in monitoring patients with disseminated disease. Histopathologically, there is a mixed granulomatous response with fibrosis. The organisms can be seen with special fungal stains such as methenamine silver (Grocott modification). In tissue, the characteristic budding pattern can be seen, although it may be necessary to search several fields to find the most typical structures (Fig. 190-16). In widespread infections, masses of small yeast forms may be mistaken for *Histoplasma*.

TREATMENT The treatment of choice in most cases is itraconazole, which can produce remissions in 3 to 6 months.[50] Ketoconazole is an alternative. Relapses can occur, and, where possible, patients should be reviewed periodically after primary therapy. In very extensive infections and in severely ill patients, such as those with the progressive disseminated type of infection, intravenous amphotericin B may be necessary. Severe pulmonary or intra-oral fibrosis may remain after treatment.

Infections Due to *Penicillium marneffei* (Penicilliosis, Penicilliosis Marneffei)

P. marneffei infection is a more recently recognized disease found in Southeast Asia. *P. marneffei* is a member of the common genus *Penicillium*.[51] It shows an unusual pattern of dimorphism in that it develops yeast-like cells that reproduce with septal formation, dividing the cells into two. It is inhaled via the lungs, and it is not known whether there is a primary cutaneous form of the infection.

EPIDEMIOLOGY The natural source of *P. marneffei* is unknown. Infections are confined to Southeast Asia, particularly Thailand, South China, and Vietnam (see eFig. 190-16.1 in on-line edition). However, there are reports in other Asian countries, including northeast India, and imported cases are seen in Europe and the United States. Natural infections are known to occur in bamboo rats of the genus *Cannomys*, which are large burrowing rodents. The infection affects otherwise healthy individuals as well as those with immune defects and is most common after the rainy season.[52] Patients with AIDS appear to be particularly susceptible to this infection.



▲ **FIGURE 190-16** Biopsy of oral mucosal lesion showing multiple budding *Paracoccidioides brasiliensis*.

CLINICAL FINDINGS There has been no work to demonstrate that there is a sub-clinical form of *Penicillium* infection, even though this is likely. Patients usually present with localized pulmonary or disseminated disease. The chest signs are those of chronic pulmonary disease.[53,54] More than 50 percent of AIDS patients with this infection have multiple skin lesions, which are umbilicated papules that may enlarge and ulcerate. They are usually widely scattered on the face and trunk. Other organs, including the liver, gastrointestinal tract, spleen, and bone marrow, may be affected.

DIFFERENTIAL DIAGNOSIS The main differential diagnosis is with other disseminated mycoses, such as histoplasmosis and cryptococcosis, which also can be found in the endemic area in AIDS patients. Biopsy and, when necessary, culture will distinguish between the different causes.

LABORATORY TESTS *P. marneffei* forms characteristic yeast-like cells that are divided by a septum in tissue and are best seen in histopathologic sections stained with methenamine silver. These cells are small (2 to 4 μm) and difficult to see in blood films or skin or bone marrow smears, but they may be highlighted with stains such as leishmanin. In culture, *P. marneffei* is a green or grayish mold that produces typical *Penicillium* conidiophores and a diffusible red pigment. There is no commercial serologic test as yet, although antigen detection systems and polymerase chain reaction have both been used in diagnosis.

TREATMENT In severe cases, amphotericin B is necessary. In many cases, however, there is a good response to itraconazole (200 to 400 mg daily). In AIDS patients, this is continued after initial therapy to prevent relapse.[54]

Cryptococcosis (Torulosis, European Blastomycosis)

Cryptococcosis is the infection caused by the encapsulated yeast *C. neoformans*. Although the main portal of entry is through inhalation into the lungs, the disease usually presents with signs of extrapulmonary dissemination such as meningitis. Cutaneous lesions can develop as a result of dissemination or, rarely, through inoculation. It is associated with HIV infection.[55]

EPIDEMIOLOGY Cryptococcosis has a worldwide distribution although exposure rates probably differ markedly in different countries. *C. neoformans* has three variants: (1) *C. neoformans* var. *neoformans*, (2) *C. neoformans* var. *grubii*, and (3) *C. neoformans* var. *gattii*.

These correspond to three clusters of serotypes: (1) D, (2) A, and (3) B or C.[56] The *neoformans* and *grubii* varieties can be isolated from pigeon excreta and are more common in AIDS patients; the *gattii* form is found in the debris of certain eucalyptus trees in the tropics and California, but it is less often isolated from AIDS patients. Two sexual varieties called *Filobasidiella neoformans* and *F. bacillispora* correspond to the *neoformans/grubii* and *gattii* varieties, respectively. Patients with certain immunodeficiency states caused by AIDS, malignant lymphomas, sarcoidosis, collagen disease, carcinoma, and those receiving systemic glucocorticoid therapy are particularly susceptible. The incidence of cryptococcosis in patients with established AIDS varies in different countries from 3 percent to 6 percent in the United States, to 3 percent in the United Kingdom, to more than 12 percent in parts of Africa (e.g., Zaire). Strains of serotype D are more likely to be found in skin lesions, which occur in 10 percent to 15 percent of cases of disseminated cryptococcosis.

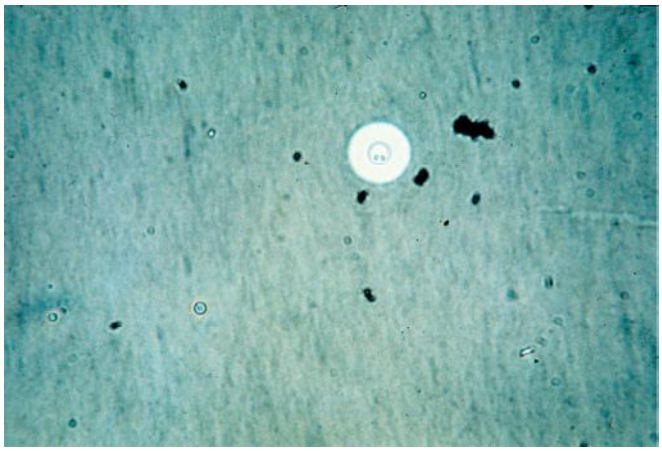
CLINICAL FINDINGS The advent of the AIDS epidemic has affected the epidemiology of cryptococcosis considerably, and in areas such as northern Thailand, it is one of the main secondary complications of HIV infection.[55] There is probably a sub-clinical form of cryptococcosis because unaffected individuals may have positive skin tests. However, the most common clinical manifestation of disease is meningoencephalitis. This presents with classic signs of meningismus, changes in consciousness, mental changes, and nerve palsies. In AIDS patients, these signs may be only weakly expressed. Pulmonary infection can be found in about 10 percent of those with meningitis. Chest signs include the appearance of nodular shadows, cavitation, and pleural effusion. Patients with AIDS often present with fever and mild headache and few other features of infection.[55] Cutaneous lesions may develop in about 10 percent of cases but are seldom pathognomonic.[57–60] Acneiform papules or pustules progressing to warty or vegetating, crusted plaques, ulcers, and hard infiltrated plaques or nodules are characteristic of widespread systemic infection (Fig. 190-17). Cold abscesses, cellulitis, and nodular lesions also occur. In otherwise healthy patients or those with sarcoidosis, lesions may be solitary, and in such patients, they may be the only clinical manifestation of infection.

▲ **FIGURE 190-17** Cryptococcosis, disseminated. Multiple, discrete, skin-colored papules and nodules resembling molluscum contagiosum are seen on the face of a male with advanced human immunodeficiency virus disease. (Used with permission from Loïs Vaillant, MD.)

In primary cutaneous cryptococcosis with direct inoculation of organisms into the skin, the skin lesions are usually solitary nodules that break down and ulcerate. Local lymphadenopathy also develops. The term *primary cutaneous cryptococcosis* is also used loosely to describe solitary lesions of cryptococcosis, but in many such cases there is also evidence of dissemination to other internal organs. It is important to investigate all patients who present with cutaneous lesions for evidence of dissemination to other sites.[58]

DIFFERENTIAL DIAGNOSIS Cryptococcal skin lesions may mimic a range of other conditions, particularly other systemic mycoses in AIDS patients. It is important to biopsy and culture suspicious lesions in immunocompromised patients.

LABORATORY TESTS Cryptococci are large (5 to 15 μm), budding cells with capsules that are best observed by direct microscopy of India ink or Nigrosin mounts (Fig. 190-18). The organism is not difficult to grow in culture. Various biochemical features, such as the production of urease and the ability to pigment on Guizotia seed medium, are characteristic. Serologic tests are rapid and specific. The main test is an antigen-detection assay using latex agglutination or enzyme-linked immunosorbent assay, and this is



▲ **FIGURE 190-18** Cryptococcosis. India ink preparation of cerebrospinal fluid.

simple and very rapid to perform on blood or CSF. Very high titers are found in AIDS patients in serum and CSF. Non-AIDS patients with single, localized skin lesions are often antigen-negative.

In tissue sections, the large pleomorphic yeasts stimulate either a granulomatous reaction or very little inflammation. The capsules of the cells can be stained using the mucicarmine or Alcian blue stains.

TREATMENT The most frequently used drug regimen in the non-AIDS patient is intravenous amphotericin B combined with flucytosine. In patients with single skin lesions and no other signs of infection, alternatives such as fluconazole or itraconazole can be used. In AIDS patients, there is a very high relapse rate, and the usual policy is to give a 10- to 14-day course of amphotericin B with or without flucytosine, followed by long-term fluconazole.[61] However, it may be possible to stop long-term suppressive therapy in patients receiving HAART. Fluconazole given on its own is an alternative approach.

Cutaneous Aspects of Systemic Opportunistic Mycoses

Skin lesions are not common with the opportunistic fungal infections, but they can occur in some, particularly in certain predisposed groups. When they occur, their presence may be very helpful because it is possible to biopsy easily accessible lesions in order to establish the diagnosis.

Systemic Candidiasis (See Chaps. 189 and 198)

Systemic candidiasis follows dissemination of *Candida* sp. from the gastrointestinal tract or via the bloodstream. Skin lesions may occur particularly in two situations: (1) In neutropenic patients, there is often a severe disseminated disease with widespread skin nodules and associated muscle pains,[62] and (2) in intravenous drug abusers, candidiasis may present with a follicular, pustular rash in the beard area and scalp. Other lesions include retinal and vitreal deposits and abscesses around the costochondral junctions.[63]

Systemic candidiasis is usually treated with intravenous amphotericin B (conventional or lipid-associated) or fluconazole. Resistance to some azole drugs, such as fluconazole and ketoconazole, is more common with certain non-*albicans Candida* sp., and these antifungal agents should be avoided in infections caused by these species.

Zygomycosis (Mucormycosis, Phycomycosis)

Zygomycosis is a rare disease caused by zygomycete fungi such as *Rhizomucor*, *Absidia*, and *Rhizopus*. *Cunninghamella bertholletiae* and *Saksenaea vasiformis* are less common causes. Zygomycetes cause disease in patients with poorly controlled diabetes, neutropenia, or renal disease. Direct invasion through abrasions has been reported following trauma due to a natural disaster (e.g., during a mud slide or tsunami).[64] They can invade necrotic burned areas or involve the facial skin secondary to invasive infection of the paranasal sinuses (Fig. 190-19). Zygomycete infections also have been caused by close apposition of the skin with contaminated dressing materials in the case of *R. rhizopodiformis*[65] or with wooden tongue depressors in the case of *R. microsporus*.[66] The zygomycete fungi have a tendency to invade blood vessels, causing widespread infarction. Infections may respond to intravenous amphotericin, and recent results with lipid-associated amphotericin B formulations have been encouraging.

Other Opportunistic Mycoses

Other fungi causing systemic infections also may produce skin lesions in the process of bloodstream dissemination. The best known of these organisms are *Aspergillus*, *Scedosporium*, *Trichosporon*, and *Fusarium*. Skin infection is seen mainly in severely immunocompromised patients such as those with neutropenia.

Aspergillus may produce large necrotic lesions such as ecthyma gangrenosum, but smaller papules and cold abscesses also can occur.[67] *Fusarium* infections may produce widely distributed target-like lesions that may undergo central necrosis and, in some cases, digital cellulitis and superficial white onychomycosis.[68] Treatment for all these infections is usually amphotericin B.

LABORATORY FINDINGS Laboratory confirmation of the diagnosis is fraught with difficulties chiefly because many of the organisms are also commensals in human sites; because they occur in severely ill patients, the capacity to produce diagnostic antibody titers is compromised. The interpretation of laboratory data is consequently difficult and has to be related to the clinical state of the patient. Ideally, a histologic diagnosis should be made, although biopsy may be impossible because of the risk of bleeding. In many cases, the diagnosis of a systemic mycosis is presumptive, and treatment therefore is given empirically.

Actinomycosis and Nocardiosis

Actinomycosis is an infection caused by filamentous bacteria that form large granules (sulfur granules) in abscess cavities. Draining sinuses communicate from the center of the abscess to the skin or mucosal surface. Nocardiosis is an acute and chronic infection also caused by filamentous bacteria. These lead to localized skin, subcutaneous, and systemic infections. Actinomycosis and nocardiosis are discussed in detail in Chap. 185 and in the on-line version.

SECTION 31

VIRAL AND RICKETTSIAL DISEASES

CHAPTER 191

Viral Diseases: General Considerations

Ammar M. Ahmed
Vandana K. Madkan
Natalie Mendoza
Stephen K. Tyring
Douglas R. Lowy

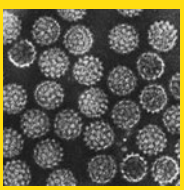
Skin lesions are a prominent feature of many viral diseases. These lesions are either a direct result of viral replication in the epidermis or a secondary effect of viral replication elsewhere in the body. In the latter case, the cutaneous manifestations may be the first or most prominent sign of a systemic infection that requires thorough evaluation and appropriate diagnostic testing. Although most viral infections with skin lesions are mild and self-healing, occasionally severe illness and even life-threatening complications can develop, especially in immunocompromised populations.[1] Fortunately, recent advances in laboratory testing have shortened the time for diagnosis of a number of viral infections. To complement advances in diagnosis, there are several effective antiviral agents for treating certain viral diseases with cutaneous manifestations, and other potential antiviral agents are in clinical trials. Consequently, making the correct diagnosis in viral infection has important implications for therapy as well as for prognosis. It may also contribute to the surveillance and control of infectious disease within a community. Preventive vaccines are of monumental importance. They have nearly or completely eradicated several viral infections, most notably smallpox, and the emerging development of new vaccines against other viruses could dramatically reduce their morbidity and associated health care costs.

DEFINITION

Viruses form a diverse group of infectious, acellular organisms that share a distinctive composition and a unique mode of replication.[2–5] Although certain viruses encode a small number of enzymes, viruses do not possess functional ribosomes or other cellular organelles. They multiply only inside host cells, where they make use of the cellular synthetic apparatus to produce their components. It is because their replication depends on the host cell that viruses are often referred to as *obligate intracellular parasites*.

The most important element of a virus is its genetic information (the viral *genome*), which may be either DNA or RNA, depending on the type of virus.[6,7] The life cycle of a virus may be divided into two parts. In one part, the virus exists as an extracellular particle (also called a *virion*), in which the viral genetic information is surrounded by a highly organized protein coat (the *capsid*) that can be seen by electron microscopy. The virion serves to transmit the viral genetic information, functionally intact, to a susceptible host or to spread the infection within an infected host. In the second part of the viral life cycle, the viral genetic information is present inside a cell, where it is usually found in a nonparticulate form. The duration of this intracellular phase is extremely variable, from a few hours in acute infections to years when a virus establishes latency.

VIRAL DISEASES AT A GLANCE



- Cutaneous lesions are an extremely common, and often the only, manifestation of many viral infections.
- Viruses can produce skin lesions either by direct replication in the epidermis, as is the case with papillomaviruses, poxviruses, and several herpesviruses, or as a secondary manifestation of replication elsewhere in the body.
- The direct effects of viral replication on epidermal cells and the inflammatory response of cell-mediated immunity combine to produce cutaneous lesions.
- Neoplastic transformation or viral latency followed by reactivation occurs with certain viruses.
- Laboratory diagnosis is by viral culture, microscopy, detection of viral nucleic acids or viral antigens, and/or serologic testing.
- Many effective antiviral drugs exist, and others are currently in development.
- Preventive techniques, most notably vaccines, have to date been the most effective means for controlling viral infection.

CLASSIFICATION

Viruses that infect animals are divided into several large families according to the size, shape, and structure of the virion and the type of viral nucleic acid within it, as shown in Table 191-1. Viruses of a given family can be identified

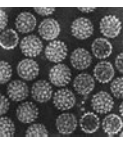
TABLE 191-1
Selected Animal Virus Groups

Group	Size (nm)	Symmetry	Envelope	Nucleic Acid	Capsid Assembly	Examples of Viruses
Herpesvirus	120–200	Icosahedral	Yes	DNA	Nucleus	Herpes simplex virus (types 1 and 2), varicella-zoster virus, cytomegalovirus, EBV, KSHV/HHV-8
Papillomavirus	50–55	Icosahedral	No	DNA	Nucleus	Papillomaviruses
Polyomavirus	45–50	Icosahedral	No	DNA	Nucleus	SV40
Poxvirus	240 × 300	Complex	No	DNA	Cytoplasm	Molluscum contagiosum, orf, milker's nodules virus, variola virus, vaccinia virus
Retrovirus	80–120	?	Yes	RNA	Cytoplasm	HIV, HTLV
Paramyxovirus	150–300	Helical	Yes	RNA	Cytoplasm	Measles virus, mumps virus
Togavirus	40–60	Icosahedral	Yes	RNA	Cytoplasm	Rubella virus, some arboviruses
Parvovirus	20	Icosahedral	No	DNA	Nucleus	Erythema infectiosum
Hepadnavirus	40–50	Icosahedral	No	DNA	Nucleus	Hepatitis B virus
Adenovirus	70–80	Icosahedral	No	DNA	Nucleus	Multiple human serotypes
Picornavirus	20–30	Icosahedral	No	RNA	Cytoplasm	Enterovirus (coxsackievirus, echovirus, poliovirus), rhinovirus
Bunyavirus	90–100	Helical	Yes	RNA	Cytoplasm	Some arboviruses
Arenavirus	85–120	?	Yes	RNA	Cytoplasm	Lassa virus
Coronavirus	80–120	Helical	Yes	RNA	Cytoplasm	Several human serotypes
Orthomyxovirus	80–120	Helical	Yes	RNA	Cytoplasm	Influenza types A + B + C
Rhabdovirus	70–80	Helical	Yes	RNA	Cytoplasm	Rabies virus
Reovirus	50–80	Icosahedral	No	RNA	Cytoplasm	Rotavirus, reovirus

EBV = Epstein-Barr virus; HHV-8 = human herpesvirus-8; HIV = human immunodeficiency virus; HTLV = human T-cell lymphotropic virus; KSHV = Kaposi sarcoma–associated herpesvirus.



by physical methods such as the size and shape of their virions by electron microscopy, by antigenic cross-reactivity, or by nucleic acid homology. Although viruses are grouped principally according to their virion morphology and nucleic acid composition, a given family of viruses usually shares functional, genetic, biochemical, and immunologic features. Within a given family, viruses may be further classified according to their relatedness at the nucleic acid level, their antigenic cross-reactivity, and the host cells that they infect.

In certain virus families (such as herpesviruses and retroviruses), the capsids are located inside a virion envelope (composed of lipid, protein, and carbohydrate), which is required for infectivity (see Table 191-1). The viral envelope is sensitive to drying, so that infectivity is lost on dry surfaces. The virions of other viruses (e.g., papillomaviruses) do not possess an envelope, so their capsids are called *naked*. Because the capsid proteins are usually stable in dry environments, viruses whose virions lack an envelope typically remain infectious for long periods after drying.

Fig. 191-1 shows examples of virions from the three main families of viruses that multiply in the epidermis (papillomaviruses, herpesviruses, and poxviruses). The viral genomes of these three families are composed of DNA. As noted earlier, papillomaviruses possess naked (nonenveloped) capsids, and herpesviruses have enveloped virions. Poxvirus virions are large, have a very complex structure, and are enveloped, but their envelope is not required for their virions to be infectious. Hence, poxviruses can remain infectious after drying.

VIRAL REPLICATION

The viral replication cycle, which has been studied in detail in tissue culture, involves several more or less sequential steps: attachment (adsorption), penetration, uncoating, biosynthesis, virion assembly, and release. Attachment of virions to cells involves a specific interaction between the viral capsid or envelope (for those viruses that possess enveloped virions) and receptors on the cell surface. For example, human immunodeficiency virus (HIV) enters cells via an interaction between viral envelope protein and two classes of receptors: cellular CD4 receptors and chemokine receptors.[8] Cells that lack the appropriate cell surface receptors for a particular virus will not be infected by that virus. Although most people are quite susceptible to HIV infection, rare individuals who lack the appropriate chemokine receptors or who have modified versions of them may be relatively resistant to HIV infection or the development of acquired immunodeficiency syndrome.[9,10]

After the virion penetrates into the cell, cellular enzymes degrade the envelope and capsid (uncoating), which begins the nonparticulate phase of the virus life cycle. During biosynthesis, the viral genome instructs the infected cell to produce the proteins encoded by the viral genes. Nonvirion proteins (proteins that are not structurally incorporated into the mature virion) of certain viruses may redirect the cell to synthesize proteins required by the virus at the expense of those required for normal function of the cell. Many tumor viruses, including papillomaviruses, encode nonvirion proteins that increase cell growth and lead to inappropriate control of cell division.

Each virus has its characteristic site of replication within the cell. Papillomaviruses and herpesviruses are assembled

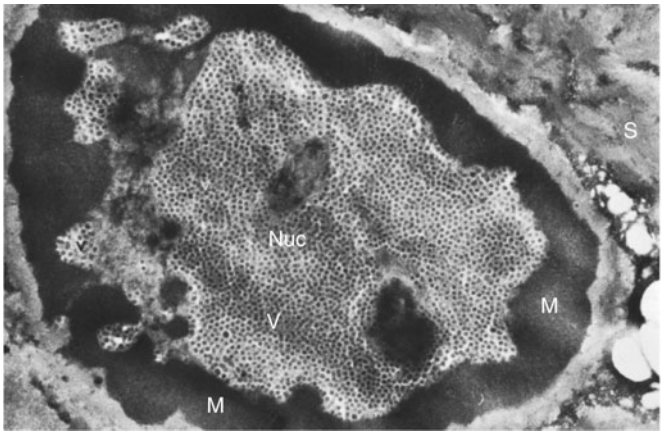
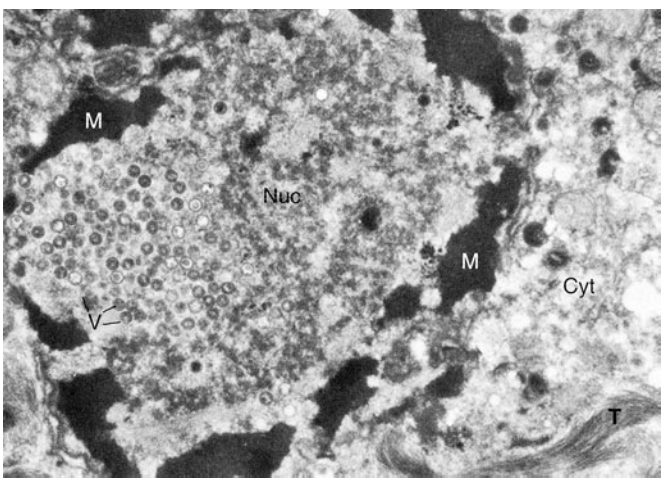
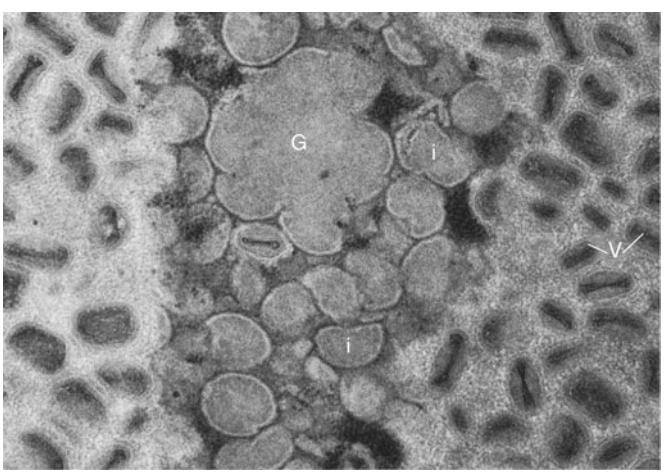
in the nucleus (Figs. 191-2 and 191-3). Poxviruses, which are the only DNA viruses that replicate in the cytoplasm, synthesize their virions in organized cytoplasmic "viral factories" (Fig. 191-4). The virions of most viruses, including papillomaviruses, herpesviruses, and poxviruses, are released after cell death and lysis. However, enveloped viruses whose virions are assembled at the cell surface (such as retroviruses and paramyxoviruses) are released by budding from intact cells; with these viruses, productive infection and release of virions may or may not be accompanied by toxic effects on the infected cell.



▲ **FIGURE 191-2** Papillomavirus-infected cell. Electron micrograph (×20,000). Nucleus (Nuc) of a stratum corneum cell, filled with papillomavirus virions (V); chromatin is marginated (M). Mature keratin can be seen in an adjacent cell (S).

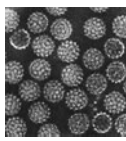


▲ **FIGURE 191-3** Cell infected with varicella-zoster virus (a herpesvirus). Electron micrograph (×24,000). Portion of cell of the stratum spinosum. The nucleus (Nuc) contains varicella-zoster virions (V). Chromatin is marginated at (M). Virions (V) and tonofilaments (T) are shown in the cytoplasm (Cyt).



▲ **FIGURE 191-4** Cell infected with molluscum contagiosum (a poxvirus). Electron micrograph (×45,000). Cytoplasm of a spinosum cell filled with mature molluscum contagiosum virions (V), immature virus forms (i), and viroplasm in a gyrate pattern (G).

Typically, hundreds or thousands of new virions are produced from each infected cell, and they, in turn, infect previously uninfected cells. One cycle of viral replication may last from 3 to 36 hours, depending on the virus and cell



involved. Interruption of any step will prevent the development of new infectious virions.

Each virus can infect and replicate in only a limited number of cell types. The spectrum of susceptible cells depends on the virus. Human papillomaviruses (see Chap. 196) can productively infect a very narrow range of cells, namely, certain differentiating human epidermal cells. Other viruses can infect a much broader range of cells. Herpes simplex viruses (HSVs) (see Chap. 193) can replicate in many different human and nonhuman cell types.

Even within a given tissue, a virus may be infectious only for cells with a specific degree of differentiation. The important role of the differentiated state of the cell in determining whether or not a virus will undergo replication is seen in the skin lesions of molluscum contagiosum (see Chap. 195). Because molluscum contagiosum virus (MCV) particles are sometimes found in cells of the upper dermis, the virus must be capable of attachment to and penetration of these cells. MCV does not, however, replicate in dermal cells, which indicates that an intracellular block to MCV synthesis exists in the dermal cells. MCV particles are also found in the basal layer of epidermal cells, but synthesis of new viral components does not begin until the cells reach the suprabasal layers. This observation implies that MCV replication can take place only in partially differentiated epidermal cells.

CELLULAR CONSEQUENCES OF VIRAL INFECTION

Typically, infected cells develop gross and often characteristic cytopathic changes and eventually die. Infections of this type are termed *cytocidal* or *lytic*. However, as mentioned earlier, certain enveloped viruses can replicate without causing irreversible damage to the host cell. Two other phenomena seen in certain noncytocidal infections are neoplastic transformation[11,12] and viral latency.[13,14] Tumor viruses, when they transform cells, alter the normal control of cellular proliferation. In general, tumor viruses (such as the polyomavirus SV40) do not synthesize new virions in neoplastically transformed cells, although such transformation requires the continued expression of a portion of the viral genome. It is interesting to note that SV40 is exclusively cytocidal for some cell types (permissive infection), induces transformation exclusively in other cells (nonpermissive infection), and induces both types of infection in still other cell types (semipermissive infection), which again underlines the importance of the host cell in affecting the outcome of infection. Epidermal cells are semipermissive for papillomavirus infection. Virus-induced neoplasia is discussed in greater detail in Chap. 111.

Viral latency is a common mechanism for evading the host immune response. Latently infected cells either produce very small numbers of new virions so that spread to uninfected cells is minimal or they synthesize no virions but retain an intact and potentially inducible viral genome.

PATHOGENESIS OF VIRAL INFECTIONS IN THE SKIN

There are three general patterns of viral infection.[14] The most typical is that of acute infection followed by viral clearance, usually by immune mechanisms. This pattern occurs frequently with viruses that produce exanthemas, such as measles. Another pattern is that of acute infection followed by latent infection, which may then be followed by viral reactivation. In viruses with cutaneous manifestations, this pattern occurs often with HSV (see Chap. 193), varicella-zoster virus (VZV) (see Chap. 194), and papillomavirus (see Chap. 196). A third pattern is that of chronic infection, as occurs with HIV. Active subacute or chronic infections lasting months to years can also occur with papillomaviruses and MCV, even in immunocompetent hosts.

Transmission of an infecting virus to a susceptible individual can occur through several routes. In warts, herpes simplex, chickenpox, herpes zoster, molluscum contagiosum, and smallpox, viral shedding from human skin lesions represents an important source in the transmission of virus to other people. For other viruses with cutaneous manifestations, respiratory secretions, blood, genital secretions, or animal vectors are involved in carrying virus to susceptible individuals. The skin, specifically, is affected by three different routes: direct inoculation, systemic infection, or local spread from an internal focus. The skin lesions that result may be produced by the direct effect of virus replication on infected cells, the host response to the virus, or the interaction of replication and host response.

The viruses of warts, molluscum contagiosum, vaccinia, orf, milker's nodules, and (primary) herpes simplex, all of which infect the skin by direct inoculation, replicate in the epidermis. Their viral cytopathic effects account for the appearance of early lesions. The immune system presumably contributes to the evolution of these lesions by inducing an inflammatory response. The incubation period is generally short, because the lesions develop at the site of inoculation. For warts, however, the incubation period is longer, presumably because the virus replicates slowly or cell-to-cell spread of virus occurs to only a limited extent.

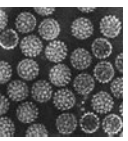
In systemic infections, the skin is infected during viremia, so that the dermis is generally infected earlier than the epidermis. It is not known how the distribution of viral exanthemas is determined. In chickenpox (see Chap. 194) and smallpox (see Chap. 195), the damage from cytocidal infection of the skin is a direct cause of the lesions. In contrast, there is suggestive evidence from patients with impaired cellular immunity that the lesions of rubella and measles (see Chap. 192) result at least partly from a cell-mediated immune response to the virus. The basis of most exanthemas associated with enteroviral infections remains to be established; there is significant cytocidal viral replication in the skin in hand-foot-and-mouth disease (see Chap. 192).

Recurrent herpes simplex and herpes zoster represent the local spread of virus to the skin after reactivation of the latent virus present in sensory nerve ganglia. Cytocidal infection clearly plays an important role in these lesions, although lesions may contain less virus than during primary infection, presumably because of immunity.

HOST RESPONSE

The severity of illness induced by a particular virus varies considerably from person to person. Although the size of the viral inoculum and the portal of entry play some role, it is believed that host factors usually account for most of this variation. Both immunologic and nonimmunologic responses appear to be important,[14–17] and both innate and adaptive immunity play key roles in the coordinated immune response.[18] Conversely, viral infection may have significant direct and indirect effects on the immune system, especially infection with those viruses that target lymphoid cells, such as Epstein-Barr virus and HIV.[8]

Antibody responses to viral infection represent the major host defense against



re-infection by the same virus.[19] The prophylactic administration of type-specific antibodies can prevent or modify some primary viral infections, even in patients with impaired cellular immunity. There are several mechanisms by which antibodies may inhibit the spread of virus. These include neutralization of virus through prevention of viral attachment to target cells (which may be increased by complement), enhancement of viral uptake by phagocytic cells, and complement-mediated immune lysis of infected cells. However, humoral immunity is thought not to contribute to the recovery from most primary viral infections, because viral infection of patients with isolated deficiencies of humoral immunity usually follows a normal course.

Specific cell-mediated immunity (CMI) is also elicited during viral infections and influences the course of many viral infections. CMI controls viral spread and promotes clearance of the virus, although it may sometimes increase the degree of cellular pathology (as in the eruption of measles). Patients with impaired CMI often have difficulty handling primary or recurrent viral infection. Such patients are at risk of developing severe primary virus infections, problematic reactivations of dormant viruses such as VZV and cytomegalovirus, and persistent warts, herpes simplex eruptions, and other viral cutaneous lesions. Virus-specific cytotoxic lymphocytes, natural killer cells, and antibody-dependent cell-mediated cytotoxicity all can inhibit infection under experimental conditions, and these are thought to be the primary players in clearing viral infections.

Inflammatory cells may produce some of their antiviral effects via the production of interferons, a unique family of closely related cytokines that are active against viruses.[20] Interferon, which can be induced by foreign RNA or DNA (including viral nucleic acids), is secreted into the extracellular fluid. Resistance to viral infection is induced in those cells that come in contact with the interferon. Virtually all viruses are capable of inducing interferon and are susceptible to its action, but viruses differ greatly in their degree of interferon induction and in their sensitivity to its effects. Interferon is responsible for recovery in several types of viral infection in mice, and the presence of interferon correlates with the recovery phase of several human viral infections. Genetic factors may also play a role in determining the outcome of viral infections. In animal models, cellular genes can determine the susceptibility to viral infection at several levels, including virion attachment to cells, viral replication, and viral-induced immune responses.[21]

CLINICAL MANIFESTATIONS

Viral infections can produce a wide spectrum of mucocutaneous lesions, from single papules to generalized pustulation to large, fungating tumors. Table 191-2 lists the viruses that most commonly cause a number of distinguishable skin lesions. There are several cutaneous eruptive diseases that appear to be viral exanthemas based on clinical presentation and seasonable variability but for which a specific viral cause has never been proven. Asymmetrical periflexural exanthem of childhood and pityriasis rosea (see Chap. 41) are two such diseases (although some evidence does link pityriasis rosea to infection with human herpesvirus 7).[22]

Even during a single episode of viral infection, the observable lesions often change considerably as they evolve. For example, in many infections due to HSV, VZV, or coxsackievirus, the lesions begin as papules with erythema, progress to frank vesicles, and are followed by pustules, crusts, or shallow ulcers. In certain viral infections the lesions are very specific (e.g., the verrucous papules seen with papillomavirus infection), and a diagnosis can be made without any further testing. In other viral infections the lesions are either extremely non-specific (e.g., urticaria or erythema multiforme) and cannot be accurately distinguished from lesions of nonviral etiology, or semi-specific for a limited number of viral diagnoses (e.g., the vesicles seen in HSV, VZV, coxsackievirus, and echovirus infections). In both of these circumstances additional diagnostic procedures may help clarify the cause. Evaluation of systemic signs and symptoms is crucial in formulating a differential diagnosis of skin eruptions and is particularly valuable in infections by viruses that do not replicate in the epidermis, such as Epstein-Barr virus and cytomegalovirus.

TABLE 191-2
Viral Exanthems

TYPE OF RASH	ASSOCIATED VIRUS
Macular/maculopapular	Rubella Echovirus (especially 9, 16) Coxsackievirus (especially A5, A9, A16, B5) Epstein-Barr virus (infectious mononucleosis) Human herpesvirus 6 (roseola) Rubeola virus Arbovirus (dengue fever) Parvovirus B19 (erythema infectiosum) Hepatitis B and C viruses Human immunodeficiency virus 1
Papular	Human papillomaviruses Orf virus Human herpesvirus 8 (Kaposi sarcoma) Milker's nodule virus Molluscum contagiosum Human immunodeficiency virus 1
Patches	Epstein-Barr virus (oral hairy leukoplakia)
Petechial/purpuric	Coxsackieviruses A5, A9 Hemorrhagic fever viruses Rubella virus (congenital infection) Cytomegalovirus (congenital infection) Echovirus 9 Epstein-Barr virus

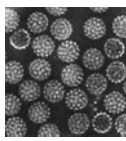
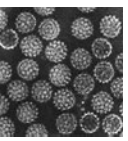
DIAGNOSIS OF VIRAL INFECTIONS

Five major approaches are used in the laboratory to diagnose viral infection: viral culture, microscopy, detection of viral nucleic acids, detection of viral antigens, and serologic testing.[23–25] As with all laboratory tests, the results must be interpreted in the context of the clinical setting. Coincidental infection with a virus unrelated to the illness should always be considered. For many viruses, considerable progress has been made in the development of relatively rapid assays that are sensitive and specific.[23,24,26] Most of these newer assays



depend on the ability to detect small amounts of viral nucleic acids and/or viral antigens.

Culture of the virus has represented the traditional gold standard for viral diagnosis. Virus isolation is most useful if the suspected pathogen can be readily propagated and positive results can be obtained in a short time. If necessary, more precise identification of the cultured virus can be carried out with specific tests for viral nucleic acid or viral antigen. Culture techniques for HSV are quite sensitive, with diagnostic changes in cells often appearing within 1 to 2 days of inoculation. The closely related VZV is much more difficult to grow in culture, which frequently leads to false-negative results.



When virus isolation is to be attempted, specimens should be obtained as early in the disease as possible. In vesicular conditions, fluid from an early vesicle is often a good source of virus. Lesional specimens are less likely to give positive results with nonvesicular exanthemas. Specimens are collected in a sterile tube with 2 to 5 mL of a buffered isotonic balanced salt solution containing penicillin and streptomycin. Preferably, they should be transported on ice immediately to the laboratory. If this is not practical, specimens should be frozen [at –70°C (–94°F), if possible]. The suspected pathogen(s) should be indicated, because it may determine the type of cell culture or test animal to be inoculated.

The direct identification of a virus in clinical specimens can theoretically be accomplished more quickly than identification through tests that rely on culturing the virus. This approach may be especially useful for detecting those viruses difficult to propagate in culture and those such as papillomaviruses for which no reproducible culture system is available. Direct analysis may identify characteristic cells, as with Tzanck smears for herpesviruses (this test will not distinguish between HSV and VZV) or characteristic inclusion bodies, as in MCV-infected cells. For those lesions that contain large numbers of viral particles, electron microscopy of a lesion or its extract may provide morphologic identification of the virus,[25] although this method is labor intensive and not readily available.

Whereas culture systems confront virus-specific constraints, any virus should theoretically be detectable by recognition of viral nucleic acid if there is sufficient knowledge of the viral genome to design specific probes and primers. The use of such assays has had a progressively greater impact on direct identification, initially through Southern hybridization and in situ hybridization, and more recently through application of the polymerase chain reaction (PCR).[23,24,26] This latter technique, which can specifically amplify minute quantities of viral nucleic acid, has revolutionized diagnostic virology. Assays based on PCR and related techniques are extremely sensitive, often being able to detect as few as 1 infected cell in 10,000, and highly specific. The main pitfall of PCR is that its great sensitivity makes it very susceptible to yielding false-positive results via cross-contamination with minute quantities of viral nucleic acid. However, meticulous attention to detail and appropriate controls can usually overcome this potential liability. In situ PCR, which combines the sensitivity of PCR with histologic localization, is an even more sophisticated technique for viral detection.

Rapid diagnostic tests for viral antigens are useful and widely available. Fluorescent antibody detection is commonly used to identify and distinguish between HSV-1, HSV-2, and VZV infections. Radioimmunoassay, enzyme-linked immunosorbent assay, immunoelectron microscopy, and immunoperoxidase techniques are other methods of identifying viral antigen by the use of virus-specific antibody.

Serologic studies to detect viral antibodies may be important for epidemiologic purposes, for identification of infection with viruses such as HIV and hepatitis B virus, and for those situations in which acute sera contain diagnostic antibodies, as with heterophile antibodies in infectious mononucleosis. In general, the most accurate serologic method of diagnosing acute viral illness is comparison of immunoglobulin G antibody titers from acute and convalescent sera, which limits its use in that setting to making a retrospective diagnosis. A single positive titer for immunoglobulin M antibody can also suggest acute illness. Acute specimens should be taken as early in the illness as possible and convalescent specimens 2 to 4 weeks later. Serum should be separated immediately from the coagulated blood and refrigerated or preferably frozen at –20°C (–4°F) until antibody tests can be run simultaneously on both specimens. A fourfold or greater rise in antibody titer between acute and convalescent sera generally indicates recent infection. A variety of assays are used to measure antibody levels, each detecting a certain type of antigen-antibody reaction, with the type of virus partly determining the utility of any particular assay.

THERAPY AND PREVENTION

Most antiviral drugs are virostatic, not virocidal. More than 40 drugs are now approved for the treatment of viral infections, and several of these have a key role in the treatment of cutaneous viral infections. Viral enzyme inhibitors, chemotherapeutic agents, and immunomodulatory drugs are among the systemic and topical medications used to treat such infections. Although significant progress has occurred in antiviral therapy in recent decades, especially in the treatment of infections by HIV, herpesviruses, and influenza virus, prophylaxis of viral infection has thus far proved more successful than the specific treatment of established infection for most viruses. Vaccines have been extremely useful in the prevention of a variety of viral illnesses[19,27,28] and represent one of the premier medical achievements of the twentieth century. In 2006, the U.S. Food and Drug Administration approved two new antiviral vaccines: a prophylactic VZV vaccine for the prevention of herpes zoster in persons 60 years of age and older, and a prophylactic vaccine against genital human HPV infection in women for prevention of cervical cancer caused by HPV-16 and HPV-18 and genital warts caused by HPV-6 and HPV-11. In addition to the numerous viral vaccines that are currently licensed for use, investigational vaccines are currently being developed for HSV, cytomegalovirus, dengue virus, West Nile virus, and HIV, among others.[29] Recombinant DNA techniques are making it possible to develop effective, non-infectious subunit vaccines composed only of viral protein (as with the vaccines against HPV and hepatitis B virus), rather than traditional vaccines, which contain either an attenuated strain of the pathogen or an inactivated preparation of the entire virus.[30,31] In addition to vaccines that induce active immunity, the passive administration of type-specific antibody soon after exposure is useful in select clinical situations, for example, in immunocompromised children exposed to varicella. Sensitive procedures for the detection of hepatitis B virus, hepatitis C virus, and HIV in potential blood donors has drastically reduced the incidence of transmission of these agents by transfusion. Other public health measures such as safer sex, single use of needles, control of mosquitoes, and proper hand washing continue

to be paramount in the prevention of viral disease.

MEASLES

Epidemiology

Measles, or rubeola, has a worldwide distribution and remains a leading public health burden, with 30 to 40 million cases and 530,000 deaths in 2003.[1] The risk of mortality is highest in developing countries, with most deaths due to complications of the disease.

Before the development of a vaccine, measles epidemics occurred every 2 to 5 years during winter and spring months in children 5 to 9 years old.[2,3] There continues to be a decline in the number of reported cases in the United States each year as vaccination strategies have improved, particularly in immigrant populations. During 2004, a total of 37 cases were reported to the Centers for Disease Control and Prevention by local and state health departments.[4] Improved immunization programs in developing countries have also prevented outbreaks and reduced measles-associated morbidity and mortality.

Etiology and Pathogenesis

Measles virus, a member of the Paramyxoviridae family, is a heat-labile virus with an RNA core and outer lipoprotein envelope.[2,3] Measles is spread by direct or airborne contact with infectious droplets. The incubation period is typically 8 to 12 days, with patients being contagious from 1 to 2 days before onset of symptoms to 4 days after appearance of the rash.[3] Both humoral and cell-mediated immunity are needed to control measles virus infection. Immunoglobulin M (IgM) antibodies are detected initially with onset of the rash, followed by a rise in measles-specific IgG titers. The humoral response controls viral replication and confers antibody protection, whereas the cell-mediated response eliminates infected cells.[2] A transient immunosuppression occurs during measles virus infection, causing depressed delayed-type hypersensitivity and T-cell counts as well as an increased risk of bacterial infections.[2] This process, as well as long-term immunity against measles, is not well understood but may be due to a weak T helper 1 response to the virus.[5]

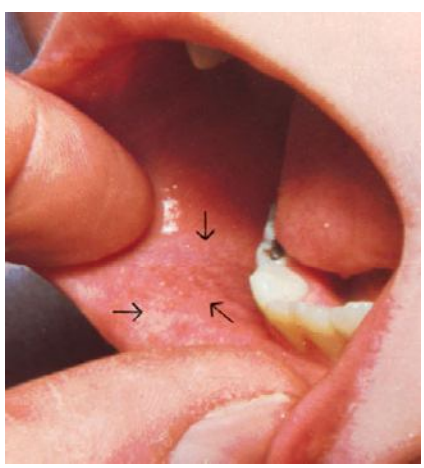
Clinical Findings

HISTORY The prodrome is typically characterized by fever [up to 40°C to 40.5°C (104°F to 105°F)], malaise, conjunctivitis (palpebral, extending to lid margin), coryza, and cough (brassy or barking), which may last up to 4 days.[2,3] Koplik spots, the pathognomonic enanthem of measles, begin as small, bright red macules that have a 1- to 2-mm blue-white speck within them. They are typically seen on the buccal mucosa near the second molars (Fig. 192-1) 1 to 2 days before and lasting 2 days after the onset of the rash (see eFig. 192-1.1 in on-line edition).[2,3] Individuals with pre-existing partial immunity (e.g., patients who received exogenous immunoglobulin) may have less severe symptoms but a prolonged incubation period (14 to 20 days). Conversely, immunosuppressed patients may have more severe disease and can present without the typical rash.[3]

MEASLES AT A GLANCE

- Rubeola.
- Epidemic disease; worldwide distribution.
- Fever, malaise, conjunctivitis, coryza, cough, Koplik spots.
- Generalized erythematous macules and papules that spread from the forehead and behind the ears to the trunk and extremities; begins to fade in 4 to 5 days.
- More severe disease in immunocompromised or malnourished individuals.

CUTANEOUS LESIONS The exanthem is characterized by erythematous, non-pruritic, macules and papules that begin on the forehead and behind the ears (Fig.



▲ **FIGURE 192-1** The pathognomonic Koplik spots appear as tiny white lesions surrounded by an erythematous halo "grains of sand." They precede the generalized rash by 1 to 2 days.

▲ **FIGURE 192-2** The rash appears behind the ears, on the forehead, and face and spreads slowly downward over the neck, shoulders, trunk, and then distally over the upper and lower extremities.

192-2). The rash quickly progresses to involve the neck, trunk, and extremities (Fig. 192-3). The hands and feet are involved. Lesions may coalesce, especially on the face and neck (see eFig. 192-3.1 in on-line edition). The rash usually peaks within 3 days and begins to disappear in 4 to 5 days after the order of its appearance. Desquamation may occur as the rash resolves.

RELATED PHYSICAL FINDINGS The entire illness may last up to 10 days, with some individuals also having vomiting, diarrhea, abdominal pain, splenomegaly, pharyngitis, and generalized lymphadenopathy.[2] Immunosuppressed patients are at higher risk for pneumonitis, encephalitis, and other fatal complications.[2,6] Viral shedding may also be more persistent in these individuals.[7]

Atypical measles infection is rare, but seen in individuals who received formalin-inactivated measles vaccine (1963 to 1967) and were subsequently exposed to wild-type virus.[2] Symptoms are often more severe with high fever, interstitial pneumonia, pleural effusions, extremity edema, hepatitis, and hyperesthesias occurring more commonly. Coryza, conjunctivitis, and Koplik spots are usually not present. The rash may be maculopapular, hemorrhagic, vesicular, or urticarial and spreads centripetally, making it difficult to distinguish from Rocky Mountain spotted fever.[2]

Laboratory Tests

Laboratory abnormalities may include monocytosis, leucopenia, and thrombocytopenia. During the prodrome stage, virus can be found in nasopharyngeal secretions, blood, and urine. The pharyngeal virus shedding ends by the second day of the rash. Virus may be seen in the urine until 4 days after rash onset. Viral culture has a low sensitivity for finding the virus. Indirect enzyme-linked immunoassay (ELISA), polymerase chain reaction (PCR), and real-time (RT)-PCR assays can detect measles virus in clinical specimens such as nasopharyngeal secretions, blood, and urine.[8] Serologic studies demonstrate measles virus infection with a documented increase in IgM and/or IgG antibody titers. IgM increases with the onset of the rash and lasts approximately 1 month whereas IgG appears 2 weeks after rash onset and peaks 4 to 6 weeks later.[3,9] Many laboratories may have access to viral immunofluorescence tests that quickly detect measles in throat or nasopharyngeal specimens.[10] In the United States, measles should be reported to the local health department.

Differential Diagnosis (Box 192-1)

Complications

Age-specific rates of complications are highest among children less than 5 years old and adults over 20 years. The most common complications of measles virus infection are otitis media, pneumonia, laryngotracheobronchitis, and diarrhea.[3,11] Hepatitis, thrombocytopenia, and encephalitis occur less commonly. Thrombocytopenia-associated purpura may be severe. Pneumonia is the most common fatal complication of measles in children and the most common complication overall in adults.[2,12] The disease severity is worse in immunocompromised and malnourished individuals,

▲ **FIGURE 192-3** Measles. Classic morbilliform exanthem with red papules spreading from forehead and postauricular to neck, trunk, and then extremities.

Box 192-1

Differential Diagnosis of Measles

Most Likely

- Drug hypersensitivity reaction
- Rubella

Consider

- Rocky Mountain spotted fever (atypical cases)
- Henoch-Schönlein purpura (atypical cases)
- Other viral infection (parvovirus, enterovirus, adenovirus, human herpesvirus-6, Epstein-Barr virus)

Always Rule Out

- Kawasaki disease
- Graft-versus-host disease (recent bone marrow transplant)

often resulting in the development of Hecht giant cell pneumonia.[13]

Prognosis and Clinical Course

Clinical diagnosis of measles is typically made with onset of the characteristic rash as the prodromal symptoms can mimic influenza-like illnesses. Uncomplicated measles is self-limited, lasting 10 to 12 days. Malnutrition, immunosuppression, poor health, and inadequate supportive care can worsen the prognosis in any patient. In developing nations, measles is a major cause of infant mortality.

Treatment

Treatment for measles in the majority of cases is supportive. Patients with secondary bacterial infections need to be treated with appropriate antibiotics. Ribavirin may be considered, as it has been shown to inhibit measles virus in tissue culture and reduce the severity and duration of measles in some cases.[2,3,18] In trials with patients with subacute sclerosing panencephalitis, however, no benefit was noted with the use of ribavirin.

Malnutrition and vitamin A deficiency can depress cell-mediated immunity in children, increasing the risk and severity of childhood infections. Measles virus infection decreases serum levels of vitamin A and can lead to higher risk of mortality from disease. Vitamin A supplementation is recommended for all children with measles who live in communities where vitamin A deficiency is known or where measles fatality rate is 1 percent.[3,19] In the United States, supplementation is considered for children 6 months to 2 years who are hospitalized with measles and its complications or for children more than 6 months of age who are at risk for vitamin A deficiency (immunodeficiency, severe malnutrition).[3] More recent studies of vitamin A have led to some controversy regarding its use.[20]

All individuals at risk (children less than 1 year of age, pregnant women, unimmunized, immunocompromised, exposed to measles virus) should receive immunoglobulin prophylaxis within 6 days of exposure.[3] If given within 72 hours of exposure, the individual will not be infected with the virus.[2] Healthy individuals should receive 0.25 mL/kg of intramuscular immunoglobulin, and immunocompromised patients require 0.5 mL/kg.[3] Exposed patients (excluding pregnant women and those with impaired immune systems) should also be given the measles vaccine 5 months later to confer lasting protection (Box 192-2).

Box 192-2

Treatments for Measles

- First line
  - Supportive care
  - Treat secondary infections
  - Vitamin A[a]
  - Immune globulin, IM[a]
  - Measles vaccine
- Second line
  - Ribavirin[a]

[a]In select cases, please see text.

Prevention (Immunizations)

The incidence of measles has decreased worldwide as a direct result of immunization. A single dose of the live attenuated measles vaccine produces detectable levels of antibody in 95 percent of individuals, conferring lifelong immunity.[2,3]

Common potential side effects of measles vaccine include fever and transient morbilliform rash that resolve without treatment. Less common adverse reactions include thrombocytopenia and transient neurologic reactions.[3,22]

Measles vaccine administration is contraindicated in individuals who have a moderate to severe illness as well as those allergic to eggs or neomycin. It is also contraindicated in pregnant women and those with impaired immune systems [cancer, non–human immunodeficiency virus (HIV) immune deficiency disease, immunosuppressive therapy]. Patients off chemotherapy or immunosuppressive medications for 3 months can receive the measles vaccine.

There have been many unconfirmed, unsubstantiated but widely publicized reports suggesting a potential link between measles-mumps-rubella (MMR) vaccine and the development of autism and possibly inflammatory bowel disease. Current scientific evidence does not support a causal link between MMR vaccine and autism or inflammatory bowel disease.[23]

RUBELLA

Epidemiology

Rubella virus has a worldwide distribution with outbreaks occurring most frequently in late winter and early spring months.[27] School-aged children, adolescents, and young adults most often develop the disease. Epidemics occasionally occur in developing countries, especially where vaccines are unavailable.

Since introduction of the rubella vaccine in the United States in 1969, the incidences of rubella and congenital rubella syndrome have drastically declined with no widespread epidemics occurring in the United States. Occasional outbreaks have largely been attributed to failure to vaccinate susceptible individuals.

RUBELLA AT A GLANCE

- German measles, 3-day measles.
- Epidemic disease; worldwide distribution.
- Short prodrome; rash of 2- to 3-day duration.
- Enlargement of cervical, suboccipital, and postauricular glands.
- High risk of fetal malformations with congenital infection (microcephaly, congenital heart disease, deafness), particularly in the first trimester.

Etiology and Pathogenesis

Rubella is an enveloped RNA virus in the Togaviridae family.[27,31] The virus is spread through direct or droplet contact from nasopharyngeal secretions.[27] Infected individuals shed virus for 5 to 7 days before and 14 days after onset of disease,[31] with viremia unlikely after the rash occurs. In most individuals, infection leads to lifelong immunity.

Congenital rubella occurs when a nonimmunized, susceptible, pregnant woman is exposed to the virus. Transplacental infection of the fetus occurs during the viremic stage. The risk is greatest to a fetus exposed to the virus in the first trimester. Congenitally infected infants may shed the virus through urine, blood, and nasopharyngeal secretions for up to 12 months after birth, thus being a potential source of viral exposure to other susceptible individuals.[27,31]

Clinical Findings

HISTORY Primary rubella infection is typically a mild, sub-clinical disease,

particularly in adults.[27,31] The prodrome is characterized by low-grade fever, myalgias, headache, conjunctivitis, rhinitis, cough, sore throat, and lymphadenopathy; symptoms that may last up to 4 days and often resolve with appearance of rash. Up to 50 percent of children with primary rubella infection may have a sub-clinical infection[32] or present only with lymphadenopathy or rash (no prodrome).[31] Conversely, older adults may have more severe and persistent prodromal symptoms that may make distinction from rubeola difficult in some situations. The presence of Koplik spots in the mouth favors rubeola. As the prodrome resolves and the rash begins to appear, some patients develop an enanthem consisting of tiny red macules on the soft palate and uvula (Forschheimer spots).[33] This enanthem is not diagnostic for rubella.

CUTANEOUS LESIONS The exanthem, occurring 14 to 17 days after exposure, is characterized by pruritic pink to red macules and papules that begin on the face, quickly progressing to involve neck, trunk, and extremities (Fig. 192-4 and At a Glance image).[31] Lesions on the trunk may coalesce, whereas those on the extremities often remain more discrete. The rash usually begins to disappear in 2 to 3 days, unlike rubeola, which can be more persistent and clears the head and neck first. Desquamation may follow resolution of the rash.

RELATED PHYSICAL FINDINGS Lymphadenopathy is usually most severe in the posterior cervical, suboccipital, and postauricular lymph nodes and is noted up to 7 days before the rash appears.[27] Enlargement of the nodes may persist for several weeks.

Adults, particularly women (up to 70 percent), may develop arthritis with rubella infection.[27] Both small and large joints may be affected. Joint symptoms often first appear as the rash fades and can last several weeks. In some individuals, the symptoms may become persistent or recurrent. Joint swelling may progress to form a joint effusion.

▲ **FIGURE 192-4** Rubella. Erythematous macules and papules appearing initially on the face and spreading to trunk, arms, and legs within 24 hours.

Laboratory Tests

Serum complete blood cell count usually shows leukopenia with relative neutropenia. Increased numbers of atypical lymphocytes or abundant plasma cells may be noted as well. Patients with meningeal involvement have lymphocytes in the cerebrospinal fluid (CSF). Viral culture (nose, throat, blood, urine, CSF, synovial fluid) is sensitive but often difficult due to the unstable nature of the virus.[31] Diagnosis is typically made using serology to detect rubella-specific IgM antibody (up to 8 weeks after infection) or to document a fourfold rise in antibody titer in acute and convalescent-phase serum.[27,33] Hemagglutination-inhibition, complement fixation, immunofluorescence assay, and ELISA are some of the methods used to detect antibodies.[31,33] As with measles, rubella cases should be reported to local health departments.

Congenital Rubella Syndrome

Women who are infected with rubella during pregnancy may only exhibit minor clinical symptoms. The effects, however, of rubella infection on the fetus can be profound,[31] with the greatest risk of fetal malformation in the early stages of pregnancy. Up to 85 percent of fetuses exposed to rubella within the first 4 weeks develop serious sequelae such as: microcephaly with mental retardation, congenital heart disease (ventricular septal defect, patent ductus arteriosus), sensorineural deafness, cataracts, low birth weight and fetal death.[27,31,33]

Diagnosis of congenital rubella infection is obtained by isolating rubella virus in the throat, urine, or CSF of the affected neonate. Serologic testing is not as sensitive but is easily available for confirmatory testing.[31]

Differential Diagnosis (Box 192-3)

Box 192-3

Differential Diagnosis of Rubella

Most Likely

- Drug hypersensitivity reaction
- Rubeola (measles)

Consider

- Other viral infection (enterovirus, adenovirus, parvovirus, human herpesvirus-6)

Always Rule Out

- Streptococcal scarlet fever

For differential diagnosis of congenital rubella syndrome with blueberry muffin lesions, see Box 192-9.

Complications

Rarely, rubella infection may lead to encephalitis (1 in 6000 cases),[33] with mortality rates varying from 0 percent to 50 percent.[33] Other rare complications include: peripheral neuritis, optic neuritis, myocarditis, pericarditis, hepatitis, orchitis, and hemolytic anemia.[31] Transient thrombocytopenia has been described in 1 in 3000 children (usually girls); first appearing within days of rash onset and lasting days to months.[31,35] Recently, a case of rubella-associated hemophagocytic syndrome in an infant was described.[36]

Prognosis and Clinical Course

Rubella is typically a self-limited disease. Infants who have congenital rubella are infectious until viral shedding from the nasopharynx and urinary tract ends. The majority of infants (85 percent) infected in utero excrete virus in the first month of life; 1 percent to 3 percent continue to excrete virus in the second year of life.[27,33] Pregnant women caring for these infants are at risk for developing rubella. Clinical course depends on how severely affected the fetus is from intrauterine infection.

Treatment

Treatment of primary, uncomplicated rubella is supportive. In nonpregnant individuals, rubella vaccine administration within 3 days of exposure may theoretically prevent illness, though this is yet to be proven.[27] Immune globulin is not routinely recommended as post-exposure prophylaxis of rubella-susceptible pregnant women. Limited data indicate that intramuscular immune globulin (0.55 mL/kg) may decrease clinically apparent infection from 87 percent to 18

percent if given to an exposed, susceptible pregnant woman.[27] However, absence of clinical signs after administration of immune globulin does not assure that congenital infection did not occur.

Neonates with congenital rubella syndrome require supportive care as well as appropriate attention to significant health issues. These infants are contagious and should be isolated to prevent transmission to susceptible individuals.[27,31] Contact isolation is recommended for these infants until they are at least 12 months old or if repeated cultures are negative after 3 months of age.

Prevention (Immunizations)

Rubella vaccine is typically administered as part of a three-fold vaccine (MMR) at 12 to 15 months of age and again at 4 to 6 years of age. Seroconversion after a single dose of MMR vaccine occurs in 95 percent individuals.[27] It is imperative that individuals at risk for rubella infection are immunized, such as health care workers, military recruits, college students, and recent immigrants.[27] Individuals are considered immune to rubella if they have documented vaccination with a live MMR on or after their first birthday, serologic evidence of rubella immunity, or were born after 1957 (except women of childbearing age).[33]

Potential adverse reactions to rubella vaccine occur in susceptible individuals and include: fever, morbilliform rash, lymphadenopathy, and arthralgia.[27]

Pregnant woman should not be immunized with rubella to minimize risk to the fetus. Any woman receiving the rubella vaccine should not become pregnant for 28 days. Infants of vaccinated breast-feeding mothers may become infected with rubella via breast milk. Typically they develop a mild erythematous exanthem of macules and papules with no serious effects.[33] As rubella infection confers lifelong immunity, a woman who is re-exposed during pregnancy has a low risk of having her fetus contract congenital rubella. Concern about possible infection can be addressed by looking for IgM antibodies in fetal serum (cordocentesis).

ERYTHEMA INFECTIOSUM AND PARVOVIRUS B19 INFECTION

Epidemiology

Erythema infectiosum (fifth disease) is worldwide in distribution, can occur throughout the year, and can affect all ages. It tends to occur in epidemics, especially associated with school outbreaks in the late winter and early spring. Serologic studies show increasing prevalence of antibodies with age. Various studies indicate that from 15 percent to 60 percent of children 5 to 19 years of age and 30 percent to 60 percent of adults are seropositive.[37] Seroprevalence increases to greater than 90 percent in the elderly.[37] Previous infection with B19 seems to confer lifelong immunity.

The incubation period for erythema infectiosum is from 4 to 14 days.[38] After intranasal inoculation of parvovirus-infected serum to healthy volunteers, low-grade fever and non-specific complaints occurred at the time of viremia, 6 to 14 days after inoculation, and the rash appeared at day 17 or 18.[39]

Parvovirus B19 is thought to be transmitted primarily by the respiratory route via droplet aerosol during the viremic phase, and B19 DNA has been found in respiratory secretions of viremic patients.[39] After the rash of erythema infectiosum appears, B19 is not found in respiratory secretions and is usually not present in the serum. This suggests that persons with erythema infectiosum are infectious only before the onset of the rash.

PARVOVIRUS B19 AT A GLANCE

- Causes erythema infectiosum, fifth disease.
- Fifth disease in children with "slapped cheeks" followed by an erythematous, lacy eruption on the trunk and extremities.
- Symmetric polyarthritis, particularly of the small joints.
- Causes papular purpuric gloves-and-socks syndrome with pruritic erythema, edema, and petechiae of the hands and feet, fever, and oral erosions in adolescents.
- Aplastic crisis in patients with increased red blood cell turnover, chronic anemia in immunocompromised persons, and fetal hydrops.

The virus seems to be effectively spread after close contact. The secondary attack rate among susceptible household contacts is approximately 50 percent. Transmission may occur via blood transfusion, from blood products, and vertically from mother to fetus.[40] The transmission of B19 through blood transfusion is particularly problematic because the nonenveloped virus is not killed by the solvent detergents or heat that are used to inactivate HIV and hepatitis viruses.[41]

Etiology and Pathogenesis

The B19 virus belongs to the family Parvoviridae and the genus *Parvovirus*.[42] B19 lacks an envelope and contains single-stranded DNA. It is the smallest single-stranded DNA–containing virus known to infect humans, measuring 18 to 26 μm in diameter. Parvoviruses are widespread in veterinary medicine, but animal parvoviruses are not thought to be transmissible to humans.[41]

The pathogenesis of erythema infectiosum is unknown, but the mechanism may involve immune complexes. The more serious manifestations of parvovirus infection relate to the fact that the virus infects and lyses erythroid progenitor cells. Evidence suggests that the blood group P antigen (globoside) is a receptor of parvovirus. Because some individuals lack P antigen, they are not susceptible to infection with B19.[43] In patients with increased red blood cell destruction or loss who depend on compensatory increase in red cell production to maintain stable red cell indices, B19 infection may lead to transient aplastic crisis. Such patients include those with anemia associated with acute or chronic blood loss. When parvovirus infects the erythroblasts in a developing fetus with decreased red cell survival, the result may be hemolysis and anemia.[44] Anemia may trigger congestive heart failure, edema (fetal hydrops), and possibly fetal death.

Clinical Findings

PARVOVIRUS B19 IN CHILDREN Most infections caused by B19 are asymptomatic and unrecognized. Fifth disease, the most common clinical picture associated with the virus, usually begins with nonspecific symptoms such as headache, coryza, and low-grade fever approximately 2 days before the onset of the rash.[45] Patients may have headache, pharyngitis, fever, malaise, myalgias,

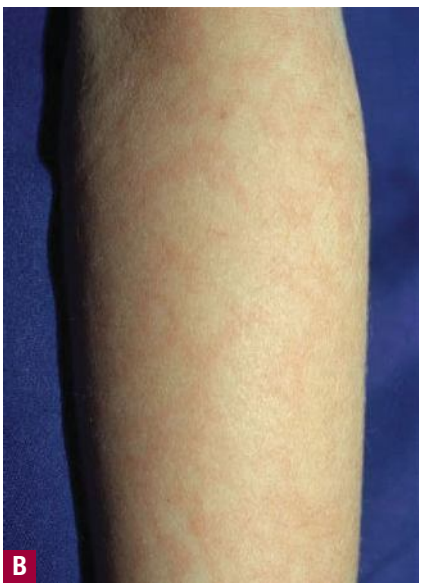
coryza, diarrhea, nausea, cough, and conjunctivitis coinciding with the rash. Approximately 10 percent of children with erythema infectiosum develop arthralgias or arthritis. Large joints are affected more often than small joints.[45] Occasionally, children may present with chronic joint complaints suggestive of juvenile rheumatoid arthritis.[46]

The characteristic rash begins with confluent, erythematous, edematous plaques on the malar eminences, the "slapped cheeks" (Fig. 192-5). As the facial rash fades over 1 to 4 days, pink to erythematous macules or papules appear on the trunk, neck, and extensor surfaces of the extremities. These lesions have some central fading, giving them a lacy or reticulated appearance (Fig. 192-6).[45] The rash can be morbilliform, confluent, circinate, or annular, and there have been reports of palmar and plantar involvement.[38] The eruption typically lasts 5 to 9 days, but can recur for weeks or months with triggers such as sunlight, exercise, temperature change, bathing, and emotional stress. In some outbreaks, pruritus is a major feature of the rash in children.[38]

There have been occasional reports of parvovirus B19 associated with vascular purpura, including Henoch-Schönlein purpura.[47] An enanthem consisting of erythema of the tongue and pharynx and red macules on the buccal mucosa and palate can occur.

PARVOVIRUS B19 IN ADULTS Acute arthropathy is the primary manifestation of B19 viral infection in adults.[48] It occurs mainly in women and affects the small joints of the hands, the knees, other joints, such as the spine and costochondral joints, are involved. This symmetric polyarthritis is usually of sudden onset and is self-limited but can be persistent or recurrent for months. It may mimic Lyme arthritis or rheumatoid arthritis.

▲ **FIGURE 192-5** Erythema infectiosum. Child with the characteristic "slapped cheek."



▲ **FIGURE 192-6** Erythema infectiosum. **A.** Lacy, reticulated macules and papules on proximal extremities. **B.** Lacy macules on leg.

The constitutional symptoms are usually more severe in adults than in children.[49] Fever, adenopathy, and a mild arthritis without a rash is the usual course. Women are more likely than men to have joint complaints and rash, whereas men often present with only a flu-like illness.[48] Some adults may have fatigue, malaise, and depression for weeks after the infection. Asymptomatic infection can certainly occur in adults as well as in children. In one outbreak, 26 percent of adults were reported to be asymptomatic.[48] Parvovirus B19 can cause numbness and tingling of the fingers with or without other features of fifth disease.[50] Pruritus that is sometimes severe can occur with or without a rash. It has been suggested that if pruritus is a complaint in a patient with acute-onset arthritis, parvovirus should be considered as a possible cause.

The rash in adults, if present at all, is usually macular and blotchy or lacy, often on the extremities, and rarely demonstrates the characteristic slapped-cheek appearance.[48] Other cutaneous manifestations associated with B19 infection in adults include purpura, vesicles and pustules, palmo-plantar desquamation, a morbilliform exanthem with Koplik spots, and livedo reticularis.

PAPULAR PURPURIC GLOVES-AND-SOCKS SYNDROME In 1990,[51] a unique syndrome of pruritic erythema and edema of the hands and feet with petechiae, fever, and oral erosions was described. This rare exanthem, now known as *papular, purpuric gloves-and-socks syndrome,* seems to affect teenagers and adults. However, it can affect children also.[52] Patients usually have mild prodromal symptoms of fatigue and low-grade fever, myalgias, and arthralgias. Subsequently, itchy, painful, symmetric edema and erythema of the distal hands and feet occurs.[53] Purpuric papules appear on the hands and feet with abrupt demarcation at the wrists and ankles. The enanthem, if present, arises on the lips, soft palate, and buccal mucosa. The syndrome resolves spontaneously within 2 weeks. Although many viruses have been implicated as causative agents for papular, purpuric gloves-and-socks syndrome, B19 is the virus proven to cause the syndrome.[54]

Laboratory Tests

In patients with erythema infectiosum, laboratory results are usually normal, including reticulocyte count, hematocrit, and tests of liver and renal function. Patients with aplastic crisis have reticulocytopenia and anemia, the severity of which depends on the degree of the underlying anemia. Reticulocytopenia, anemia, lymphopenia, neutropenia, and thrombocytopenia can occur in healthy individuals with B19 infection, although these are usually not significant enough to cause clinical symptoms. The erythrocyte sedimentation rate is rarely elevated, and rheumatoid factor has been positive in some cases of parvovirus-associated arthritis.

Detection of recent infection is usually performed with assays for IgM antibody. Radioimmunoassay or ELISA techniques can detect IgM within a few days after

onset of illness. IgM can be measured for up to 6 months in many cases, although there is a decline in titer in the second month after onset. IgG can be identified with the same techniques by the seventh day of illness and lasts for years and is therefore best for documenting past infection. Parvovirus antibody is often not detectable in immunodeficient persons. B19 virus can be detected in serum during viremia by a variety of techniques including radioimmunoassay, counterimmunoelectrophoresis, and ELISA. The most specific tests are dot-blot hybridization[55] and the PCR,[56] which may allow identification of B19 DNA in serum, urine, respiratory secretions, CSF, and bone marrow. B19 DNA can be detected with PCR for up to 4 months after the onset of illness.[57]

Special Tests

Differential Diagnosis (Box 192-4)

Complications

As more attention is focused on parvovirus B19, an increasing number of complications are recognized. Sub-clinical infection is quite common. However, this virus can be responsible for a variety of hematologic, rheumatologic, and neurologic abnormalities.

Box 192-4

Differential Diagnosis of Parvovirus B19 Infection

Most Likely
- Erythema infectiosum
- Drug reaction
- Enteroviral infection
- Erysipelas on the cheek
- Papular purpuric gloves-and-socks syndrome
- Hand-foot-mouth disease

Consider
- Erythema infectiosum
- Roseola
- Rubella
- Measles
- Collagen vascular disease (systemic lupus erythematosus, dermatomyositis)
- Papular purpuric gloves-and-socks syndrome
- Atypical measles

Always Rule Out
- Erythema infectiosum
- Scarlet fever
- Papular purpuric gloves-and-socks syndrome
- Rocky Mountain spotted fever
- Kawasaki disease

TRANSIENT APLASTIC CRISIS Parvovirus B19 is the most common cause of transient aplastic crisis in patients with chronic hemolytic anemias.[59] This has been demonstrated in sickle cell anemia, hereditary spherocytosis, heterozygous β-thalassemia, pyruvate kinase deficiency, and autoimmune hemolytic anemia, as well as in other conditions of decreased red cell production or increased red cell destruction. The aplastic crisis may be the initial manifestation of the underlying hematologic disease.[60]

CHRONIC B19 INFECTION In immunocompromised patients, B19 infection can cause a serious, prolonged anemia from persistent lysis of red blood cell precursors.[62] Parvovirus-related chronic anemia has been reported in HIV-infected patients, as well as in transplant recipients and those with congenital immunodeficiencies, acute leukemias, lupus erythematosus, and during the first year of life without immunodeficiency. These patients respond dramatically to intravenous γ globulin, suggesting that antibody is the main defense to human parvovirus infection.[63]

FETAL B19 INFECTION Fetal infection with B19 may result in either an unaffected fetus or spontaneous abortion (especially in the first half of pregnancy), hydrops fetalis in the second half of pregnancy, congenital anemia, and even late fetal death.[64] Nonimmune fetal hydrops is the most common complication of intrauterine infection with B19. Because B19 virus can infect erythroid precursors, extensive hemolysis can occur in the fetus, leading to severe anemia, tissue anoxia, high-output heart failure, and generalized edema. The fetus may show ultrasonographic evidence of subcutaneous edema, ascites, pleural effusion, pericardial effusion, placental edema, and polyhydramnios. The overall risk of fetal death is not clearly known, but recent studies suggest that this risk is approximately 6.5 percent with maternal infection.[64] The risk of fetal death for a woman with unknown serologic status is estimated to be less than 2.5 percent after a household exposure and less than 1.5 percent after a significant work exposure. It seems that in B19-infected pregnant women, most fetuses are not infected; if they are infected, usually there is not an adverse outcome.[65] Furthermore, approximately one-half of women of childbearing age are immune to parvovirus infection because of prior infection.

OTHER COMPLICATIONS

Prognosis and Clinical Course

Parvovirus B19 infection in healthy individuals is self-limited. The rash of erythema infectiosum and the parvovirus arthropathy usually resolve in 1 to 2 weeks, but can recur or persist for months. If untreated, transient aplastic crisis can be fatal, but most patients recover in 1 week. Chronic anemia from B19 usually resolves if treated with γ globulin. Fetal hydrops can lead to fetal death if not treated.

Treatment

There is no specific treatment available for parvovirus B19 infection. Erythema infectiosum is a benign condition, and usually no treatment is necessary. Supportive therapy for relief of fatigue, malaise, pruritus, and arthralgia may be needed. The chronic anemia of persistent B19 infection may be treated successfully with commercially available intravenous immunoglobulin, which contains neutralizing anti-B19 antibodies. Transient aplastic crisis, which can be life-threatening, may require oxygen therapy and blood transfusion.

Serologic testing for B19 IgG and IgM should be offered to pregnant women who are exposed to parvovirus B19. Infected pregnant women are followed by frequent ultrasonograms. Evidence of hydrops fetalis warrants umbilical cordocentesis to check for anemia, viral DNA, IgG, and IgM. The management of infected fetuses is controversial. Some physicians advocate observation because spontaneous resolution is common. Fetuses with severe anemia and compromise are usually managed with intrauterine exchange transfusion, but this procedure does carry risk (Box 192-5).

Box 192-5

Treatments for Parvovirus B19 Infections

Erythema infectiosum	Supportive treatment of fatigue, malaise, pruritus, arthralgias.
Chronic anemia	IV immune globulin.
Transient aplastic crisis	Oxygen and/or blood transfusion may be necessary.
Hydrops fetalis	Possible intrauterine exchange transfusion.

Prevention

There is currently no vaccine to prevent parvovirus B19 infection. Candidate vaccines are in clinical trials.[76] It is not known whether immunoglobulin given around the time of exposure prevents infection or alters the course of the disease.

Because patients with erythema infectiosum are no longer infectious by the time they develop the illness, control measures directed toward these individuals are not likely to be effective. If these persons are hospitalized, no special precautions need to be taken. Because the virus is transmitted before the rash appears, the disease is easily spread in situations of close prolonged contact such as schools, day care centers, workplaces, and homes.

Patients with aplastic crisis or immunosuppression with chronic B19 anemia may have high-titer viremia and are particularly infectious. These individuals should be placed in respiratory and contact isolation if hospitalized, and pregnant health care providers should not care for them directly. Hospital workers are at risk of contracting nosocomial infections from these patients[77] and could spread the virus to patients if adequate precautions are not taken.

EPSTEIN-BARR VIRUS

Epidemiology

Epstein-Barr virus (EBV) is a worldwide pathogen with more than 90 percent of adults latently infected.[78] In developed countries, most cases of primary infection occur during adolescence or early adulthood, and clinically may present as infectious mononucleosis.[79] Primary infection may occur during childhood; however, is often sub-clinical, probably because children are better able to clear the infection. In developing countries, most of the population is infected during childhood, thus infectious mononucleosis is much less common.

EBV is transmitted primarily by saliva through close contact.[80] Viral replication occurs during primary infection, allowing infectious viral particles to be shed from the oropharynx. There are also reports of EBV acquired via blood transfusion.[81] It is also thought that EBV may be transmitted through breast milk[82] and genital secretions.[83]

Etiology and Pathogenesis

EBV, also called *human herpesvirus 4 (HHV-4)*, belongs to the Herpesviridae family and is approximately 180 to 200 nm in diameter.[80] The double-stranded DNA genome encodes approximately 100 proteins and is enclosed within a capsid. The capsid is surrounded by an envelope, composed primarily of glycoprotein gp350. CD21 is present on the surface of B cells and binds with gp350, allowing entry of EBV into the cell.

EBV infects B lymphocytes directly within the oral mucosa or infects mucosal epithelial cells, which then infect the B lymphocytes.[84–86] The infected B cells are activated, and their population is expanded. These B lymphocytes allow dissemination of the virus throughout the lymphoreticular system.[87] A clonal expansion of cytotoxic T lymphocytes allows recovery from primary infection and is the source of the atypical lymphocytes associated with EBV infection.[88] Symptoms are likely a result of this immunologic response.

EBV establishes an indefinite latent infection within the B cells, during which time low levels of the latent proteins are produced.[87] The previously linear DNA forms a circular structure, called an *episome*. Thereafter, B cells may re-activate and re-infect the oropharynx; replication and shedding of the viral DNA allows transmission of the virus to new hosts.[80,87]

EPSTEIN-BARR VIRUS AT A GLANCE

- Human herpesvirus 4.
- In developed countries, primary infection most often occurs during adolescence/early adulthood.
- Infectious mononucleosis characterized by the triad of fever, lymphadenopathy, and pharyngitis.
- Morbilliform exanthem with primary infection; most common after administration of ampicillin/amoxicillin.
- Oral hairy leukoplakia, nasopharyngeal carcinoma, Burkitt lymphoma, Hodgkin disease, Kikuchi histiocytic necrotizing lymphadenitis, and certain types of cutaneous T-cell lymphoma associated with Epstein-Barr virus infection.

Clinical Findings

HISTORY There is an incubation period of 30 to 50 days. Primary infection with EBV in adolescents and adults typically results in infectious mononucleosis, or the "kissing disease." The classic triad of fever, lymphadenopathy, and pharyngitis are noted in more than 50 percent of patients.[80] The fever may range from 37.5°C (99.5°F) to 40.5°C (104.9°F) and lasts 1 to 3 weeks. Lymphadenopathy is tender and characteristically found in the posterior cervical chain. Examination of the posterior pharynx may vary from mild erythema to grossly enlarged tonsils with white exudates.[87]

CUTANEOUS LESIONS Seventy percent to 100 percent of patients with infectious mononucleosis develop an eruption when antibiotics, specifically ampicillin, are administered.[85] Similar rashes have been reported with other antibiotics, such as amoxicillin, cephalexin, erythromycin, and levofloxacin. The rash typically begins 7 to 10 days after the initial administration of antibiotics. A pruritic, erythematous, morbilliform, or scarlatiniform eruption is noted on the trunk and extremities. The rash has been described as *copper-colored*. Coalescence may be observed on the extensor surfaces and dependent areas. (Fig. 192-7A,B and see eFig. 192-7.1 in on-line edition). The palms, soles, or oral mucosa may be involved. Clearance, which is usually within 7 days,[89] is accompanied by prominent desquamation.[90] The rash is thought to be a result of EBV-induced antibodies that are produced in response to the administered drug; these antibodies subsequently form immune complexes, which fix complement.[85] This exanthem does not usually indicate a permanent allergy to the medication.[91]

An exanthem due to EBV alone may also occur in a minority of cases (approximately 5 percent to 15 percent).[85,89] This rash is also morbilliform and pruritic; however, usually it commences during the first few days of illness and resolves faster, typically in 1 to 6 days.[89,90] Periorbital and eyelid edema may be seen in up to 50 percent of those with infectious mononucleosis.[92] In approximately 25 percent of cases, an enanthem is noted. Six to 20 petechiae, measuring 0.5 to 1.0 mm, may be visualized at the junction of the hard and soft palate. Lesions may coalesce forming larger lesions.

Erythema multiforme, erythema nodosum, acrocyanosis, erythema annulare centrifugum, pityriasis lichenoides, palmar dermatitis, cold urticaria, and granuloma annulare have all been re-

▲ **FIGURE 192-7** **A.** Epstein-Barr virus mononucleosis. Copper-colored papules on trunk and extremities after taking oral amoxicillin. **B.** Closer view of rash with Epstein-Barr virus mononucleosis. (Used with permission from Helmut Hintner, MD.)

ported during infection with EBV.[90] Genital ulcers have also been observed during primary infection with EBV (Fig. 192-8).[93] Typically occurring after the onset of fever and lymphadenopathy, ulcers are painful, deep, and red-violaceous in color. The base of the ulcer can be clear, seropurulent, or with granulation tissue. The ulcers heal in approximately 2 weeks, and treatment is symptomatic.

▲ **FIGURE 192-8** Two scrotal ulcerations in a patient with documented Epstein-Barr virus infection.

EBV is currently the most common cause of Gianotti-Crosti syndrome (GCS; see Chap. 106).[94] In children, primary infection with EBV is often mild or asymptomatic; as a result, typical features of infectious mononucleosis may not be observed.[90]

RELATED PHYSICAL FINDINGS Associated symptoms and signs may include fatigue, rigors, headache, and hepatosplenomegaly.[95]

Laboratory Tests

Most patients with infectious mononucleosis demonstrate a lymphocytosis, often with lymphocytes accounting for more than 50 percent of the absolute white blood cell count.[96] Atypical lymphocytes are a hallmark, typically more than 10 percent atypical lymphocytes; most of these cells represent activated T cells responding to infected B cells.[80] Mild, transient neutropenia[97] and thrombocytopenia[98] are common. Transaminases are elevated in more than 80 percent of patients with infectious mononucleosis.[99]

The presence of heterophile antibodies confirms most cases of infectious mononucleosis.[88] Heterophile antibodies recognize antigens on the erythrocytes from a number of different species including horses, sheep, bulls, and humans; however, they do not recognize EBV. They are thought to be a result of polyclonal stimulation during the viral infection,[100] and can occasionally be detected (false positives) in other illnesses such as lymphoma, hepatitis, or autoimmune disease.[88] Heterophile antibodies typically appear within 1 week of the onset of symptoms, peak within 2 to 5 weeks, and may persist for up to 1 year. They are not the ideal diagnostic test in children less than 4 years old, as sensitivity is quite low.[95] In the past, the Paul-Bunnell test had been used with sheep erythrocytes.[88,96] Currently, the more sensitive monospot test is used, which is a latex agglutination assay with horse erythrocytes to look for heterophile antibodies. Up to 10 percent of patients with EBV mononucleosis never develop heterophile antibodies; this is referred to as *heterophile-negative mononucleosis*.

A number of antibodies specific to EBV develop in the course of disease as well.[88,95] Measurement of these specific antibodies may be warranted if infectious mononucleosis is suspected and heterophile antibodies are negative. IgM and IgG antibodies form to viral capsid antigen (VCA) and are both present at onset of disease. IgM VCA antibodies wane after approximately 3 months; IgG VCA antibodies persist for life and are a marker for previous infection. IgG antibodies to EBV nuclear antigen develop 6 to 12 weeks into the course of disease and also persist for life. IgG to early antigen develops at the onset of disease and is made up of two subsets of antibodies, anti-D and anti-R. The presence of anti-D antibodies suggests recent infection, although 30 percent of patients do not produce antibodies at all. Anti-R antibodies have no clinical significance. Thus, primary infection may be most easily diagnosed in the presence of IgM and IgG VCA antibodies as well as negative IgG EBV nuclear antigen antibodies.[101]

Histopathology

The morbilliform exanthem associated with EBV demonstrates non-specific histopathologic findings.[102] There is usually a mild perivascular infiltrate of inflammatory cells. Specific cutaneous manifestations may show their characteristic pathologies.

Differential Diagnosis (Box 192-6)

Complications

Complications of infectious mononucleosis occur in approximately 20 percent of patients and include airway obstruction, autoimmune hemolytic anemia or thrombocytopenia, neutropenia,[87] myocarditis, and hepatitis.[80] Neurologic complications occur in approximately 5 per-

Treatment for Epstein-Barr Virus Infectious Mononucleosis

First line	Fever, throat discomfort, myalgias, headache. Splenomegaly.	Acetaminophen/nonsteroidal anti-inflammatory drugs. Avoid contact sports until spleen size normalizes to prevent splenic rupture.
Second line	Impending airway obstruction, thrombocytopenia, hemolytic anemia.	Systemic corticosteroids.

cent of patients.[87] Examples include encephalitis, meningitis, and Guillain-Barré syndrome.[80] The risk of splenic rupture is estimated at 0.1 percent and is spontaneous in greater than one-half of cases.[103] Between 3 percent and 30 percent of patients with infectious mononucleosis also have concomitant group A streptococcal pharyngitis.[96] Finally, in some patients, fatigue and hypersomnia can persist up to 6 months.[104]

Prognosis and Clinical Course

Recovery from infectious mononucleosis is typically gradual over 2 to 3 weeks without specific treatment.[88] Disease may be more protracted in older adults. Chronic active EBV infection occurs rarely.[80] It begins as a primary EBV infection and persists for more than 6 months with severe illness and histologic evidence for organ disease. EBV DNA or antigens can be demonstrated from tissue, and usually EBV antibody titers are significantly elevated.

Treatment

Treatment for uncomplicated infectious mononucleosis is symptomatic (Box 192-7).[95] Acetaminophen or nonsteroidal anti-inflammatory agents may be useful in treating the fever or throat discomfort. Because splenomegaly is often an associated finding, contact sports should be avoided until the spleen has returned to its normal size to avoid splenic rupture.

Systemic corticosteroids may decrease the duration of fever or pharyngeal symptoms, but in general, are not recommended for uncomplicated disease.[79]

Prevention

Because infectious mononucleosis is often mistaken for a bacterial infection, antibiotics may initially be used to treat. Antibiotics should be avoided in infectious mononucleosis as an exanthem is much more likely to occur in this setting.

Vaccinations are currently being investigated and may prove to be helpful in preventing EBV infections in the future, particularly in high-risk patients.[80]

Oral Hairy Leukoplakia (See Chap. 198)

Lymphoproliferative Disease and Malignancy

The latent infection established by EBV has been linked to the development of several malignancies, including nasopharyngeal carcinoma, Burkitt lymphoma, and Hodgkin lymphoma.[80] EBV-associated malignancies occur mainly in patients who are immunocompromised due to HIV infection, congenital immunodeficiencies, or those who receive immunosuppressant therapy such as organ transplant recipients. It is thought that the latent infection of B cells allows transformation and immortalization, allowing the development of a neoplasm to occur.[113] Different EBV genes are expressed in each type of malignancy and the biology is quite complex.

Kikuchi Histiocytic Necrotizing Lymphadenitis

GIANOTTI-CROSTI SYNDROME

Epidemiology

GCS, also known as *infantile papular acrodermatitis* and *papular acrodermatitis of childhood,* is a common, self-limited dermatosis seen worldwide. It affects infants and children between the ages of 6 months and 12 years with the peak age of presentation being 1 to 6 years of age. In children, there is neither an ethnic nor sexual predilection.[128,129] There have been only scattered case reports in adults.

Etiology and Pathogenesis

GCS is a cutaneous reaction pattern associated with viruses, bacteria, and vaccines. Historically, it was thought to be induced exclusively by hepatitis B, but over time other infectious triggers were identified. When hepatitis B is the causative agent, sub-type ayw is most frequently seen.[130] Associated triggers include hepatitis B and EBV most commonly, but other associated viruses include cytomegalovirus, enterovirus, respiratory syncytial virus, rotavirus, adenovirus, echovirus, pox virus, poliovirus, coxsackie virus, parvovirus, HIV, hepatitis A, hepatitis C, and parainfluenza virus. Bacterial pathogens include *Mycoplasma pneumoniae, Borrelia burgdorferi, Bartonella henselae,* and group A β-hemolytic streptococcus. Immunizations that have been associated include influenza, diphtheria, tetanus, pertussis, bacillus Calmette-Guérin, *Haemophilus influenzae* type b, and oral polio vaccine. The exact pathogenesis of GCS is not known but may be due to a viral antigenemia or circulating immune complexes.[131] Virus-like particles have been seen in cytoplasmic vacuoles and lysosomes in lesional skin.[132]

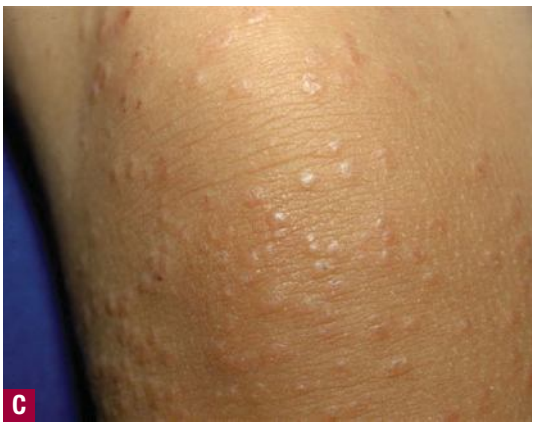
GIANOTTI-CROSTI SYNDROME AT A GLANCE

- Papular acrodermatitis of childhood.
- Common, self-limited dermatosis.
- Monomorphic dome-shaped or flat-topped papules symmetrically distributed on face and extensor extremities.
- Associated with multiple viral triggers and immunizations.
- Historically associated with hepatitis B infection, but now more often triggered by Epstein-Barr virus.

Clinical Findings

HISTORY Before the onset of the exanthem, a non-specific prodrome of upper respiratory tract infection with fever and pharyngitis plus low-grade fever may be present.

CUTANEOUS LESIONS Typically, patients develop multiple coalescing, monomorphous, flat-topped or dome-shaped, red-brown papules and papulovesicles (Fig. 192-9 and see eFig.192-9.1 in on-line edition). Lesions can be pruritic and, rarely, hemorrhagic. Papules vary from 1 to 10 mm in diameter (see Fig. 192-9C)[133] and are distributed symmetrically on the cheeks, extensor surfaces of the extremities, and the buttocks. The trunk, palms, and soles are usually, but not al-



▲ **FIGURE 192-9** Monomorphous crusted papules on face (**A**) and extensor extremities (**B**) in a patient with Gianotti-Crosti syndrome. **C.** Flat-topped, 2- to 4-mm papules with very uniform appearance.

Box 192-8

Differential Diagnosis of Gianotti-Crosti Syndrome

Most Likely
- Papular urticaria
- Pityriasis rosea

Consider
- Erythema multiforme
- Lichen planus
- Lichenoid drug eruption
- Pityriasis lichenoides et varioliformis acuta
- Molluscum contagiosum
- Hand-foot-mouth disease
- Follicular eczema
- Erythema infectiosum

Always Rule Out
- Infectious mononucleosis
- Henoch-Schönlein purpura
- Scabies

ways, spared. Occasionally, the small papules coalesce into large plaques. Cutaneous lesions evolve over a few days and last for 2 to 8 weeks.

RELATED PHYSICAL FINDINGS Constitutional symptoms, including malaise, low-grade fevers, and diarrhea, are sometimes seen at time of presentation, but are usually mild. Patients can develop lymphadenopathy, especially of the cervical, axillary, and inguinal chains.[134]

Laboratory Tests

In most patients, the diagnosis is established on clinical findings and no further diagnostic testing is necessary. In patients with hepatomegaly, further diagnostic testing, including complete blood cell count and liver enzymes, may be warranted. Lymphocytosis or lymphopenia are common and do not require further diagnostic evaluation. If there are elevations in the liver enzymes, evaluation for hepatitis or EBV should be performed. If hepatitis is suggested, checking anti–hepatitis A IgG and IgM, hepatitis B surface antigen and core antibody, and anti–hepatitis C IgG is indicated.

Differential Diagnosis (Box 192-8)

Complications

Complications are rare with the majority of cases having a self-limited and mild course. On rare occasions, when GCS is associated with hepatitis B infection, chronic liver disease with subsequent liver failure can occur.[131]

Prognosis and Clinical Course

In the vast majority of cases, GCS is a self-limited, benign process. The course is quite variable, with the skin findings lasting anywhere from 5 days to 12 months.[134,135] Lesions heal without scarring, and, rarely, post-inflammatory hypopigmentation or hyperpigmentation is seen. Lymphadenopathy can last for several months.[130] In cases associated with hepatitis B, an anicteric viral hepatitis evolves and may not be seen until 2 weeks after cutaneous lesions are seen. Most of the time, the hepatitis is self-limited.

Treatment

No treatment is necessary in the majority of cases. In some patients, medium potency topical steroids may decrease the duration of lesions when applied once daily for 1 to 2 weeks. However, patients should be monitored closely because worsening of findings with topical steroid use has been documented.[136] In severe cases, systemic, pulsed corticosteroids may be administered.[137] Oral antihistamines or topical anti-itch lotions may diminish severe pruritus.

Prevention

There is no known way to prevent GCS.

HUMAN CYTOMEGALOVIRUS

Epidemiology

Human cytomegalovirus (HCMV) is ubiquitous around the world. The seroprevalence in the population increases with age, with 10 percent to 20 percent of children infected before they reach puberty.[138] By adulthood, the prevalence of HCMV is 40 percent to 100 percent. For unclear reasons, there is a higher prevalence in developing countries and areas of low socioeconomic status. HCMV is the most common congenital viral infection in humans with an incidence of 0.2 percent to 2.2 percent of live births in the United States.[139] Five percent to 17 percent of congenital infections exhibit neurodevelopmental sequelae.[140] Nearly all HIV-infected patients are infected with HCMV.[141] It is a significant cause of morbidity in bone marrow transplant (BMT) and solid organ transplant (SOT) patients, with 50 percent to 90 percent of patients infected.[139]

Etiology and Pathogenesis

HCMV, which corresponds to HHV-5, is a member of the Herpesviridae family,

CYTOMEGALOVIRUS AT A GLANCE

- Human herpesvirus 5.
- High prevalence in the population.
- Establishes latent infection and capable of re-activation in immunosuppressed states.
- Primary infection is mainly asymptomatic; it is the cause of severe morbidity and mortality in utero and in immunocompromised patients.
- Petechiae and blueberry muffin syndrome with congenital infection.
- Congenital infection is major cause of hearing loss.
- Infected cells are cytomegalic with intranuclear inclusions.

and the prototype of the β-Herpesviridae subfamily. The 230-kbp virion is composed of a double-stranded DNA linear genome encapsulated in an icosahedral capsid enclosed in a lipid bilayer membrane, which contains multiple membrane glycoproteins.[139] HCMV is distinguished by its salivary gland tropism, slow growth, and species specificity.

Humans are the only known reservoir for HCMV, and transmission occurs from person to person. Close contact is required as the virion is labile to heat and drying.[139] Transmission can also occur via saliva, fomites, sexual activity, blood transfusions, organ transplantation, intrauterine perinatal exposure, and breast milk.[85,142,139]

The virus disseminates throughout the body in leukocytes via the bloodstream. It can infect various organs depending on the age of the host.[140] As with other herpesviruses, HCMV establishes latency in the host after recovery from acute primary infection. HCMV remains latent in $CD34^+$ myeloid progenitor cells in bone marrow.[143] Productive infection can result in cell lysis, but organ dysfunction during symptomatic infection is a combination of infected cell dysfunction and the inflammatory response to the infection.[144]

Infection of cells results in cytomegaly and nuclear inclusions, hence the name *cytomegalovirus*. These "protozoan" cells were noted by Ribbert in 1881 in organs of a stillborn. The disease later became known as *cytomegalic inclusion disease*. In 1960, the term *cytomegalovirus* was proposed to replace salivary gland virus and salivary inclusion disease virus.[145]

Clinical Findings

CONGENITAL HUMAN CYTOMEGALOVIRUS INFECTION ***History.*** Congenital HCMV (cytomegalic inclusion disease of the newborn) occurs mostly in children of primiparous women with primary infection during pregnancy. Fifty-five percent of maternal primary HCMV infections results in intrauterine HCMV infection of the fetus, and approximately one-third of those are symptomatic.[146] Re-activation or secondary HCMV infection of a HCMV-immune woman during pregnancy rarely results in symptomatic HCMV infection for the baby.[146]

Cutaneous Lesions. Cutaneous findings in the newborn include a petechial rash secondary to thrombocytopenia, jaundice due to hepatitis and blueberry muffin lesions (Fig. 192-10) from dermal erythropoiesis. In one study, approximately 70 percent of children with symptomatic congenital HCMV infections had petechiae and jaundice.[147] Dermal erythropoiesis, also known as *thrombocytopenic purpura* or *blueberry muffin syndrome*, can also be seen with congenital rubella,[148] toxoplasmosis, and blood dyscrasias. These purpuric lesions are present at birth and evolve during the first 24 to 48 hours of life. They are papular and range from 2 to 10 mm in diameter. Lesions are initially dark blue to violaceous and fade to red or copper-brown. They regress during the first 6 weeks of life despite continued presence of the virus. Histology shows plaque-like aggregates of nucleated cells and non-nucleated erythrocytes in the reticular dermis.[149]

Related Physical Findings. Related findings include hepatosplenomegaly in virtually all newborns, microcephaly, periventricular calcifications, ventriculomegaly, encephalitis, chorioretinitis, hearing loss or neurodevelopmental sequelae, intrauterine growth retardation, and postnatal failure to thrive. Studies show that 22 percent to 65 percent of symptomatic and 6 percent to 23 percent of asymptomatic children have hearing loss after congenital HCMV infection.[150]

▲ **FIGURE 192-10** Newborn with congenital human cytomegalovirus infection: Blueberry muffin baby. (From Groark SP, Jambel RM: Violaceous papules and macules in a newborn. Dermal erythropoiesis associated with congenital cytomegalovirus infection. *Arch Dermatol* **114**:116, 1989, with permission.)

PERINATAL HUMAN CYTOMEGALOVIRUS INFECTIONS ***History.*** Perinatal infection with HCMV is very different from congenital HCMV infection, without diffuse visceral or central nervous system involvement.[146] Transmission of the virus occurs via cervical secretions, breast milk, or blood transfusions between 4 and 16 weeks of age. It is usually asymptomatic, although it may be manifested by self-limited lymphadenopathy, hepatosplenomegaly, or afebrile pneumonitis.

Cutaneous Lesions. There are usually no cutaneous findings with perinatal HCMV infection. Uncommon presentations for HCMV infection in infants and children include scleroderma, GCS,[128,151] gray pallor, hepatosplenomegaly with self-limited respiratory deterioration in preterm infants,[152] and cutaneous vasculitis.[152]

HUMAN CYTOMEGALOVIRUS INFECTION IN IMMUNOCOMPETENT ADULTS AND CHILDREN ***History.*** Although primary HCMV infection in the immunocompetent patient is usually asymptomatic, some can present with an infectious mononucleosis-like picture.[153] Approximately 10 percent of infectious mononucleosis cases are caused by HCMV. Symptoms and signs are indistinguishable from EBV-induced mononucleosis, including fever, malaise, splenomegaly, hepatitis, peripheral, and atypical lymphocytosis. Unlike EBV mononucleosis, HCMV-induced mononucleosis patients do not typically have pharyngitis and lymphadenopathy.[154] Given the lack of heterophile anti-

bodies, HCMV mononucleosis is also known as *heterophile-negative mononucleosis*. *Post-perfusion syndrome* is the term used when HCMV mononucleosis occurs between 3 to 6 weeks after exposure to blood products.[155]

Cutaneous Lesions. A few patients with HCMV mononucleosis develop a rubelliform or morbilliform eruption; if given ampicillin, 80 percent to 100 percent develop a morbilliform rash within 1 week (see eFig. 192-10.1 in on-line edition).[156] There have been reports of erythema nodosum[157] and urticaria[85] associated with acute HCMV mononucleosis.

HUMAN CYTOMEGALOVIRUS AND THE IMMUNOCOMPROMISED ***History.*** Immunocompromised patients are at risk for HCMV primary infection as well as reactivation resulting in persistent viremia and disseminated systemic disease.[158] Immunosuppressive agents such as azathioprine and cyclophosphamide alone can re-activate HCMV disease, as can systemic corticosteroids in conjunction with other immunosuppressive agents.

SOLID ORGAN TRANSPLANT RECIPIENTS. SOT recipients not infected with HCMV receive an organ from an HCMV-positive individual are at highest risk of developing HCMV disease post-transplantation. Other risk factors include therapy with anti–T-cell antibody (OKT3)[159] and those who undergo HHV-6 seroconversion.[160] Initial infection of the transplanted organ is followed by pneumonitis, enteritis, hepatitis, retinitis, and central nervous system disease.[161]

BONE MARROW TRANSPLANT PATIENTS. The risk of HCMV disease in BMT patients is lower with the use of seronegative donors and use of leukocyte-depleted blood products.[162] Risk factors for re-activation include a seropositive recipient, graft-versus-host disease (GVHD), and T-cell depletion of allograft. Pneumonitis has a 60 percent to 80 percent mortality without treatment and 50 percent mortality with antiviral treatment and cytomegalovirus immune globulin.

HUMAN IMMUNODEFICIENCY VIRUS–INFECTED PATIENTS. HCMV retinitis was seen in up to 25 percent of HIV-infected patients before the use of highly active antiretroviral therapy (HAART).[163] Now, immune recovery vitreitis with posterior segment inflammation is seen as CD4 counts recover after initiation of HAART.[164] Encephalopathy, peripheral polyradiculopathy, pneumonitis,[161] and colitis[165] may occur.

▲ **FIGURE 192-11** Infant with acquired immunodeficiency syndrome and diaper dermatitis–like disseminated human cytomegalovirus. (From Thiboutot DM et al: Cytomegalovirus diaper dermatitis. *Arch Dermatol* **127**:396,1991, with permission.)

Cutaneous Lesions. Cutaneous manifestations of HCMV disease in immunocompromised patients are rare compared with involvement of other organs. Perianal and rectal ulceration are most common (Fig. 192-11).[166] Also seen are indurated hyperpigmented nodules or plaques,[167] papular and purpuric eruptions,[166] vesiculobullous lesions,[168] purpura, petechiae,[169] indurated plaques, and nodules (see eFig. 192-11.1 in on-line edition). Verrucous and necrotic nodules have been reported in HIV-infected patients.[158] Some of these cutaneous manifestations may be caused by infection of the endothelium of cutaneous blood vessels.[170]

Laboratory Tests

The gold standard for diagnosis of HCMV infection is viral culture from blood using human fibroblasts. Infection is determined by cytopathic effect. However, it takes days to several weeks to see the cytopathic effect in culture. The diagnosis of congenital HCMV infection can be made by detection of virus in urine or saliva via culture or PCR (Fig. 192-12).[172]

The characteristic histologic feature of cytomegalovirus (CMV) infection is cytomegalic cells with nuclear inclusions (Fig. 192-13). In the skin, enlarged endothelial cells with large intranuclear inclusions and a clear halo are seen in small dermal vessels.[173] Histologic diagnosis is specific but sensitivity is low.[174]

Various fast and reliable methods for detection of HCMV antigens and nucleic acids in cells and tissue are available. These include HCMV antigenemia assay (detects pp65 in peripheral blood neutrophils), hybrid capture assay (detects HCMV DNA in leukocytes), and quantitative and qualitative PCR.[119]

In immunocompetent individuals, IgM is usually positive during primary infection. The reported sensitivity of commercially available ELISA for HCMV IgM varies. Rheumatoid factor and EBV-IgM may yield false-positive results.[175] IgG may be negative during active infection, but subsequent fourfold rise in IgG titer is indicative of infection.

The diagnosis of invasive CMV disease can be challenging because the presence of the virus does not mean causality given that the virus establishes latency after primary infection.

Differential Diagnosis (Boxes 192-9 and 192-10)

Complications

Possible complications of postnatal HCMV infection include interstitial pneumonia, hemolytic anemia, splenic infarction, thrombocytopenia and hemolytic anemia, hepatitis, Guillain-Barré syndrome, meningoencephalitis, myocarditis, arthritis, and gastrointestinal/genitourinary syndromes (i.e., colitis, esophagitis, cervicitis, and urethral syndromes).[140,146]

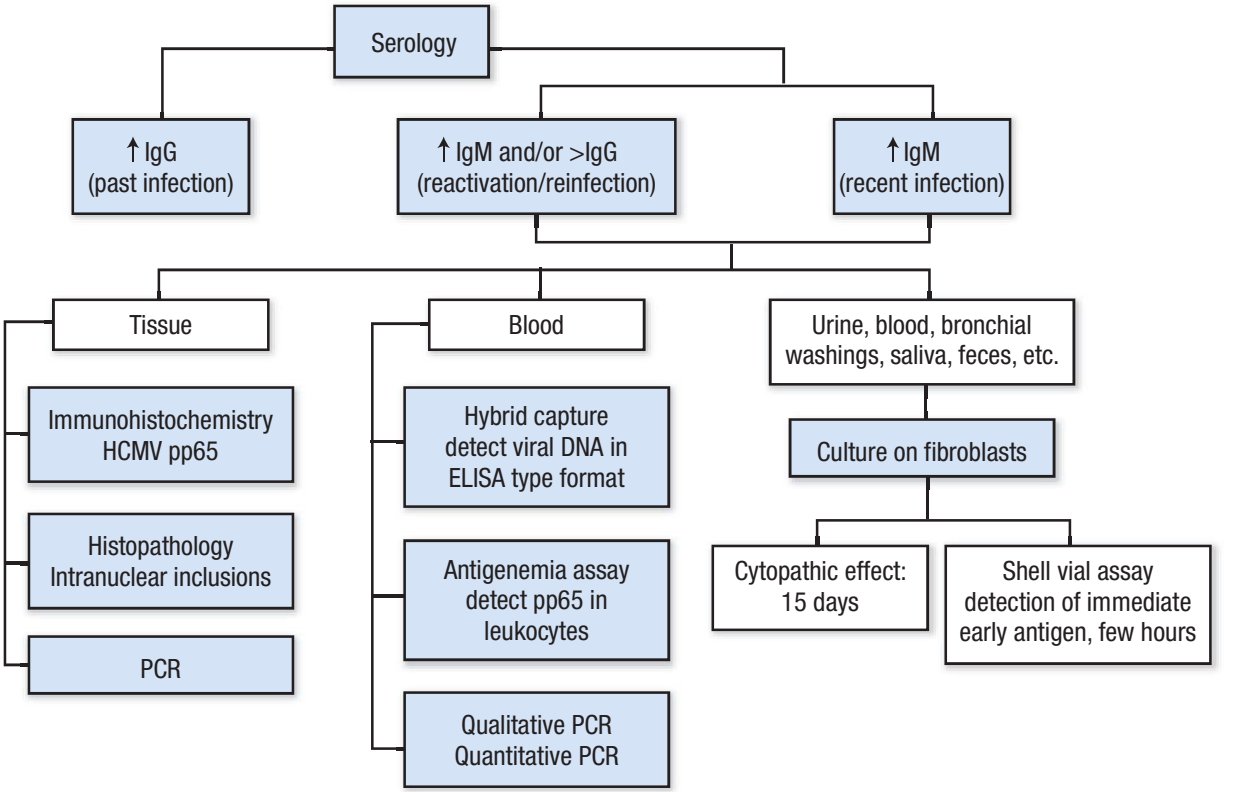
Prognosis and Clinical Course

HCMV disease in immunocompetent individuals is usually self-limited. In immunocompromised patients with systemic HCMV disease, the prognosis is poor and mortality 85 percent.[176]

Treatment

HCMV infection in immunocompetent hosts is usually asymptomatic or self-limited, not requiring treatment with antiviral drugs. Ganciclovir, valacyclovir, foscarnet, and cidofovir have been approved for systemic treatment of HCMV disease.[177] HAART is effective in suppressing HCMV viremia and preventing CMV retinitis in acquired immunodeficiency syndrome patients without end-organ disease.[178] Ganciclovir and valacyclovir are also used for HCMV prophylaxis.[40,177]

None of these drugs is recommended for treatment of symptomatic congenital HCMV infection.



▲ **FIGURE 192-12** Algorithm demonstrating the various methods for diagnosis of active human cytomegalovirus (HCMV) infection. ELISA = enzyme-linked immunosorbent assay; Ig = immunoglobulin; PCR = polymerase chain reaction.

Prevention

Prevention of HCMV infection in transplanted patients can be achieved with use of blood and tissues from HCMV-negative donors.[162] Preemptive (at time of high risk for disease but before symptoms) or prophylactic treatment can be used for immunocompromised individuals at risk of infection from blood transfusions or organ transplantation with ganciclovir.[146] Risk factors evaluated for preemptive therapy include CMV viremia and GVHD. The use of prophylactic versus preemptive therapy remains controversial.[179,180]

HUMAN HERPESVIRUS 6

Epidemiology

HHV-6 has been identified as a causative agent for exanthem subitum (ES), also known as *roseola infantum* and *sixth disease*.[181] ES is usually seen in children ages 6 months to 4 years.[182–184] The seroprevalence of HHV-6 in the adult population is greater than 95 percent.[185] Seroprevalence is high in the first few weeks of life and subsequently declines as maternal antibodies wane. It rises again by 1 year of age, with its peak between 3 to 5 years of age, and declines with advancing age.[184,186–188] There is a discrepancy between the seropreva-

lence of HHV-6 and the incidence of ES, mainly thought to be due to the varied clinical manifestations of HHV-6 infection and sub-clinical HHV-6 infection.[189] Primary HHV-6 infection in children can result in a sub-clinical infection or an acute febrile illness without cutaneous manifestations.[190,191]

There is seasonal variation of HHV-6 infection with highest incidence in spring; summer and fall epidemics have also been reported.[85]

Etiology and Pathogenesis

HHV-6 is a member of the β-Herpesviridae subfamily. There are two distinct variants by restriction enzyme analysis, HHV-6a and -6b.[192] They are different in their immunologic, biologic,[193] and genetic[192] characteristics. HHV-6b causes ES, but it is unclear what diseases, if any, are caused by HHV-6a.[194]

The cellular receptor for HHV-6 is CD46.[195] The mode of transmission is proposed to be via nasopharyngeal viral shedding from healthy individuals.[196] Airborne transmission is likely via saliva.[197] HHV-6 has been isolated from the saliva of healthy individuals[182,184] and viral shedding is intermittent, not associated with changes in antibody titers.[184] HHV-6 DNA is found in the cervix of infected women,[198] raising the question of possible perinatal infection, although children of mothers with positive swabs do not acquire early HHV-6 infection. HHV-6 DNA has also been found in fetal tissue from spontaneous abortions.[199,200] HHV-6 is not transmitted through breast milk.[85] Transmission in transplant patients can occur via the grafted organ.[201,202] The incubation period for HHV-6 infection is 5 to 15 days, with an average of 10 days. Viremia in immunocompetent children lasts 3 to 4 days in ES, whereas viremia from HHV-6 re-activation in allogeneic BMT patients lasts weeks.[203]

HHV-6 replicates in salivary glands,[204] where it can establish a persistent infection.[185] It is tropic for $CD4^+$ T lymphocytes in vitro[205,206] and establishes latency in human peripheral blood monocytes/macrophages[207] and early bone marrow progenitors.[208] HHV-6 genome is able to integrate into the host cell DNA at the ends of chromosomes 1, 17, and 22.[185]

HHV-6 can re-activate from latency in immunosuppressed individuals.[85,201,209] A synergistic effect on disease of HHV-6 and CMV has been described in renal transplant recipients.[210,211] HIV and HHV-6 also appear to be synergistic.[146] The clinical importance of this finding remains to be elucidated. Unlike in transplant patients, there does not seem to be one specific clinical syndrome of HHV-6 infection in HIV-infected patients.[185]

HUMAN HERPESVIRUS 6 AT A GLANCE

- Causes exanthema subitum (roseola infantum, sixth disease).
- Febrile seizures often without rash in children.
- High seroprevalence in general population by 1 year of age.
- Re-activation in immunocompromised individuals is cause of morbidity.

Clinical Findings

HISTORY Primary infection with HHV-6 results in an acute febrile illness typically in children 6 months to 1 year of age.[185] The fever lasts approximately 3 to 7 days[185] and can be followed by the characteristic rash of roseola in a minority of children.[191,212,213]

HHV-6 infection is seen in 40 percent to 50 percent of transplant recipients (BMT more than SOT) and peaks at 2 to 4 weeks post-transplantation. Approximately one-half of these infections result in symptomatic disease with bone marrow suppression.[214]

CUTANEOUS LESIONS ***Exanthem Subitum.*** Palpebral edema can be evident from the first to third day of fever, resulting in a "sleepy" appearance, and resolves after a day of the exanthema.[215] Erythematous papules on the soft palate (Nagayama spots) may precede the viral exanthema.[215] The exanthem is seen from 1 day before to 1 to 2 days after the fever fades and lasts for 3 to 5 days.[215] It is characterized by rose red macules or papules 2 to 5 mm in diameter, surrounded by a white halo. These are distributed mainly on the neck and trunk and sometimes on the face and proximal extremities (Fig. 192-14).[140] Desquamation is not usually seen.

Transplant Recipients. A rash similar to acute GVHD has been described in pediatric patients undergoing BMT who have HHV-6 re-activation.[216,217] Fever and/or rash are the most common manifestations of HHV-6 infections in SOT recipients.[185]

Human Immunodeficiency Virus Patients. HHV-6 can be an opportunistic pathogen in HIV patients, causing encephalitis and pneumonitis in some cases.[185] But most case reports do not show one consistent clinical syndrome in HIV patients.[185]

▲ **FIGURE 192-14** **A,B.** Exanthem subitum in an infant showing truncal pink macules and some papules that appeared 1 day after defervescence.

Rosai-Dorfman Disease. (See Chap. 149) HHV-6 genome has been detected in tissue from patients with sinus histiocytosis with massive lymphadenopathy or Rosai-Dorfman disease,[218] and immunohistochemical studies suggest a possible pathogenic involvement.[219]

RELATED PHYSICAL FINDINGS Patients with ES may have high fever, malaise, inflamed tympanic membranes, conjunctival injection, gastrointestinal and respiratory tract symptoms, cervical lymphadenopathy, and bulging fontanelle.[215,220]

A mononucleosis-like infection, which is EBV- and CMV-negative, has been attributed to HHV-6 in children and adults.[140]

Laboratory Tests

Although laboratory results may be variable in HHV-6 primary infection, one can see leukopenia (between 3000 to 6000 cells/mm^3) with an increased percentage of lymphocytes between days 3 and 6 of the illness. White blood cell count elevation can be seen at the beginning of the febrile phase.

HHV-6 infection is usually benign and self-limited; however, in atypical cases, serologic studies may be valuable. This can be done by ELISA or by indirect immunofluorescence. Anti–HHV-6 IgM antibodies are a marker of recent infection or re-activation, but 5 percent of adults may be IgM seropositive at any time. IgM develops after 5 to 7 days of infection, peaks at 2 to 3 weeks, and disappears in 2 months. IgM alone is not reliable.[221] A fourfold IgG increase between acute and convalescent sera IgG indicates active infection.

Laboratory tests vary in their ability to distinguish latent virus from actively replicating virus. PCR detection of HHV-6 DNA in cell-free serum, plasma, or CSF indicates active replication, whereas a positive PCR from cellular material does not indicate active replication because the virus can be found latent in cells. Viral culture is not used routinely because it is technically difficult and may take more than 1 week. A combination of a positive serum IgM with positive PCR of whole blood DNA in patients older than 3 months of age has excellent specificity and sensitivity, and positive and negative predictive value for primary infection.[190,222] Although not routinely available, quantitative PCR allows fast, sensitive, and absolute quantitation of viral load, making it a method of choice.

Complications

Febrile seizures are thought to occur in 10 percent of children with primary HHV-6 infection.[185] Rarely, encephalitis has been reported in children with fatal or severe sequelae such as hemiparesis.[190] Although usually a benign infection, rare complications include hepatitis, hemophagocytic syndrome, pneumonitis, and thrombocytopenia.[185,189] Hemophagocytic syndrome has been reported on re-activation of HHV-6 in an immunocompetent adult.[223]

HHV-6 infection or re-activation in the immunocompromised can also result in hepatitis,[202] pneumonitis,[224,225] bone marrow suppression,[226,227] and graft dysfunction or rejection.[211] Re-activation of HHV-6 in the immunocompromised host can result in encephalitis and/or encephalopathy.[185] There have been reports of fulminant multifocal demyelinating disease in both immunocompetent and immunocompromised patients. The contribution of HHV-6 infection to progressive multifocal leukoencephalopathy or multiple sclerosis is being studied.[185]

Prognosis and Clinical Course

ES is benign and self-limiting. Treatment may be necessary for atypical cases with complications and in immunosuppressed patients. Primary infection can be fatal in the immunocompromised host.

Treatment

There are no controlled clinical trials, and no compounds have been formally approved for treatment of HHV-6 infection. The same drugs used for HCMV treatment and prophylaxis have been used for HHV-6. The activities of various antiviral compounds against HHV-6 have been tested in vitro.[228,229] Several case reports support the clinical effectiveness of ganciclovir in HHV-6 treatment and prophylaxis.[185] Foscarnet and cidofovir might also prove to be useful.[185] New antiherpesvirus drugs are being developed, although most are not active against HHV-6.[185] Further studies are needed before treatment and prophylaxis can be recommended.

Prevention

Prophylaxis with ganciclovir may prevent HHV-6 re-activation in BMT and stem cell transplant recipients,[230] but low-dose prophylaxis may facilitate the development of resistance. Preemptive therapy (treatment after systemic detection of virus but before clinical symptoms of disease) has been proposed instead.[185]

HUMAN HERPESVIRUS 7 AT A GLANCE

- Causes a small subset of cases of exanthem subitum.
- Primary infection typically occurs later in life than human herpesvirus 6 infection.

HUMAN HERPESVIRUS 7

Epidemiology

In seroconversion studies, 10 percent of ES cases are caused by HHV-7.[231] Primary infection occurs during childhood, but later than[232] and at a slower rate than infection with HHV-6[233]; both viruses are ubiquitous in adulthood. HHV-7 can be isolated from saliva samples of healthy seropositive adults.[234]

Etiology and Pathogenesis

HHV-7 is a member of the β-Herpesviridae family. It has significant homology to HHV-6; however, it is serologically and biologically distinct. It was initially isolated from CD4$^+$ T lymphocytes from a healthy adult.[235] CD4 has been identified as the cellular receptor for HHV-7.[236]

HHV-7 establishes persistent infection in salivary glands,[237] and transmission might be through saliva.[189] Latent virus can be activated in vitro from peripheral blood mononuclear cells[238] and its DNA can be found in CD4$^+$ T cells. Similar to many other herpesviruses,[239,240] HHV-7 can downregulate expression of CD4[241] and major histocompatibility complex class I,[242] which may play a role in establishment of latency or pathogenesis. Re-activation of HHV-7 occurs more often than re-activation of HHV-6.[233]

Clinical Findings

EXANTHEM SUBITUM HHV-7 causes a small subset of ES cases. When HHV-7 is associated, ES tends to occur later in life than when HHV-6 is associated.[190] The rash associated with HHV-7 is

lighter in color and occurs later in the course of the disease than HHV-6–associated ES.[243]

PITYRIASIS ROSEA (See Chap. 41) HHV-7 DNA has been isolated from skin biopsy specimens, peripheral blood mononuclear cell, and plasma of patients with pityriasis rosea and not controls.[244] However, these findings have not been confirmed by other studies.[245–247] It is possible that the inflammatory milieu in pityriasis rosea activates HHV-7 and HHV-6 within the lesions, but there is no evidence for causality.

LICHEN PLANUS HHV-7 DNA and virion-like structures have been found in lesional lichen planus skin samples compared to non-lesional skin and psoriatic skin samples.[248] Although suggestive, further studies are needed to establish a causal relationship.

HHV-7 has also been found to be the associated with febrile seizures in children.[249]

Laboratory Tests

There is limited cross-reactivity between HHV-7 and HHV-6 in serologic studies.[250] Due to high prevalence, a single positive IgG is not sufficient to establish a diagnosis. Culture from peripheral blood mononuclear cells takes 1 to 3 weeks, and it is not widely available. PCR is more widely available and is useful for timely diagnosis. Diagnosis of active infection by PCR can only be made from acellular material such as CSF, serum, or plasma, because the virus is latent in peripheral blood mononuclear cells and tissue. Immunohistochemical studies for viral antigens in biopsy specimens can be performed.[251]

Differential Diagnosis (Box 192-11)

Complications

Complications of HHV-7–associated ES include acute hemiplegia and febrile seizures with CSF findings consistent with encephalitis[252] and hepatitis.

Prognosis and Clinical Course

Exanthem subitum is a self-limiting disease, which does not require specific antiviral treatment. Disease in immunocompromised can be more serious and require treatment.

Box 192-11

Differential Diagnosis for Human Herpesvirus-6– and Human Herpesvirus-7–Associated Exanthem Subitum

Most Likely
- Human herpesvirus–associated exanthemsum subitum
- Drug hypersensitivity reaction
- Enterovirus (including coxsackie, echovirus)

Consider
- Rubella (German measles)
- Measles/rubeola
- Adenovirus
- Epstein-Barr virus
- Fifth disease (erythema infectiosum, parvovirus)

Always Rule Out
- Scarlet fever
- Kawasaki disease

Treatment

Treatment for HHV-7 has not been evaluated in clinical trials but could be guided by treatment recommendations for HHV-6.

ENTEROVIRUSES

Human enteroviruses may cause a variety of exanthems and clinical syndromes. They are small, single-stranded RNA picornaviruses and include echovirus, coxsackievirus A and B, enterovirus, and poliovirus.[253] Most enteroviral infections are benign. However, non-polio enteroviruses are the most common cause of aseptic (viral) meningitis.[254] Enteroviruses can also cause life-threatening infections with encephalitis, myocarditis, and sepsis.[254] Two distinct enteroviral exanthems include hand-foot-mouth disease (HFMD) and herpangina, which are discussed in the sections Hand-Foot-Mouth Disease and Herpangina. Enteroviral infections are seen throughout the year, but many epidemics occur in the summer and fall. The viruses are primarily spread via the fecal-oral route.

The exanthems seen with enteroviruses are often non-specific and not very dramatic, with small pink macules and papules that resolve in a few days. Petechiae and purpura are frequently present (Fig. 192-15A,B). When a petechial rash due to an enterovirus accompanies high fever and meningeal signs and symptoms, the clinical picture may mimic meningococcemia.

Hand-Foot-Mouth Disease

EPIDEMIOLOGY HFMD is a disease with worldwide distribution that is usually self-limited. There is a slight male predominance. Children less then 10 years of age are most frequently affected and infected adults rarely show signs of infection. Similar to exanthems caused by other enteroviruses, HFMD occurs more during summer and fall in temperate climates and throughout the year in the tropics.[171,255–261] Outbreaks may be sporadic or in epidemics. The largest recorded epidemic was in Taiwan in 1998. This epidemic affected over 120,000 people and caused 78 deaths.[262]

Transmission is via fecal-oral route and, less commonly, respiratory inhalation. There is a high transmission rate among household contacts as has been documented with studies of epidem-

▲ **FIGURE 192-15** **A,B.** Purpuric macules and papules in a 4-year-old girl with enteroviral infection.

HAND-FOOT-MOUTH DISEASE AT A GLANCE

- Viral exanthem seen mostly commonly in children in summer and fall.
- Erosions in the mouth and papulovesicles on the palms and soles.
- Caused by enteroviruses including coxsackievirus A16 and enterovirus 71.
- Self-resolving without serious sequelae in the majority of cases but may have serious complications when caused by enterovirus 71.

ics.[263] Once inhaled or ingested, virus replication ensues in the oropharynx and/or gastrointestinal tract with subsequent viremia. The incubation period of HFMD is believed to be short, lasting 3 to 6 days, with viral shedding lasting up to 5 weeks.[263]

ETIOLOGY AND PATHOGENESIS HFMD is caused by a number of non-polio enteroviruses, including coxsackieviruses A5, A7, A9, A10, A16, B1, B2, B3, B5, echoviruses, and other enteroviruses. The most common causes are coxsackie A16 and enterovirus 71. Enteroviruses belong to the Picornaviridae family, which are single-stranded RNA viruses.

CLINICAL FINDINGS ***History.*** After an incubation phase of 3 to 6 days, affected individuals may complain of a low-grade fever, malaise, abdominal pain, and upper respiratory tract symptoms.

Cutaneous Lesions. Nearly all cases of HFMD have painful oral lesions. These are generally few in number and are found on the tongue (Figs. 192-16A and 192-17A), buccal mucosa, hard palate, and, less frequently, the oropharynx. The lesions start as bright pink macules and papules that progress to vesicles with surrounding erythema. These quickly erode and form yellow to gray erosions surrounded by an erythematous halo. The time between vesicle and erosion is short, and most patients have erosions by the time they visit their physician.

Cutaneous peripheral lesions are present in two-thirds of patients and appear soon after the oral lesions.[264] The lesions are most common on the palms, soles (see Figs. 192-16B,C and 192-17B,C), sides of hands and feet, buttocks (see eFig. 192-17.1 in on-line edition) and, occasionally, external genitalia, and on the face and legs. They evolve similarly to the oral lesions, starting as red macules that become clear oval, elliptical (football-shaped), or triangular vesicles with surrounding red halos (see Figs. 192-16 and 192-17) The number of lesions ranges from few to numerous. After crusting, they heal in 7 to 10 days.

Related Physical Findings. HFMD usually begins with a non-specific prodrome, including low-grade fever [38°C to 39°C (100.4°F to 102.2°F)] that lasts 1 to 2 days, malaise, and, occasionally, abdominal pain or upper respiratory tract symptoms. Sore throat or sore mouth is common and may lead to poor oral intake and dehydration. Cervical and submandibular lymphadenopathy may be present.

LABORATORY TESTS No laboratory tests are indicated. If an epidemic is suspected, stool and throat cultures may be helpful in determining the strain and, therefore, possible complications.

SPECIAL TESTS Historically, enteroviral infection was verified by viral culture, which lacked sensitivity, and suckling mouse inoculation, which detected neutralizing antibodies. Recently, PCR has been found to be very effective in detection and identification of enterovirus serotypes. PCR may be very useful if it becomes widely available.

▲ **FIGURE 192-16** **A.** Toddler with vesicles and surrounding erythema on the tongue from hand-foot-mouth disease. **B,C.** Elliptical, "football-shaped" vesicles with halo of erythema on the palms and soles in the same patient.

▲ **FIGURE 192-17** **A.** Hand-foot-mouth disease is clinically identical in adults. Shallow ulcerations on the tongue that are part of the oral lesions of hand-foot-mouth disease caused by coxsackievirus A16 infection. **B,C.** Vesicular lesions on the fingers and feet.

DIFFERENTIAL DIAGNOSIS (Box 192-12)

COMPLICATIONS Patients rarely experience complications from HFMD. One rare complication, called *eczema coxsackium*, occurs in individuals with eczema. These patients develop disseminated cutaneous viral infection similar to that seen in eczema herpeticum.[265] The most common serious complication associated with HFMD is aseptic meningitis. Aseptic meningitis is rarely life-threatening, and patients do not develop permanent sequelae. Epidemics in Taiwan of enterovirus 71 have resulted in severe disease with encephalitis, encephalomyelitis, polio-like syndromes, myocarditis, pulmonary edema, pulmonary hemorrhage, and death.[259,260,266] Serious complications are less frequent in cases associated with coxsackievirus A16 than with enterovirus 71.[259]

Box 192-12

Differential Diagnosis of Hand-Foot-Mouth Disease

Most Likely
- Herpangina

Consider
- Varicella
- Aphthous stomatitis
- Drug eruption
- Erythema multiforme

Always Rule Out
- Herpes gingivostomatitis

PROGNOSIS AND CLINICAL COURSE HFMD is usually a benign, self-limited illness that resolves within 7 to 10 days. Occasionally, cases associated with more prolonged fever, systemic symptoms, diarrhea, and joint pains have been reported.[267]

PREVENTION During epidemics, public health measures should be instituted to decrease morbidity. Measures such as universal precautions, dissuading attendance at childcare centers or kindergarten, and isolating affected individuals have been suggested.[268]

Herpangina

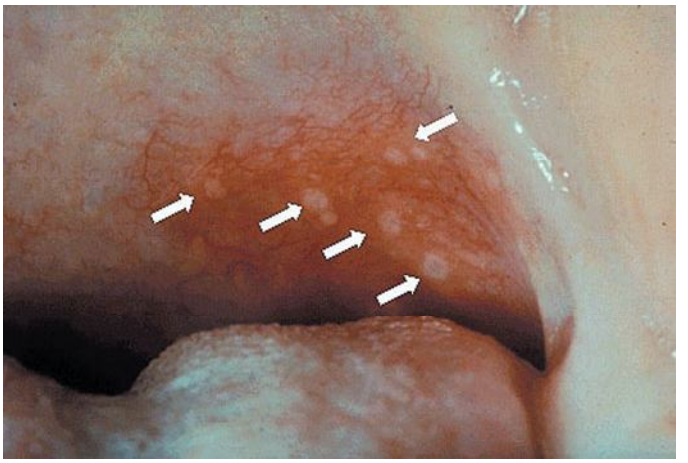
EPIDEMIOLOGY Herpangina is a self-limited enanthem seen in children around the world. There is no ethnic or sexual predilection. Children are affected most commonly between 3 and 10 years of age. Most outbreaks in temperate climates are seen in the summer and fall. Herpangina is caused by multiple types of coxsackie viruses (most frequently sub-types A8, A10, and A16), echoviruses, and enteroviruses.[269] Transmission is via fecal-oral, respiratory inhalation, or oral-oral spread in the majority of cases.

ETIOLOGY AND PATHOGENESIS Enteroviruses belong to the family of Picornaviridae, which are single-stranded RNA viruses. Herpangina may occur sporadically or in epidemics. Epidemics have been traced to coxsackievirus A types 1, 2, 3, 4, 5, 6, 8, 10, 22, and B1 as well as echovirus types 16 and 25 and enterovirus 71. Replication ensues in the pharynx and gastrointestinal tract, with subsequent viremia. The incubation period is about 4 days,[270] and viral shedding may continue for days to months.

CLINICAL FINDINGS ***History.*** The presenting signs and symptoms of herpangina are sudden onset of fever, chills, sore throat, headache, abdominal pain, vomiting, and body aches. The fever ranges from 37.5°C to 41.5°C (99.5°F to

HERPANGINA AT A GLANCE

- A viral enanthem seen in small children in summer and fall in temperate climates.
- Papulovesicles on the tonsillar pillars, uvula, and soft palate that progress to erosions.
- Caused by enteroviruses, including coxsackievirus and echoviruses.
- Self-resolving over several days without serious sequelae in the majority of cases.



▲ **FIGURE 192-18** Typical appearance of the oropharyngeal lesions of herpangina (*arrows*). Acute, multiple papulovesicular lesions quickly progress to form shallow ulcerations with brisk marginal erythema.

106.7°F). There may be a prodrome of listlessness, irritability, and anorexia a few hours before the onset of fever.

Cutaneous Lesions. Lesions are 1 to 2 mm, yellow-white papulovesicles with surrounding erythema that progress to erosions (Fig. 192-18). They are seen most frequently on the anterior pillars of the tonsillar fauces (or tonsillar pillars), followed by the uvula, tonsils and soft palate. They are less frequently seen on the tongue and buccal mucosa. The number of lesions may vary from very few to numerous. Resolution occurs over 5 to 10 days.

LABORATORY TESTS No laboratory tests are indicated.

SPECIAL TESTS Historically, enteroviral infection has been verified by viral culture that lacked sensitivity and suckling mouse inoculation looking for neutralizing antibodies. Recently, PCR has been found to be very effective in detection and identification of enterovirus serotypes. PCR could be very useful if it were to become widely available.[271]

DIFFERENTIAL DIAGNOSIS (Box 192-13)

COMPLICATIONS Occasionally, patients suffer febrile seizures associated with the fever that is present in the first few days of infection. There have been rare case reports of serious complications, including myocarditis, encephalitis, meningitis, and pulmonary edema.

TREATMENT The main goal of treatment is pain management. Viscous lidocaine, antihistamine mouthwashes, and allopurinol mouthwash may be of benefit in relieving symptoms.

PROGNOSIS AND CLINICAL COURSE The fever rarely lasts longer then 4 days, whereas oral lesions spontaneously resolve several days after their eruption. The prognosis is good, and the course is most often benign.

PREVENTION Once infected, a person has lifelong immunity to that particular strain. Recurrence of herpangina may occur but would be from one of the other strains.

ROTAVIRUS

Epidemiology

Rotavirus is a major cause of diarrheal illness in children under 2 years of age.[272] Rotaviral infections occur worldwide, affecting children in both developing and developed countries.[273] In the United States, the peak of rotaviral infections occurs in the winter. Typically, rotavirus appears in the southwestern United States in November and reaches the Northeast by March.

Rotavirus is transmitted primarily by the fecal-oral route.[274] It has also been postulated that transmission via respiratory droplets and contaminated water is possible. The virus may survive on hands for at least 4 hours, and, in addition, 10 infectious rotaviral particles may be all that is needed to transmit the infection. Once transmitted, viral shedding may commence as early as 48 hours before the development of symptoms and continue for 4 to 7 days thereafter. Asymptomatic shedding is also common.[275] Because of frequent diaper changing and contact between infected toddlers, day care centers often have outbreaks.[274] The fact that soap and water alone are relatively ineffective in removing virus from contaminated hands allows easier transmissibility.[276]

Children between the ages of 6 months and 2 years are most often affected. There is a male predominance that is poorly understood.[277] Adults can also become infected; they are often household members of infected children.[278]

- Herpetic gingivostomatitis

ROTAVIRUS AT A GLANCE

- Occurs worldwide; peak occurs in the winter.
- Transmission occurs primarily by fecal-oral route; major cause of diarrhea in children under age 2 years of age.
- Belongs to the Reovirus family.
- Skin manifestations may include exanthems, Gianotti-Crosti syndrome, and acute hemorrhagic edema of infancy.

Etiology and Pathogenesis

Rotaviruses belong to the family Reoviridae and the genus *Rotavirus*.[279]

The pathogenesis of skin manifestations associated with rotavirus is unknown, largely because there have been few reports of associated skin findings with varied morphologies.

Clinical Findings

HISTORY After an incubation period of 1 to 3 days, symptoms of rotaviral infection commence.[274] Typically, fever and vomiting are followed by non-bloody diarrhea (often 10 to 12 episodes per day), which occasionally results in moderate to severe dehydration.[277,282,283] Respira-

tory symptoms and otitis media may be present. It has been noted that rotavirus is associated with respiratory symptoms and otitis media in up to 50 percent of cases.[274] In general, illness is less severe in adults.[278] Vomiting and diarrhea are usually present; however, fever and respiratory symptoms are absent.[278]

CUTANEOUS LESIONS Rotaviral infections are not associated with specific dermatologic manifestations; however, several clinical pictures have been reported. A generalized exanthem possibly related to rotavirus has been described.[284,285] Pink-red macules and papules appear 3 to 6 days after the onset of the diarrhea and as defervescence occurs. The asymptomatic rash progresses from the trunk to the extremities and, finally, to the face within hours. The exanthem then fades over approximately 3 days in the same order as it appeared.

Other dermatologic manifestations have been described. GCS occurs in response to a number of different viruses. Two toddlers had GCS with diarrhea 4 and 7 days before the eruption, and rotavirus was isolated from the stool cultures.[286] A third case of Gianotti-Crosti was reported without gastrointestinal symptoms.[287] Rotavirus was isolated from the stool culture, and all other suspected viruses yielded negative results. A child with acute hemorrhagic edema of infancy was found to be associated with a rotaviral infection.[287]

RELATED PHYSICAL FINDINGS It has been noted that rotavirus is associated with respiratory symptoms and otitis media in up to 50 percent of cases.[274]

Laboratory Tests

Laboratory values may be unremarkable; however, it is not unusual to find a mild hyperchloremic metabolic acidosis.[288] Occasionally, liver transaminases may be mildly elevated. Hypernatremia, elevated albumin, and elevated uric acid, when detected, are likely the result of dehydration. Fecal leukocytes may be detected; however, they are usually not significant.[288]

Special Tests

Differential Diagnosis

The diagnosis of rotaviral infection is usually made on clinical grounds in conjunction with identification of rotavirus as the etiologic agent. In general, rotaviral infection is clinically indistinguishable from other enteric viruses; however, diarrhea associated with rotavirus may be more severe and more frequently involve vomiting and fever.[274] Diagnoses that may be considered include enterovirus, ES, adenovirus, and rubella.

Complications

Rotaviral infections may lead to persistent gastrointestinal symptoms, including diarrhea, gastroparesis, and lactose deficiency. Immunosuppressed patients and malnourished patients in developing countries are most at risk for protracted disease.[293] In addition, there have been many associated conditions/syndromes reported, including seizures,[294] encephalopathy,[295] aseptic meningitis,[296] hepatic abscess,[297] acute myositis,[298] pneumonia,[299] sudden infant death syndrome,[300] Reye syndrome,[301] biliary atresia,[302] and Kawasaki disease.[303] It has also been suggested that rotaviruses have been associated with necrotizing enterocolitis[304] and intussusception.[305]

Prognosis and Clinical Course

Rotaviral infection in the United States resolves, on average, within 5 to 7 days, without any sequelae.[282,288] In developing countries, where poverty and malnutrition are common, children are most likely to experience chronic symptoms.[293] Death from rotaviral infection is not uncommon in developing countries due to dehydration.[280]

Treatment

Because there are no specific antiviral agents directed against the rotavirus, therapy is aimed at correcting dehydration and electrolyte imbalance. Oral rehydration is necessary. The World Health Organization recommends the oral rehydration solution, which consists of an isotonic salt solution with glucose supplementation or oral rehydration solution light, which has reduced osmolarity.[306] Intravenous fluids may be necessary if the patient is unable to rehydrate orally or if there is severe dehydration and should ideally consist of lactated Ringer or normal saline. Antibiotics are ineffective, and antimotility agents are not recommended for young children.

Prevention

Infection control is an important means of preventing rotaviral infections.[306] It is important to disinfect contaminated surfaces with quaternary ammonium compounds that contain 40 percent alcohol[274,306] or chlorhexidine gluconate in 70 percent ethanol.[274] Because of the morbidity and mortality associated with rotaviral infections in the developing and developed world, the development of a safe and effective vaccine has become a priority over the past 20 years.[307]

UNILATERAL LATERO-THORACIC EXANTHEM AT A GLANCE

- Asymmetric periflexural exanthem of childhood.
- Children 1 to 5 years of age.
- Pink papules that start in a large flexural region, become bilateral, but remain asymmetric.
- Probably viral etiology.

UNILATERAL LATEROTHORACIC EXANTHEM

Epidemiology

Unilateral laterothoracic exanthem (ULE), also known as *asymmetric periflexural exanthem of childhood,* has a seasonal variation and occurs most frequently in late winter and early spring.[308] It typically occurs in children from 1 to 5 years of age but may be seen from 8 months to 10 years. Rare cases in adults have been reported.[309] There is a slight female predominance.

Etiology and Pathogenesis

The etiology is unknown, but because of its seasonality and associated viral symptoms, a viral trigger is suspected. The distinct clinical presentation may be a manifestation of a variety of infectious agents. The pathogenesis is also unknown.

▲ **FIGURE 192-19** **A.** Asymmetric erythematous exanthem in left axilla consistent with unilateral laterothoracic exanthem. **B.** Coalescence of tiny, pink, rough papules in axilla with left axillary lymphadenopathy.

Clinical Features

HISTORY Mild upper respiratory tract, low-grade fever, or gastrointestinal tract symptoms precede the eruption in a majority of patients.

Conjunctivitis and fatigue may be present.

CUTANEOUS LESIONS The lesions are usually 1- to 2-mm pinpoint, pruritic, pink papules that begin in a large flexural region like the axillae or groin and spread centrifugally (Fig. 192-19). A variety of morphologies have been described, including macules, papules, morbilliform, annular, scarlatiniform, and annular. The initial lesion is often a pink papule with a surrounding pale halo.[308] The eruption typically becomes bilateral and more widespread, but a unilateral and asymmetric distribution remains. The eruption is often quite pruritic.

RELATED PHYSICAL FINDINGS Lymphadenopathy is seen in 70 percent of patients. This often manifests as a large (1 to 3 cm) mobile lymph node at the site where the rash starts.

Box 192-14

Differential Diagnosis of Unilateral Laterothoracic Exanthem

Most Likely
- Allergic or irritant contact dermatitis
- Scarlet fever

Consider
- Other viral exanthems

Always Rule Out
- Herpes zoster
- Atopic dermatitis

Laboratory Tests

No laboratory tests are indicated.

Differential Diagnosis (Box 192-14)

Complications

There has not been documentation of complications after ULE.

Prognosis and Clinical Course

The rash typically lasts from 2 to 6 weeks but may last as long as 2 months. Resolution is spontaneous and without scarring.

Treatment

Treatment for ULE is typically focused on controlling pruritus. This can be done with topical corticosteroids, antiitch lotions, and oral antihistamines.

Prevention

There is no known way to prevent ULE.

CHAPTER 193

Herpes Simplex

Adriana R. Marques
Stephen E. Straus

EPIDEMIOLOGY

Herpes simplex virus (HSV) infections are very common and are caused by two closely related types of HSV. Their main clinical manifestations are mucocutaneous infections, with HSV type 1 (HSV-1) being mostly associated with orofacial disease, whereas HSV type 2 (HSV-2) is usually associated with perigenital infection.

The incidence of primary infection with HSV-1, which is responsible for the vast majority of recurring labial herpes, is greatest during childhood, when 30 percent to 60 percent of children are exposed to the virus. Rates of infection with HSV-1 increase with age, and the majority of persons age 30 or older are seropositive for HSV-1.[1,2] From 20 percent to 40 percent of the population have had episodes of herpes labialis.[3] The frequency of recurrent episodes is extremely variable, and, in some studies, averages about once per year,[4] but there is evidence that the frequency and severity of recurrent HSV-1 disease decrease over time.

Acquisition of HSV-2 correlates with sexual behavior and the prevalence of the infection in the pool of one's potential sexual partners. Antibodies to HSV-2 are rare in people before the onset of intimate sexual activity and rises steadily thereafter. HSV-2 seroprevalence in the United States is 22 percent in persons 12 years of age or older.[5]

Although most patients infected with HSV-1 or HSV-2 are asymptomatic, they still can transmit the virus. Studies using DNA polymerase chain reaction (PCR) assays show that rates of detecting HSV-2 DNA in genital secretions of people who have never recognized herpes outbreaks (asymptomatic persons) are similar to the rates of shedding viral DNA in persons who have experienced symptomatic genital herpes but who are not symptomatic at the moment of testing (sub-clinical shedding).[6] It is estimated that more than 70 percent of transmission of HSV-2 is associated with asymptomatic and sub-clinical reactivation and shedding.[7] The average risk of transmission for couples discordant for genital herpes (i.e., one partner has genital herpes and the other does not) varies from 5 percent to 10 percent per year.[7,8] As with other sexually transmitted infections, the rate of acquisition of HSV-2 infection is higher for women than for men (6.8 vs. 4.4 cases per 100 person-years; relative risk, 1.55). Asymptomatic HSV-2 infection is more common among men and persons who are also seropositive for HSV-1, suggesting that prior infection with HSV-1 reduces one's likelihood of experiencing symptomatic HSV-2 infection.[9] Studies have shown that genital HSV infections significantly increase the risk for acquisition and transmission of human immunodeficiency virus (HIV).[10]

ETIOLOGY AND PATHOGENESIS

The Virus

HSV-1 and HSV-2 are members of the Herpesviridae family, a group of lipid-enveloped double-stranded DNA viruses responsible for a wide variety of common human infections. Both serotypes of HSV and the closely related varicella-zoster virus (VZV) are members of the α-Herpesviridae virus subfamily. α-Herpesviruses infect multiple cell types in culture, grow rapidly, and efficiently destroy the host cells. Infection in the natural host is characterized by lesions in the epidermis, often involving mucosal surfaces, with spread of virus to the nervous system and establishment of latent infections in neurons, from which virus periodically re-activates.

HSV-1 and HSV-2 have a high degree of genetic and antigenic homology. Both genomes are approximately the same size, are linear, and consist of two regions of unique sequence, each of which is bounded by a pair of inverted repeat elements. An analysis of herpesvirus phylogeny estimated that the two HSV types diverged from an ancestral protoherpesvirus approximately 8 million years ago.[11]

Herpesvirus replication is a carefully regulated, multi-step process. Shortly after infection, five "immediate-early" genes are transcribed. The proteins encoded by these genes stimulate the synthesis of about a dozen "early" proteins that are required for genome replication. Most current antiviral drugs interact with two of these proteins, the thymidine kinase (TK) and the viral DNA polymerase enzyme. After DNA replication, the remaining set of more than 60 "late" HSV-2 genes is expressed. They encode virion structural components and proteins needed for their proper assembly.

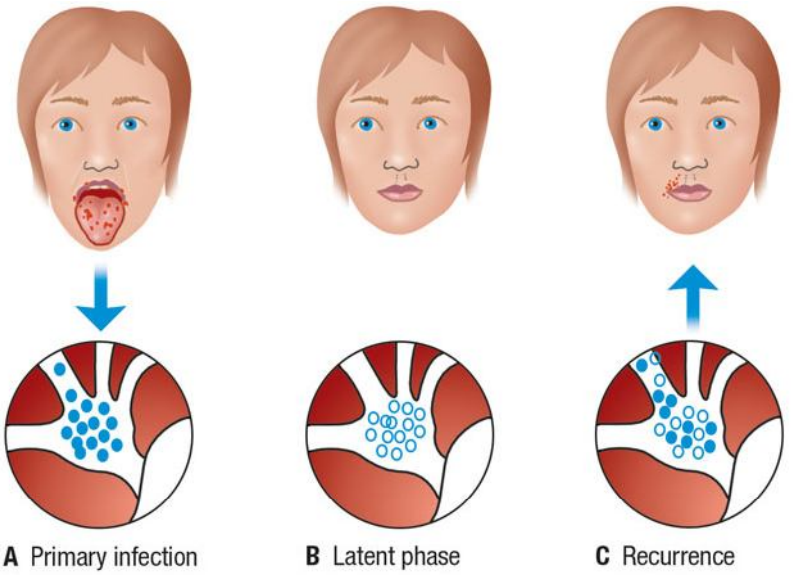
In vivo, HSV infections can be divided into three stages: acute infection,

HERPES SIMPLEX AT A GLANCE

- Herpes simplex viruses (HSVs) are common human DNA viral pathogens that intermittently re-activate. After replication in the skin or mucosa, the virus infects the local nerve endings and ascends to the ganglia where it becomes latent until re-activation.
- There are two types of HSV: HSV-1 and HSV-2. HSV-1 is mostly associated with orofacial disease, whereas HSV-2 usually causes genital infection, but both can infect oral and genital areas and cause acute and recurrent infections.
- Most of the adult population is seropositive for HSV-1, and the majority of infections are acquired in childhood. About one-fourth of adults are infected with HSV-2 in the United States. Acquisition of HSV-2 correlates with sexual behavior.
- Most primary HSV infections are asymptomatic or not recognized, but they can also cause severe disease. Most recurrences are not symptomatic (asymptomatic shedding), with most transmissions occurring by asymptomatic shedding.
- Genital herpes is the most prevalent sexually transmitted disease worldwide and is the most common cause of ulcerative genital disease, and it is an important risk factor for acquisition and transmission of human immunodeficiency virus.
- HSV can also cause diseases involving the eye, central nervous system, and neonatal infection. Cellular immunity defects are a risk factor for severe and disseminated disease.
- Diagnosis is made by viral culture, polymerase chain reaction and serology, depending on the clinical presentation.
- Treatment is with acyclovir, valacyclovir, or famciclovir. Regimens and dosages vary with the clinical setting. Resistance is rare in other than immunocompromised patients.

establishment and maintenance of the latency, and re-activation of virus. During acute infection, virus replicates at the site of inoculation on mucocutaneous surfaces, resulting in primary lesions from which virus rapidly spreads to infect sensory nerve terminals, where it travels by retrograde axonal transport to neuronal nuclei in regional sensory ganglia. In a subset of infected neurons, a latent infection is established in which viral DNA is maintained as an episome and HSV gene expression is severely restricted: of all of the viral genes, only one is abundantly transcribed during latency. In the last stage, replication re-activates with concomitant anterograde axonal transport of newly assembled virus to a peripheral site, at or near the original portal of entry (Fig. 193-1).

HSV-1 re-activates most efficiently and frequently from trigeminal ganglia, while HSV-2 re-activates primarily from sacral ganglia. The rate of re-activation of HSV appears to be influenced by the quantity of latent viral DNA in the ganglia.[12] In addition to the quantity of latent virus being a determinant of the relative rate of HSV re-activation, there are type-specific sequences within the HSV genome that appear to influence recurrence rates in particular anatomic sites.[13] In addition to viral genes, host factors strongly influence HSV re-activation. Re-activation is induced in experimentally infected animals by exposure to ultraviolet irradiation, by hyperthermia, by local trauma, and by other physiologic stressors. These model systems emulate well what occurs in similarly stressed humans.



▲ **FIGURE 193-1** Herpes labialis. **A.** With primary herpes simplex virus infection, virus replicates in the oropharyngeal epithelium and ascends peripheral sensory nerves into the trigeminal ganglion. **B.** Herpes simplex virus persists in a latent phase within the trigeminal ganglion for the life of the individual. **C.** Various stimuli initiate re-activation of latent virus, which then descends sensory nerves to the lips or perioral skin, resulting in recurrent herpes labialis.

Immune Response

Host immunity to HSV clearly influences the risk of acquiring the infection, the severity of disease, and the frequency of recurrences. The risk of severe HSV disease and the recurrence rate correlates with the level of cellular immune competence of the host. Patients with mild decreases in cellular immunity may experience only an increased number of recurrences and a slower resolution of lesions, while severely compromised patients are more likely to develop disseminated, chronic, or drug-resistant infections.

Studies of humans and mice have implicated a role for both $CD8^+$ and $CD4^+$ T lymphocyte subsets, for natural killer cells, and for inflammatory cytokines like interferon-γ in mediating protection against HSV. However, the contribution of each cell subset and cytokine in the control of HSV infection has not been clearly defined.

Patients with defects in humoral immunity have no increase in HSV disease severity, but the humoral immune response is important in reducing virus titers at the site of inoculation and in regional neural tissues during primary infection. Animals are effectively protected from disseminated and neurologic disease by passive transfer of polyclonal or monoclonal antibodies and by antibody responses elicited actively through vaccination. Moreover, the transfer of HSV-specific antibodies from the mother to the child is a key factor in protecting against neonatal herpes.

The roles of immunity in sustaining latency and in limiting re-activation of HSV are less clear. There is evidence that constant immune surveillance and engagement are required to maintain latency, mainly by HSV-specific $CD8^+$ lymphocytes and low levels of viral proteins produced in neurons.[14] Other findings implicate immunity, predominantly CD4 and CD8 lymphocytes, in defining whether virus once re-activated would spread and become clinically evident.

CLINICAL FINDINGS

The clinical manifestations of HSV infection depend on the site of infection and, as indicated in Immune Response, the immune status of the host. Primary infections with HSV, namely those that develop in persons without pre-existing immunity to either HSV-1 or HSV-2, are usually more severe, frequently with systemic signs and symptoms, and they have a higher rate of complications, than recurrent episodes.

Orofacial Infections

Herpetic gingivostomatitis (Fig. 193-2) and pharyngitis are mostly commonly associated with a primary HSV-1 infection. The symptoms of primary oral herpes may resemble those of aphthous stomatitis and include ulcerative lesions involving the hard and soft palate, tongue, and buccal mucosa, as well as neighboring facial areas. Patients with pharyngitis exhibit ulcerative and exudative lesions of the posterior pharynx that can be difficult to differentiate from streptococcal pharyngitis. Other common symptoms are fever, malaise, myalgias, pain on swallowing, irritability, and cervical adenopathy.

Re-activation of virus from these primary infections involves the perioral facial area, mainly the lips, with the outer one-third of the lower lip being the most commonly affected (Fig. 193-3). Other facial locations include the nose, chin, and cheek, and account for less than 10 percent of the cases (Fig. 193-4). Two-thirds of labial lesions involve the vermilion border, while the rest occur at the junction of the border with the skin.

▲ **FIGURE 193-2** Primary herpetic gingivostomatitis. (Used with permission from Clyde S. Crumpacker, MD.)

In patients with frequent recurrences, lesions may differ slightly in location with each episode. Immunocompetent patients tend not to experience recurrent intra-oral lesions, but can present with clusters of tiny vesicles and ulcers on the gingivae and anterior hard palate that are mildly symptomatic. Prodromal symptoms precede herpes labialis in 45 percent to 60 percent of episodes.[1] Patients experience pain, burning, or itching at the site of the subsequent eruption. Even in the immunocompetent patient, the severity of recurrent herpes labialis is extremely variable and may vary from that of prodromal symptoms alone without the subsequent development of lesions (aborted episodes) to extensive disease induced by severe local sunburn.

The progression of the classical herpes lesions has been divided according to the following stages based on their features: prodromal, erythema, and papule (the developmental stages); vesicle, ulcer, and hard crust (disease stages); followed by dry flaking and residual swelling (resolution stages). The lesions usually resolve within 5 to 15 days.

Trigger factors for oral herpes recurrences include emotional stress, illness, exposure to sun, trauma, fatigue, menses, chapped lips, and the season of the year.[15] Other well-documented triggers include exposure to ultraviolet irradiation, trigeminal nerve surgery, oral trauma, epidural administration of morphine, and abrasive, laser, and chemical facial cosmetic procedures. The exact mechanism by which these diverse factors trigger HSV re-activation is unknown.

HSV-2 causes a primary orofacial infection that is indistinguishable from that associated with HSV-1 except that it is usually in adolescents and young adults and following genital–oral contact. Moreover, HSV-2 orolabial infections are 120 times less likely to re-activate than is orolabial HSV-1 disease.

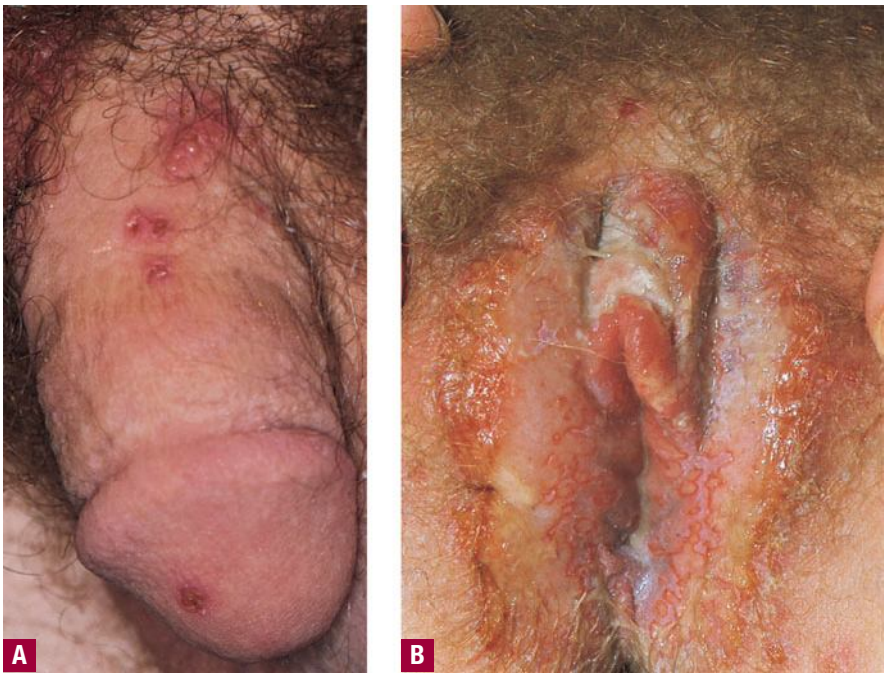
◀ **FIGURE 193-3** Herpes simplex virus infection: Recurrent herpes labialis. Grouped and confluent vesicles with an erythematous rim on the lips 24 hours after onset of symptoms.

▲ **FIGURE 193-4** Recurrent facial herpes simplex with grouped vesicles and crusting. (Used with permission from Clyde S. Crumpacker, MD.)

Genital Infection

Genital herpes is the major clinical presentation of HSV-2 infection, but it may also result from HSV-1 in 10 percent to 40 percent of the cases, primarily ones following oral–genital contact. Because of their epidemiology, acquisition of HSV-1 in a person with prior HSV-2 infection is unusual, but HSV-2 acquisition in the presence of previous HSV-1 infection is common, and infection of the genital tract with both HSV-1 and HSV-2 has been described. Patients with previously known HSV-1 genital infection who develop frequent genital herpes recurrences should be tested for HSV-2 infection.[16]

The clinical courses of acute first-episode genital herpes among patients with HSV-1 and HSV-2 infections are similar. These infections are associated with extensive genital lesions in different stages of evolution, including vesicles, pustules, and erythematous ulcers that may require 2 to 3 weeks to resolve (Fig. 193-5). In males, lesions commonly occur on the glans penis or the penile shaft; in females, lesions may involve the vulva, perineum, buttocks, vagina, or cervix. There is accompanying pain, itching, dysuria, vaginal and urethral discharge, and tender inguinal lymphadenopathy. Systemic signs and symptoms are common and include fever, headache, malaise, and myalgias. Herpetic sacral radiculomyelitis, with urinary retention, neuralgias, and constipation, can occur. HSV cervicitis occurs in more than 80 percent of women with primary infection. It can present as purulent or bloody vaginal discharge, and examination reveal areas of diffuse or focal friability and redness, extensive ulcerative lesions of the exocervix, or,



▲ **FIGURE 193-5** **A.** Primary genital herpes with vesicles. (Used with permission from Clyde S. Crumpacker, MD.) **B.** Primary herpetic vulvitis.

rarely, necrotic cervicitis. Cervical discharge is usually mucoid, but it is occasionally mucopurulent.

The rates of recurrence for genital HSV-2 infections vary greatly among individuals and over time within the same individual. Infections caused by HSV-2 re-activate approximately 16 times more frequently than HSV-1 genital infections, and average 3 to 4 times per year, but may appear virtually weekly.[3] Recurrences tend to be more frequent in the first months to years after first infection. The classical clinical manifestations of recurrent HSV-2 infection include multiple small but grouped vesicular lesions in the genital area (Fig. 193-6), but it can occur anywhere that can be covered by a pair of boxer shorts (see eFig. 193-6.1 in on-line edition), and the lesions may recur always at the same site or change location. The recurrence of genital lesions may be heralded by a prodrome of tenderness, itching, burning, or tingling, and the outbreaks are less severe than primary infection. Without treatment, the lesions usually heal in 6 to 10 days. Herpetic cervicitis is less common in recurrent disease, occurring in 12 percent of the patients. It may present without external lesions. Signs and symptoms that are less classical for genital HSV infection and which may divert one from the correct diagnosis include small erythematous lesions, fissures, pruritus, and urinary symptoms. HSV can cause urethritis, usually manifested only as a clear mucoid discharge, dysuria, and frequency. Occasionally, HSV can be associated with endometritis, salpingitis, or prostatitis. Symptomatic or asymptomatic rectal and perianal infections are common. Herpetic proctitis presents with anorectal pain, anorectal discharge, tenesmus, and constipation, with ulcerative lesions of the distal rectal mucosa. Genital herpes can recur at non-genital sites as well.

▲ **FIGURE 193-7** Herpes simplex virus infection: Herpetic whitlow. Painful, grouped, confluent vesicles on an erythematous edematous base on the distal finger were the first (and presumed primary) symptomatic infection.

Other Cutaneous Infections

HSV can infect any skin site. The common theme among virtually all of these cutaneous presentations is the requirement that virus has penetrated otherwise normal and well-keratinized tissues. Herpetic whitlow (Fig. 193-7) is the infection of the fingers by HSV acquired by direct inoculation or by direct spread from mucosal sites at the time of primary infection. Thus, a typical presentation of whitlow would be in children who suck their fingers during a

▲ **FIGURE 193-6** **A.** Genital herpes: Recurrent infection of the penis. Group of vesicles with early central crusting on a red base arising on the shaft of the penis. This "textbook" presentation, however, is much less common than small asymptomatic erosions or fissures. **B.** Genital herpes: Recurrent vulvar infection. Large, painful erosions on the labia. Extensive lesions such as these are uncommon in recurrent genital herpes in an otherwise healthy individual.

primary gingivostomatitis outbreak. It is also a well-documented occupational hazard for medical personnel. It is usually caused by HSV-1, but HSV-2 whitlow may develop as a manifestation of primary inoculation following manual–genital contact with an infected partner. The infected region becomes erythematous and edematous. Lesions are usually present at the fingertip and can be pustular and very painful. Fever and local lymphadenopathy are common. Whitlow is often misdiagnosed as a bacterial paronychial infection, but the surgical drainage, often needed for a bacterial infection, is unnecessary and potentially harmful, while antiviral therapy speeds healing. Whitlow may recur.

Cutaneous herpes can be transmitted between athletes involved in contact sports, such as wrestling (herpes gladiatorum) and rugby (herpes rugbiaforum or scrum pox), and may do so as outbreaks or small epidemics among team members. In these instances, multiple herpetic lesions may appear across the thorax, ears, face, arms, and hands, caused by facilitation of infection by trauma to the normally keratinized skin sustained during the practice of the sport. Concomitant ocular herpes can occur.

Eczema herpeticum (Kaposi varicelliform eruption; Fig. 193-8) results from a widespread infection following inoculation of virus to skin damaged by eczema. It is usually a manifestation of primary HSV-1 infection in a child with atopic dermatitis, and the expression of cathelicidins in the skin may be a factor in controlling susceptibility to eczema herpeticum in these patients.[17] Mycosis fungoides, Sézary syndrome, Darier disease, various bullous diseases of the skin (particularly if patients are receiving immunosuppressive therapy), and burns of second or third degree can also be complicated by cutaneous dissemination of HSV. The severity of eczema herpeticum ranges from mild to fatal, with mortality rates of up to 10 percent being reported before antiviral therapy was available. Mortality was usually primarily caused by bacterial superinfection and bacteremia. Common pathogens include *Staphylococcus aureus*, *Streptococcus*, and *Pseudomonas*. In a typical severe primary attack, several days after exposure vesicles develop in large numbers over the areas of active or recently healed atopic dermatitis, particularly the face, and continue to appear in crops for several days more. The vesicles become pustular and markedly umbilicated. Patients commonly have high fever and adenopathy. Viremia with infection of internal organs can be fatal. Recurrences are usually far milder than these first infections. Arriving at the correct diagnosis can be delayed because of secondary impetiginization of the lesions, but it always should be considered in children with infected eczema, particularly if the child is more ill systemically than one might anticipate with impetigo. Eczema herpeticum of the young infant is a medical emergency, and early treatment with acyclovir can prove lifesaving.

▲ **FIGURE 193-8** **A.** Herpes simplex virus infection: Eczema herpeticum on face. Confluent and discrete crusted erosions associated with erythema and edema of the face of a woman with atopic dermatitis. **B.** Herpes simplex virus infection: Eczema herpeticum on neck. Confluent crusted erosions with peripheral vesicle on neck and face in the setting of atopic dermatitis.

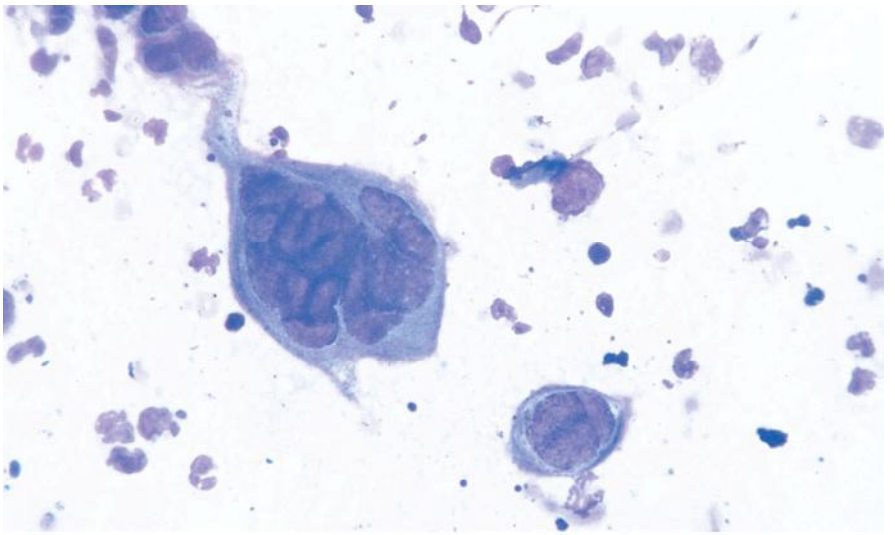
Recurrent HSV infection is the most common precipitating event in cases of recurrent erythema multiforme (see Chap. 38). HSV-associated erythema multiforme is usually an acute, self-limited, recurrent disease. The duration of the disease is usually about 3 weeks. The lesions are usually disseminated and symmetric, occurring on acral extremities and face, and there is grouping of the lesions over the elbow and knees, as well as nail fold involvement; photodistribution and isomorphic phenomenon can occur. Mucosal involvement is usually mild and restricted to the mouth. Constitutional symptoms are rare, and the skin lesions heal without scarring.

LABORATORY TESTS

The method of choice for diagnosis of HSV infection depends on the clinical presentation. In many instances, the history and clinical findings may be sufficient, but the social, emotional, and therapeutic implications of a diagnosis dictate that it be confirmed by laboratory testing when possible. For patients with lesions, virus isolation by cell culture is the method of choice. In culture, HSV causes typical cytopathic effects, and most specimens will prove positive within 48 to 96 hours after inoculation. The sensitivity of the culture depends on the quantity of the virus in the specimen. Even in the most experienced centers, only approximately 60 percent to 70 percent of fresh genital lesions are culture-positive. Isolation of the virus is most successful when lesions are cultured during their vesicular stage and when specimens are taken from immunocompromised patients or from patients suffering from a primary infection.

PCR is more sensitive than viral isolation and has been extensively used for the diagnosis of central nervous system infections and in neonatal herpes. It may also be useful for the detection of HSV in late-stage ulcerative lesions. Both viral culture and PCR assays enable typing of the isolate as HSV-1 or HSV-2. This information helps to predict the frequency of re-activation after a first-episode of HSV infection.

Direct fluorescent antibody staining of lesion scrapings and antigen detection assays can also be used but sensitivity is somewhat lower than that of viral culture.[18] The Tzanck smear can be helpful in the rapid diagnosis of herpesviruses infections, but it is less sensitive than culture and staining with fluorescent antibody, with positive results in fewer than 40 percent of culture-proven cases. It is performed by scraping the base of a freshly ruptured vesicle and staining the slides with Giemsa or Wright stain (the Papanicolaou staining method can also be used), followed by



▲ **FIGURE 193-9** Herpes simplex virus: Positive Tzanck smear. A giant, multinucleated keratinocyte on a Giemsa-stained smear obtained from a vesicle base. Compare size of the giant cell to that of neutrophils also seen in this smear. Another smaller multinucleated acantholytic keratinocyte is seen as well as acantholytic keratinocytes. Identical findings are present in lesions caused by varicella-zoster virus.

▲ **FIGURE 193-10** Herpes simplex virus infection: Chronic ulcer in an immunocompromised host. Multiple, slowly spreading, deep ulcers with central necrosis and hemorrhagic crusts on the lips, cheeks, and nose of a woman with leukemia.

examination for the multinucleated giant cells that are diagnostic of herpetic infection (Fig. 193-9). Both HSV and VZV will cause these changes. In the skin biopsy specimens, the epithelial cells are enlarged, swollen, and often separated. Multinucleated cells with intranuclear eosinophilic inclusion bodies (Cowdry type A inclusions) can be seen.

Serologic detection of antibodies to HSV can be helpful in certain settings, but the results are often misinterpreted. Its main function is in differentiating a primary episode from a recurrent infection (Table 193-1). A positive serologic test result can be useful in patients with recurrent, genital lesions that are not present at times of examination and, therefore, a positive culture cannot be obtained. Serologic testing can also be helpful for counseling patients with initial episodes of disease and their partners, especially during pregnancy, and in counseling partners of patients with genital herpes about their risk of acquiring HSV.

Until recently, serologic testing for HSV was seriously deficient because of substantial cross-reactivity between HSV-1 and HSV-2 antigens. HSV-1 and HSV-2 infections could be distinguished by Western blot assay, but this assay is expensive and only available in a few research laboratories. Recently, simple kits for type-specific serologic assays based on antigenic differences between HSV-1 and HSV-2 glycoprotein G, have become available.[19] These tests should be used by practitioners who are prepared to counsel patients about the meaning of the test results in terms of the natural history of the disease, available treatment regimens, disease transmission, and the emotional and social implications of the diagnosis.[20]

COMPLICATIONS

Immunocompromised Host

All manifestations of HSV infection seen in the immunocompetent host can also be seen in immunocompromised patients but they are usually more severe, more extensive, and difficult to treat; and, for many of them, recurrences are more frequent as well. Patients with defects of T-cell immunity are at particular risk for progressive mucocutaneous or visceral infections but, the degree of dissemination depends on the level of immunodeficiency of the host. Recurrent and persistent ulcerative HSV lesions are among the most common and defining opportunistic infections in patients with acquired immunodeficiency syndrome (Fig. 198-10). Genital herpes is very common in patients with HIV and can be persistent and severe. Oropharyngeal HSV in immunocompromised patients can present with widespread involvement of skin (see Fig. 193-10), the mucosa, and extremely painful, friable, hemorrhagic, and necrotic lesions, similar to the mucositis caused by cytotoxic agents or other infectious agents. The lesions can spread locally to involve the esophagus. Esophagitis presents with odynophagia, dysphagia, substernal pain, and multiple ulcerative lesions. Esophagitis can also arise directly by re-activation of HSV and its spread to the esophagus

TABLE 193-1
Classification of Herpes Simplex Infections According to Viral Isolation and Paired Serologic Test Results

Classification	Virus Isolated	Serology (Acute)		Serology (Convalescent)	
		HSV-1	HSV-2	HSV-1	HSV-2
Primary HSV-1	HSV-1	–	–	+	–
Primary HSV-2	HSV-2	–	–	–	+
Primary HSV-1 plus previous HSV-2 infection[a]	HSV-1	–	+	+	+
Primary HSV-2 plus previous HSV-1 infection	HSV-2	+	–	+	+
Recurrent HSV-1	HSV-1	+	– or +	+	– or +
Recurrent HSV-2	HSV-2	– or +	+	– or +	+

HSV = herpes simplex virus; – = negative; + = positive.
[a]Rare.

via the vagus nerve. Tracheobronchitis and pneumonitis can also occur by spreading of the virus from oropharyngeal HSV.

HSV can re-activate from visceral ganglia of the autonomic nervous system or disseminate hematogenously to other visceral organs (causing pneumonitis, hepatitis, and pancreatitis) and other portions of the gastrointestinal tract, as well as causing adrenal necrosis. Most of these severe infections are caused by HSV-1, but HSV-2 can do so as well. Few are ever diagnosed except at autopsy.

Ocular Infections

HSV is a leading cause of recurrent keratoconjunctivitis and its associated corneal opacification and visual loss. It is usually caused by HSV-1, except in neonates in whom HSV-2 is more prevalent. The majority of HSV eye disease is caused by re-activation of the virus in the trigeminal ganglia, but primary infections of the eye can also occur. Usually, the initial manifestation of herpetic eye disease is a superficial infection of the eyelids and conjunctiva (blepharoconjunctivitis), or corneal surface (dendritic or geographic epithelial ulcer). Deeper involvement of the cornea (stromal keratitis) or anterior uvea (iritis) represents more serious forms of the disease and can cause permanent visual loss. Acute retinal necrosis is a rare but rapidly progressive disease characterized by retinal arteriolar sheathing, uveitis, and peripheral retinal opacification with variable pain and visual loss. Bilateral involvement may occur, and retinal detachments are common. It is usually associated with HSV-1 infection, but HSV-2 retinitis has been described, and VZV causes a similar process.[21]

Neurologic Disorders

All HSV infections involve the nervous system, as neurons are the sole proven site of virus latency. Neurologic manifestations of HSV infections, however, are not universal, but highly variable in their presentation and severity. HSV meningitis is manifested by headache, fever, and mild photophobia, with lymphocytic pleocytosis in the cerebrospinal fluid (CSF). Most cases result from HSV-2 infection. It resolves spontaneously in 2 to 7 days. It is usually seen in association with primary genital HSV-2 infection. Recurrent lymphocytic meningitis (Mollaret meningitis) is associated with recurrent HSV-2 infection, often without symptomatic genital disease. Involvement of the sacral nerves with autonomic nervous system dysfunction, numbness, pelvic pain, tingling, urinary retention, constipation, and CSF pleocytosis has been reported in association with HSV infection. Symptoms usually resolve in a few days, but in some cases, the neurologic residua take weeks to months to disappear, occasionally becoming permanent. Rare cases of transverse myelitis and Guillain-Barré syndrome after HSV infection have been reported. Bell palsy is an acute, peripheral facial paresis of unknown cause and is thought to result from inflammation and subsequent mechanical compression of the facial nerve in the temporal bone. Re-activation of HSV and VZV are implicated in the pathogenesis of the disease.[22]

HSV encephalitis is the most commonly identified acute, sporadic viral encephalitis in the United States, accounting for 10 percent to 20 percent of all cases. Nearly all of the cases arising after the neonatal period (see Neonatal Herpes) are caused by HSV-1. HSV encephalitis usually presents with acute onset of focal neurologic symptoms and fever. Involvement of the temporal lobe is a characteristic feature of this disease, but overall, it is difficult to differentiate HSV encephalitis clinically from other viral encephalitides. PCR of the CSF for HSV DNA is the most sensitive non-invasive technique to help in the diagnosis. Brain biopsies had been the gold standard method to establish the diagnosis until the advent of PCR. However, even with therapy, neurologic sequelae are frequent, especially in persons older than 35 years of age. Patients with presumed HSV encephalitis should be treated empirically with intravenous acyclovir until the diagnosis is confirmed or an alternative diagnosis is made.

Neonatal Herpes

The neonate is a special category of immune-deficient host. The incidence of neonatal herpes is approximately 1 in 3500 live births. Seventy percent of neonatal HSV cases are caused by HSV-2 inoculated directly by infectious genital secretions at the time of delivery. The category of maternal infection plays a significant role in defining the risk of neonatal herpes. Primary genital herpes is associated with a risk of neonatal infection of 33 percent to 50 percent for vaginally delivered babies. Risk of transmission to a neonate is highest in women who develop primary herpes in the third trimester. This is because primary infections are usually associated with prolonged excretion of high titers of virus, and there will have been no time for the mother to mount an immune response against the virus and transfer protective antibodies to the child. In contrast, recurrent maternal infection is associated with a risk of transmission of less than 3 percent.[23] Other risk factors for development of neonatal herpes include vaginal delivery, use of invasive monitors, isolation of HSV-1, and isolation of HSV from the cervix.[24] Prolonged rupture of the membranes is also a risk factor.

Neonatal herpes infections manifest in one of three forms: skin, eye, and mouth involvement; encephalitis; or disseminated disease. The latter two forms account for more than 50 percent of cases of neonatal herpes. It is important to remember that more than 20 percent of neonates with neurologic and disseminated disease do not develop cutaneous vesicles. Without therapy, the overall mortality of neonatal herpes is 65 percent, and fewer than 10 percent of untreated neonates with central nervous system infection will develop normally. With current therapeutic modalities, most babies with skin, eye, and mouth disease survive and have normal development at 1 year. For treated babies with encephalitis, mortality is 4 percent, with about 30 percent developing normally after 1 year. For babies with disseminated disease, mortality is 30 percent, with about 80 percent of the survivors apparently developing normally after 1 year.[25]

TREATMENT

All sexually active persons should be educated regarding the nature and risks of acquiring and transmitting sexually transmitted infections, including HSV. Studies show that about one-half of the patients with asymptomatic HSV-2 infection have mild, unrecognized disease and can be taught to recognize their symptoms and signs of genital herpes. Also, patients should be counseled regarding safer sex practices. It must be emphasized that the majority of transmission occurs in asymptomatic phases and from people who have no classical lesions. Patients with genital herpes should be counseled to refrain from sexual intercourse during outbreaks and for 1 to 2 days after and to use condoms between outbreaks. Suppressive antiviral therapy is also an option for individuals concerned about

transmission to a partner (see Antiviral Therapy under Prevention).

Pregnant women who are known to have genital herpes should be reassured that the risk of transmitting herpes to the baby during childbirth is extremely low. Recommendations for the management of pregnant women with recurrent genital herpes include clinical evaluation at delivery, with delivery by cesarean section indicated if there are signs and symptoms of active infection (including prodrome).[24] But cesarean section delivery may not reliably prevent neonatal HSV infection when membranes are ruptured for long periods (≥ 24 hours). Women with primary HSV infection during pregnancy, particularly during the second and third trimesters, should be treated with antiviral therapy. For women at or beyond 36 weeks of gestation who are at risk for recurrent HSV infection, suppressive antiviral therapy also may be considered.[26] The role of culturing the mother and/or the baby for HSV is controversial. Current recommendations include culturing for HSV at the time of delivery in women with a history of genital herpes. Women with active genital lesions at delivery and their babies should be cultured serially. Cultures should be taken from eye, oronasopharynx, and suspected sites every 2 to 3 days during the first 4 weeks of life. Preemptive therapy with intravenous acyclovir has been recommended for neonates born vaginally or after prolonged rupture of membranes to a woman with a clinically apparent first episode of genital herpes at delivery.[26]

Women who are known by history and serologic tests not to have genital herpes should be counseled about signs and symptoms of HSV and how to avoid acquiring the infection during pregnancy. Serology is helpful in counseling a couple in which the male partner has recurrent genital herpes and the pregnant wife is susceptible.

Antiviral Therapy (See Chap. 232)

Many HSV infections require no specific treatment at all. Keeping the lesions clean and dry while they heal by themselves may be all that is required. Treatment is warranted for infections that are likely to prove protracted, highly symptomatic, or complicated. Acyclovir, an acyclic guanosine analogue, was the first compound shown to prevent replication of a virus at concentrations far below those that affect cellular nucleic acid synthesis. This finding was a key factor in establishing antiviral chemotherapy as a major medical intervention. Acyclovir has a highly favorable therapeutic index because of its preferential activation in infected cells and preferential inhibition of the viral DNA polymerase. It must be phosphorylated to be active, and it requires the viral TK for efficient monophosphorylation. Acyclovir inhibits HSV-1 and HSV-2 replication by 50 percent at a concentration of 0.1 and 0.3 μg/mL (range, 0.01 to 9.9 μg/mL), respectively, but is toxic at concentrations of > 30 μg/mL. Any strain that requires more than 3 μg/mL of acyclovir to be inhibited is said to be relatively drug-resistant.

Valacyclovir, the L-valyl ester of acyclovir, is an oral prodrug of acyclovir that achieves three- to fivefold higher bioavailability after oral administration, and it can be used in a more convenient dosage regimen. Famciclovir is the well-absorbed oral form of the related guanosine analogue penciclovir. Similar to acyclovir, famciclovir is converted by phosphorylation to its active metabolite penciclovir-triphosphate. The efficacy and adverse effect profile of famciclovir is comparable to that of acyclovir. Penciclovir 1 percent cream is approved by the U.S. Food and Drug Administration (FDA) for the treatment of herpes simplex labialis. Docosanol 10 percent cream is approved by the FDA for over-the-counter treatment of recurrent herpes labialis. Docosanol is a long-chain saturated alcohol that inhibits entry of lipid-enveloped virus into the cell. It decreased the healing time by 18 hours when compared with placebo.[27]

The current recommendations for antiviral treatment depend on the clinical disease, on host immune status, and whether one is treating a primary or recurrent episode or considering suppressive therapy. Box 193-1 describes the dosages and regimens for these different scenarios. For disseminated or severe herpes infections, the treatment of choice remains intravenous acyclovir 5 to 10 mg/kg every 8 hours. Some experts use acyclovir 15 to 20 mg/kg intravenously every 8 hours for life-threatening HSV infection, including encephalitis. The dose of intravenous acyclovir for neonatal herpes is 20 mg/kg per dose given every 8 hours.

For first episodes of genital HSV-2 infections, oral acyclovir, famciclovir, and valacyclovir all speed the healing and resolution of symptoms, and decrease viral shedding. When compared with placebo, acyclovir decreases time to healing from 16 to 12 days, the duration of pain from 7 to 5 days, and the duration of constitutional symptoms from 6 to 3 days.[28] Valacyclovir was compared with acyclovir in the treatment of primary episodes and shown to be equivalent.[29] But antiviral treatment of initial herpes episodes does not decrease subsequent recurrences, probably because HSV establishes latent infection within hours after inoculation and days before symptoms evolve.

Treatment of recurrent episodes of genital herpes with famciclovir, acyclovir, or valacyclovir has been shown to reduce the time of healing from about 7 to 5 days, time of cessation of viral shedding from 4 to 2 days, and duration of symptoms from 4 to 3 days when compared with placebo. Valacyclovir and acyclovir are equivalent,[30,31] and it is likely that famciclovir, if tested, would be as well.

For persons with frequent or complicated genital recurrences, long-term suppressive therapy with acyclovir or its analogues is the most effective management strategy.[32,33] Because genital herpes is not progressive in the normal host and because the rate of recurrences varies over time and may decrease after some years, it is wise to recommend a "holiday" from treatment every year or so to reassess the person's continuing need for treatment.

The use of antiviral suppressive therapy during the late phase of pregnancy to avoid neonatal herpes has also been advocated, but a formal study of the approach would require a very large number of participants because of the rare incidence of neonatal herpes. A more achievable goal is to decrease the need for cesarean deliveries caused by herpes recurrences during labor. Although analyses have been favorable for the use of acyclovir in late pregnancy (beginning at 36 weeks) to prevent clinical recurrences, cesarean sections due to genital herpes, and the risk of HSV viral shedding at delivery,[34,35] further research is needed before a recommendation can be made.

Orolabial HSV infections warrant antiviral treatment less often than do the genital infections. Primary HSV gingivostomatitis should be treated with oral acyclovir. The pediatric dose is 15 mg/kg of acyclovir suspension orally five times a day for 7 days. When it is started within 3 days of onset of the disease, this regimen decreases the duration of oral and extra-oral lesions, fever,

Box 193-1

Recommended Regimens for the Treatment of Herpes Simplex Infections

		ACCEPTABLE REGIMEN ALTERNATIVES[a]			
DISEASE		**ADULTS**	**PEDIATRIC[b]**	**DURATION**	**COMMENTS**
Orofacial herpes	Primary infection	Acyclovir, 200 mg orally five times a day. Acyclovir, 400 mg orally three times a day. Valacyclovir, 1000 mg orally two times a day. Famciclovir, 250 mg orally three times a day.	15 mg/kg of acyclovir orally five times a day.[59]	7–10 days or until resolution of symptoms.	IV acyclovir for severely ill individuals. No studies have been done in adults: Regimens are extrapolated from their effectiveness in primary genital herpes.
	Recurrent infection: Episodic treatment	Topical penciclovir, 1% cream q2h while awake.[36] Topical docosanol 10% cream five times a day.[27] Acyclovir, 400 mg orally five times a day.[60] Famciclovir, 500 mg orally two or three times a day.[37,61] Valacyclovir, 2000 mg orally twice a day for 1 day.[62] Famciclovir, 1500 mg single dose or 750 mg twice a day for 1 day.[38]		4–5 days or until lesions are healed. Valacyclovir and famciclovir were used for only 1 day.	Generally not warranted.
	Recurrent infection: Prophylaxis	Acyclovir, 400 mg orally twice a day.[40]			Start just before and during precipitating event, such as intensive ultraviolet exposure.
	Recurrent infection: Suppression of confirmed frequent recurrences	Acyclovir, 400 mg orally twice a day.[39]	There are no pediatric studies, but children with confirmed frequent recurrences may benefit from suppressive oral acyclovir therapy.		
Genital herpes	Primary infection	Acyclovir, 200 mg orally five times a day.[28] Acyclovir, 400 mg orally three times a day.[63] Valacyclovir, 1000 mg orally twice a day.[29] Famciclovir, 250 mg orally three times a day.	Acyclovir, 40–80 mg/kg/day orally divided in three to four doses (maximum 1 g/d).[64]	7–10 days or clinical resolution occurs.	
	Recurrent infection	Acyclovir, 400 mg orally three times a day. Acyclovir, 200 mg orally five times a day.[30] Acyclovir, 800 mg orally twice a day.[65] Valacyclovir, 500 mg orally twice a day.[31,66] Valacyclovir, 1000 mg orally once a day.[66] Valacyclovir, 1000 mg orally twice a day.[67,68,c] Famciclovir, 500,[c] 250, 125 mg orally twice a day.[61,69,70] Famciclovir, 1000 mg orally twice a day for 1 day (patient initiated).[71]	Acyclovir, 1000 mg/day orally in three to five divided doses.[72]	5–10 days or until clinical resolution occurs.	

(continued)

Box 193-1

Recommended Regimens for the Treatment of Herpes Simplex Infections (Continued)

		ACCEPTABLE REGIMEN ALTERNATIVES[a]			
DISEASE		**ADULTS**	**PEDIATRIC[b]**	**DURATION**	**COMMENTS**
Genital herpes (continued)	Suppression of recurrences	Acyclovir, 400 mg orally twice a day.[73] Acyclovir, 800 mg orally once a day.[74] Valacyclovir, 500, 1000 orally once a day.[75,d] Valacyclovir, 250 mg orally twice a day.[73,d] Valacyclovir, 500 mg twice a day or 1000 mg orally once a day.[67,68,c] Famciclovir, 250 orally twice a day.[76,77] Famciclovir, 125 mg, 250 mg orally three times a day.[78]	Acyclovir, 400–1000 mg/day orally in two to three divided doses.[72]		Duration of the therapy is controversial. Some authorities will offer treatment for 1 yr and then reassess the need to resume it.
	Suppression of recurrences in pregnant women	Acyclovir, 400 mg orally three times a day from 36 wk to delivery.[79,80]			Use is controversial.
	Reduction of transmission	Valacyclovir, 500 mg orally once a day.[8]			Safer sex practices should continue to be used.
Ocular herpes	Therapy	1% trifluridine drop—1 drop q2h during day and q4hs during night (maximum, 9 drops/day).[81] 0.1% IDU drop and 0.5% ointment—drop hourly during the day and q2h during night. Ointment q2h during day and q4h during night.[81] 3% vidarabine ointment—q3h during day.[81] Acyclovir, 400 mg orally five times a day.[81] Valacyclovir, 1000 mg orally 2 times a day.[82]			Undertake in consultation with an ophthalmologist. Trifluridine's corneal and conjunctival toxicity is similar to IDU's. IDU can cause corneal epithelial toxicity, follicular conjunctivitis and scarring, and closure of tear outflow channels. Vidarabine causes less corneal and conjunctival toxicity than IDU.
	Suppression of recurrences	Acyclovir, 400 mg orally twice a day.[83]	Acyclovir, 80 mg/kg/day orally in three divided doses (maximum, 1g/day) may be of benefit.[72]		Undertake in consultation with an ophthalmologist.
Other cutaneous herpes (herpes gladiatorum, herpetic whitlow, etc.)	Treatment	Acyclovir, 200 mg orally five times per day. Acyclovir, 400 mg orally three times a day. Valacyclovir, 1000 mg orally twice a day. Famciclovir, 250 mg orally three times a day.	Acyclovir, 40–80 mg/kg/day orally divided in three to four doses (maximum, 1 g/day).[72]	7–10 days or until resolution of symptoms.	No studies have been done. Regimens are extrapolated from the treatment of genital herpes. Consider suppressive antiviral therapy for patients with frequent recurrences.
Neonatal herpes			IV acyclovir, 20 mg/kg every 8 h.[84]	14–21 days.	The value of long-term suppression after initial treatment is being evaluated.
Disseminated infection		IV acyclovir, 10–15 mg/kg three times a day.	IV acyclovir, 10 mg/kg three times daily.[26]	14–21 days.	
Encephalitis		IV acyclovir, 10–15 mg/kg three times a day.	IV acyclovir, 10 mg/kg three times daily.[26]	14–21 days.	

(continued)

Box 193-1

Recommended Regimens for the Treatment of Herpes Simplex Infections (Continued)

	ACCEPTABLE REGIMEN ALTERNATIVES[a]			
DISEASE	**ADULTS**	**PEDIATRIC[b]**	**DURATION**	**COMMENTS**
Eczema herpeticum	Acyclovir, 200 mg orally five times a day. Acyclovir, 400 mg orally three times a day. Valacyclovir, 1000 mg orally twice a day. IV acyclovir, 10–15 mg/kg three times a day.	Acyclovir, 40–80 mg/kg/day orally divided in three to four doses (maximum, 1.2 g/d). IV acyclovir, 10 mg/kg three times daily.[72]	14–21 days.	No studies have been done. Use IV acyclovir in severely ill individuals. Consider suppressive antiviral therapy for patients with recurrences. Ocular involvement should be treated in consultation with an ophthalmologist.

IDU = idoxuridine.
[a]The doses are for patients with normal renal function.
[b]Oral dosage of acyclovir in children should not exceed 80 mg/kg/day. Children 40 kg and above should receive the adult dose.
[c]Human immunodeficiency virus patients.
[d]The high once-a-day and twice-daily doses of valacyclovir are more effective in patients who present with more than 10 recurrences per year.
Note: Neither valacyclovir nor famciclovir is approved by the U.S. Food and Drug Administration for use in children.

and eating and drinking difficulties. Valacyclovir and famciclovir may be equally effective, but they have not been studied in this setting and are not currently approved for use in children. Severely ill children may need to be hospitalized for hydration, and intravenous acyclovir may be necessary.

Treatment of recurrent herpes labialis with antiviral drugs in immunocompetent hosts has shown only modest benefits so far. The infections are inherently briefer and less symptomatic than genital herpes. Treatment is only effective if used very early in the disease, especially in the prodromal or erythema lesion stages. Patients who wish treatment should have the medication available and be vigilant for the earliest signs and symptoms of a recurrence. When treatment is felt to be required, the therapy of choice is penciclovir 1 percent cream every 2 hours while awake, for 4 days.[36] Treatment should be initiated as early as possible. When initiated within 1 hour of first symptom of recurrence, penciclovir sped the healing of lesions (4.8 days vs. 5.5 days) and decreased the duration of pain (3.5 days vs. 4.1 days). This regimen is approved by the FDA. Docosanol 10 percent cream is approved by the FDA for over-the-counter treatment of herpes simplex labialis. It is to be applied five times a day at the first sign of recurrence of herpes simplex labialis. There has been no direct comparison with topical penciclovir. Oral acyclovir, 400 mg five times a day for 5 days, affords marginal benefit if begun in the earliest hour or two of the outbreak. Famciclovir, 500 mg three times a day for 5 days, when started within 48 hours after experimental ultraviolet radiation, decreased the median time to healing from 6 to 4 days[37] but is not useful for the more usual sporadic cases of herpes labialis. A 1-day regimen of valacyclovir (2 g twice daily for 1 day) decreased the mean duration of cold sore episodes by 1 day when compared with placebo, if started in the prodrome period. Similarly, a single dose of famciclovir reduced time to healing of herpes labialis lesions by approximately 2 days compared with placebo.[38] Creams and ointments containing 5 percent and 10 percent acyclovir are not beneficial in recurrent herpes labialis.

The use of suppressive acyclovir for herpes labialis is controversial. In one small study, oral acyclovir, 400 mg twice a day, was effective in decreasing recurrences of herpes labialis.[39] In studies with skiers (and therefore significant and anticipated sun exposures), acyclovir 400 mg twice a day, was shown to reduce recurrences in one study,[40] whereas acyclovir, 800 mg bid, failed to prevent recurrences in another study.[41] Both perioperative famciclovir (125 or 250 mg orally twice daily given 1 to 2 days before to 5 days after the procedure) and valacyclovir (500 mg twice daily for 14 days, starting either a day before or the day of the procedure) appeared to reduce the recurrence of orofacial HSV in patients undergoing facial laser resurfacing.[42,43] Valacyclovir has also been shown to suppress recurrences of herpes gladiatorum.[44]

Herpetic eye disease should always be treated in consultation with an ophthalmologist. Options usually involve topical antivirals. These include idoxuridine, vidarabine, and trifluridine. Topical antivirals are effective in shortening the duration of dendritic and geographic keratitis, and are used to prevent corneal epithelial disease in patients with blepharitis and conjunctivitis, as well as patients on topical steroid therapy for corneal stromal inflammation and iridocyclitis. Oral acyclovir is also effective for dendritic and geographical epithelial keratitis. Suppressive acyclovir therapy reduces the rates of all types of recurrent ocular HSV disease, and it is most important for patients with a history of HSV stromal keratitis because it can prevent additional episodes and potential loss of vision.

Antiviral Resistance

The specter of drug resistance hangs over the family of antiherpes drugs, as it does over all other classes of antimicrobials. However, virtually all clinically relevant drug resistance has been seen in immunocompromised patients. The primary mechanism of acyclovir resistance is selection of viral mutants defective or deficient in TK expression. Most mutants that are TK deficient are somewhat attenuated in virulence in vivo.

The treatment of resistant HSV infection is complicated. First, one must make the diagnosis. Very few people who claim to be "resistant" to one of the antiviral drugs actually harbor resistant virus. There is a common misconception that treatment prevents all recurrences, now and forever. One should suspect resistance only in people who continue to have culture-proven outbreaks of unaltered frequency and se-

verity, especially if the lesions do not heal by themselves. When resistance is suspected, virus should be recovered and tested specifically for sensitivity to acyclovir. These tests are expensive but now widely available through commercial reference laboratories. Second, the options for patients with true resistance are few and far from ideal due to the lack of alternatives that are safe and easy to administer. Foscarnet, an organic analogue of inorganic pyrophosphate, inhibits replication of all known herpesviruses in vitro and does not require activation by TK or other kinases, and therefore can be effective in the treatment of acyclovir-resistant HSV. Foscarnet requires intravenous therapy and can cause numerous adverse reactions including nephrotoxicity, electrolytes disturbances, anemia, and seizures. Also, foscarnet-resistant herpesvirus strains have been described.

Cidofovir is an acyclic nucleoside phosphonate with broad-spectrum activity against a wide variety of DNA viruses, including herpesviruses. Being a nucleotide (rather than nucleoside) analog, it does not require the viral TK for its intracellular phosphorylation to the active form. Cidofovir has been tested in cases of acyclovir-resistant HSV and topical cidofovir has been used with success to treat progressive herpetic lesions.[45] Intravenous cidofovir is associated with considerable nephrotoxicity and requires the co-administration of saline hydration and probenecid. There is one report of a patient with acyclovir-resistant genital herpes that responded to imiquimod 5 percent cream,[46] but imiquimod caused severe inflammation in some patients with recurrent herpes labialis.[47]

PREVENTION

Strategies to prevent HSV infection have proved inadequate to address the growing epidemic of genital herpes. HSV infection can be prevented by total abstinence, as indicated by very low seroprevalence rates in cloistered nuns. Condoms reduce rates of transmission if used routinely.[48] Other than these public health approaches, most efforts involve antiviral therapy and vaccines directed at genital herpes.

Antiviral Therapy

Acyclovir, famciclovir, and valacyclovir all decrease both symptomatic and subclinical shedding of HSV-2, from about 8 percent of the days in the placebo group to 0.3 percent to 0.6 percent of the days in the treatment group, when assessed by culture.[49–52] Recently, valacyclovir 500 mg once daily was shown to be effective in reducing the transmission of HSV-2 between partners by 48 percent, and reduced clinical disease in the susceptible partner by 75 percent[8] in a randomized, placebo-controlled trial involving immunocompetent, heterosexual couples in stable relationships. This therapy can be recommended for individuals concerned about transmission to a partner, in conjunction with the use of condoms. Regarding other groups (e.g., homosexual couples, non-monogamous individuals, immunocompromised, and persons with asymptomatic HSV-2 infection), it is uncertain if the use of antiviral therapy (and which regimen) would be the most adequate to decrease transmission.

Vaginal microbicides are also being studied, mostly focusing in decreasing HIV transmission, but some of the compounds also have anti-HSV activity and may also affect HSV transmission.[53]

Vaccines

The best public health strategy to reduce infection and morbidity associated with HSV infection is development of effective vaccines. Unfortunately, no vaccine has proved to protect adequately against acquisition of HSV (prophylactic) or to reduce the number of recurrent episodes (therapeutic), although there are hopeful developments in these directions.

Recombinant glycoprotein vaccines containing immunogenic HSV proteins have been developed and tested by multiple pharmaceutical and biotechnological companies. In a preliminary study, a recombinant HSV-2 glycoprotein D vaccine with alum adjuvant decreased the frequency of symptomatic outbreaks in patients with genital herpes. A modified form of the vaccine (with added glycoprotein B and a lipid emulsion adjuvant known as *MF59*) was not found, in larger studies, to decrease the number of recurrences in patients with genital herpes, but it was able to decrease the duration and severity of a subsequent study outbreak of genital herpes.[54] Two phase III studies of the effect of this vaccine (one in monogamous seronegative partners of individuals with genital herpes, and the other in seronegative persons attending clinics for sexually transmitted diseases) failed to prevent acquisition of genital herpes infection or disease.[55] A recombinant gD2 vaccine that uses monophosphoryl lipid-A as adjuvant was protective against HSV-2 genital disease (but had limited protection against infection) in HSV-1 and HSV-2 seronegative women but not in males or HSV-1 seropositive females.[56] A double-blind, randomized controlled study in HSV-1 and HSV-2 seronegative women is under way.

A major theoretical limitation of recombinant HSV vaccines is their inability to induce broad and protective cellular immune responses. To better do so, investigators have turned their attention to DNA-based and genetically engineered live vaccines. Replication-defective viruses are capable of only a single round of replication, and therefore have no pathogenic potential while potentially inducing the full spectrum of immune responses. Also, these mutant constructs open the possibility of engineering agents with additional genes that encode antigens from other infectious agents, envisioning a vaccine that can protect against multiple infections. The use of replication-defective HSV mutants has been tested with success as a candidate vaccine in animal models.[57] Recently, a glycoprotein H–deficient virus had no effect on reducing HSV reactivation and clinical disease among individuals with recurrent genital HSV-2 infection.[58] Another replication-defective mutant, defective in ICP8 (a single-strand DNA binding protein) and part of the helicase/primase complex, has demonstrated to be immunogenic and protective in animals[57] but has not been tested in humans yet. DNA vaccines for HSV have also shown promising results in animal models. Phase I studies are being conducted.

CHAPTER 194

Varicella and Herpes Zoster

Stephen E. Straus

Kenneth E. Schmader

EPIDEMIOLOGY

Epidemiology of Varicella

Varicella is distributed worldwide, but its age-specific incidence differs in temperate versus tropical climates and in populations that have received varicella vaccine. In temperate climates in the absence of varicella vaccination, varicella is endemic, with a regularly recurring seasonal prevalence in winter and spring, and periodic epidemics that depend on the accumulation of susceptible persons. In Europe and North America in the pre-vaccination era, 90 percent of cases occurred in children younger than 10 years of age and fewer than 5 percent in individuals older than the age of 15.[1] From 1988 to 1995, there were approximately 11,000 hospitalizations and 100 deaths caused by varicella each year in the United States.[2] The risk of hospitalization and death was much higher in infants and adults than in children, and most varicella-related deaths occurred in previously healthy people.[3] In tropical and semi-tropical countries, the mean age of varicella is higher and susceptibility among adults to primary varicella-zoster virus (VZV) infection is significantly greater than in temperate climates. High levels of susceptibility to varicella among adult immigrants from tropical climates are well documented in the U.S. military, where up to 40 percent of recruits from Puerto Rico and the Philippines have been seronegative. This is important for hospitals, where susceptible health care workers may pose a significant risk of nosocomial varicella.

Widespread use of the varicella vaccine has markedly altered the epidemiology of varicella. In the United States, vaccine coverage rates among susceptible children increased from 0 percent in 1995, when varicella vaccine was licensed, to 88 percent in 2004.[4] This has resulted in a marked decline in varicella cases and varicella-related hospitalizations. From 1995 through 2000, varicella cases reported to the Centers for Disease Control and Prevention (CDC) declined by 71 percent to 84 percent, depending on surveillance area, and by 2002 the incidence of varicella had decreased from 2.63 to 0.92 cases/1000 person years.[5,6] The decline was greatest among children aged 1 to 4 years, but cases declined in all age groups, including infants and adults. The annual varicella-related hospitalization rate in the United States declined from more than 0.5 per 10,000 from 1993 to 1995 to 0.1 per 10,000 by 2001. The decline in varicella-related hospitalization rates was greatest among 0- to 4-year-old children, but rates also declined among youths aged 5 to 19 years and adults.[7]

Varicella is highly contagious. Attack rates of 87 percent among susceptible siblings in households and nearly 70 percent among susceptible patients on hospital wards have been reported. More than 95 percent of cases of varicella are clinically apparent, although occasionally the exanthem may be so sparse and transient as to pass unnoticed. A typical patient is infectious for 1 to 2 days (rarely, 3 to 4 days) before the exanthem appears, and for 4 or 5 days thereafter, that is, until the last crop of vesicles has crusted. The immunocompromised patient, who may experience many successive crops of lesions for 1 week or more, is infectious for a longer period of time. The mean incubation period of varicella is 14 or 15 days, with a range of 10 to 23 days. It is often prolonged in patients who develop varicella after passive immunization with varicella-zoster immune globulin (VZIG) or zoster immune plasma, or active post-exposure immunization with live attenuated Oka strain varicella vaccine.[8]

The major route by which varicella is acquired and transmitted is thought to be the respiratory tract, but infection may also be spread by direct contact. Varicella crusts are not infectious, and the duration of infectivity of droplets containing virus is probably quite limited. Although the infectiousness of patients with varicella is thought to depend largely upon virus shed from the mucous membranes of the upper respiratory tract, VZV has only rarely been cultured from pharyngeal secretions; however, it can be detected in the oropharynx of the majority of patients using polymerase chain reaction–based assays.[9]

Natural varicella (i.e., varicella caused by wild-type VZV) generally confers lifelong immunity to the disease. Re-exposure to the virus boosts humeral and cell-mediated immune responses but rarely leads to clinical illness. Most reported second attacks of varicella involve incorrect diagnoses; others may represent cutaneous dissemination in patients with herpes zoster (see Epidemiology of Herpes Zoster). With severe immunocompromise, re-infections manifested as varicella have been observed. In addition, persons who develop modified varicella (e.g., because they are infected early in infancy in the presence of maternal antibody or have been immunized with live attenuated varicella vaccine) may respond to exogenous exposure by developing a second, usually mild, episode of breakthrough varicella.

Epidemiology of Herpes Zoster

Herpes zoster occurs sporadically throughout the year without seasonal prevalence. The occurrence of herpes zoster is independent of the prevalence of varicella, and there is no convincing evidence that herpes zoster can be acquired by contact with other persons with varicella or herpes zoster. Rather, the incidence of herpes zoster is determined by factors that influence the host-virus relationship.

One strong risk factor is older age (Fig. 194-1A). The incidence of herpes zoster is 1.5 to 3.0 per 1000 person years in all ages and 7 to 11 per 1000 per year in persons over 60 years of age in European and North American studies.[10–17] It is estimated that there are more than a million new cases of herpes zoster in the United States each year, more than one-

VARICELLA AND HERPES ZOSTER AT A GLANCE

- Varicella (chickenpox) and herpes zoster (shingles) are distinct clinical entities caused by the varicella-zoster virus.
- Varicella, an acute, highly contagious exanthem that occurs most often in childhood, is the result of primary infection of a susceptible individual.
- The rash usually begins on the face and scalp and spreads rapidly to the trunk. Lesions are scattered rather than clustered, and progress from rose-colored macules to papules, vesicles, pustules, and crusts. In varicella, lesions in all stages are usually present on the body at the same time.
- In normal children, serious complications are rare. In adults and in immunologically compromised persons, varicella is more likely to be associated with life-threatening complications.
- Where use of varicella vaccine in susceptible children and adults is widespread, the incidence of varicella is markedly reduced.
- Herpes zoster is characterized by unilateral, dermatomal pain and rash as the result of the reactivation of endogenous varicella-zoster virus that had persisted in latent form within sensory ganglia after an earlier attack of varicella.
- The erythematous, maculopapular, and vesicular lesions of herpes zoster are clustered rather than scattered because virus reaches the skin via sensory nerves.
- Herpes zoster is most common in older adults and immunosuppressed individuals.
- Pain is the most important clinical manifestation of herpes zoster, and the most common complication is chronic pain or postherpetic neuralgia.
- Antiviral therapy and analgesics aid acute pain control; lidocaine patch (5 percent), gabapentin, pregabalin, opioids, and tricyclic antidepressants reduce postherpetic neuralgia.
- The zoster vaccine reduces the incidence of herpes zoster by one-half and the incidence of postherpetic neuralgia by two-thirds.

half of which occur in persons 60 years of age or older, and this number increase as the population ages.[11,14]

Another major risk factor is cellular immune dysfunction. Immunosuppressed patients have a 20 to 100 times greater risk of herpes zoster than immunocompetent individuals of the same age. Immunosuppressive conditions associated with high risk of herpes zoster include human immunodeficiency virus (HIV) infection, bone marrow transplant, leukemia and lymphoma, use of cancer chemotherapy, and use of corticosteroids. Herpes zoster is a prominent and early "opportunistic infection" in persons infected with HIV, in whom it is often the first sign of immune deficiency. Thus, HIV infection should be considered in individuals who develop herpes zoster.

Other factors reported to increase the risk of herpes zoster include female sex,[17] physical trauma in the affected dermatome,[18] interleukin 10 gene polymorphisms,[19] and black race,[16,17] but confirmation is required. Exposure to children and contact with cases of varicella have been reported to confer protection against herpes zoster.[17,20]

Second episodes of herpes zoster are uncommon in immunocompetent persons, and third attacks are very rare. Persons suffering more than one episode may be immunocompromised. Immunocompetent patients suffering multiple episodes of herpes zoster–like disease are likely to be suffering from recurrent zosteriform herpes simplex virus (HSV) infections.[21]

Patients with herpes zoster are less contagious than patients with varicella. The rate at which susceptible household contacts develop varicella after exposure to herpes zoster appears to be about one-third of the rate observed after exposure to varicella.[11] Virus can be isolated from vesicles and pustules in uncomplicated herpes zoster for up to 7 days after the appearance of the rash, and for much longer periods in immunocompromised individuals. Patients with uncomplicated dermatomal zoster appear to spread the infection by means of direct contact with their lesions. Patients with disseminated herpes zoster may, in addition, transmit the infection in aerosols, so that airborne precautions, as well as contact precautions, are required for such patients.

The effect of the marked reduction in the incidence of varicella, due to widespread varicella vaccination of children, on the epidemiology of herpes zoster is unclear. In the long term, the incidence of herpes zoster is likely to decline as the cohorts of children now receiving the vaccine become adults; vaccine virus-associated herpes zoster will probably be less frequent and less severe in older adults than wild-type virus–associated herpes zoster because the vaccine virus is highly attenuated. In the short term, the incidence of herpes zoster could increase because a decline in the incidence of varicella will reduce the adult population's exposure to VZV, thereby reducing immune boosting, hastening the age-related decline in immunity to VZV, and thus increasing the age-specific risk of herpes zoster. However, recent studies of herpes zoster in populations with high rates of varicella vaccination have shown little or no increase in the incidence of herpes zoster.[6,12,22]

ETIOLOGY AND PATHOGENESIS

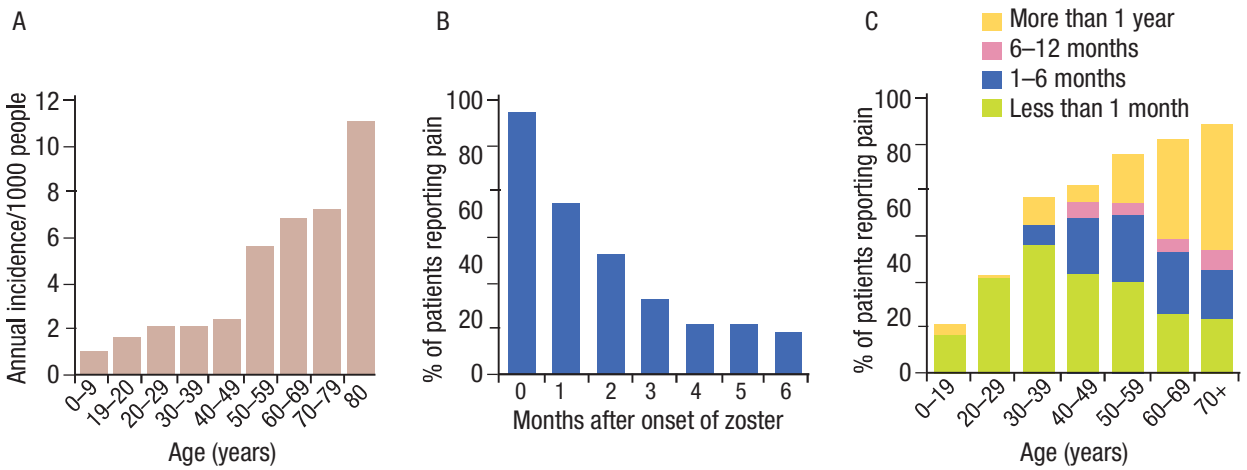
VZV is a member of the herpesvirus family.[23] Other members pathogenic for humans include HSV-1 and HSV-2; cytomegalovirus; Epstein-Barr virus; human herpesvirus-6 (HHV-6) and HHV-7, which cause roseola; and Kaposi sarcoma–associated herpesvirus, also called *HHV-8*. All herpesviruses are morphologically indistinguishable and share a number of properties, including the capacity to establish latent infections that persist for life.

The VZV genome encodes approximately 70 unique genes, most of which have DNA sequence and functional homology to genes of the other herpesviruses. Immediate early gene products regulate VZV replication. Early gene products, such as the virus-specific thymidine kinase and the viral DNA polymerase, support viral replication. Late genes encode virus structural proteins that serve as targets of antibody and cellular immune responses.

There is only one VZV serotype. Although viruses isolated from individual cases of varicella or herpes zoster worldwide are basically similar, minor variations in their nucleotide sequences allow one to distinguish wild-type from vaccine virus strains, and to "fingerprint" viruses isolated from individual patients.

Pathogenesis of Varicella

Entry of VZV is through the mucosa of the upper respiratory tract and oropharynx. Initial multiplication at this portal of entry results in dissemination of small amounts of virus via the blood and lymphatics (the primary viremia). This virus is cleared by cells of the reticuloendothelial system, the major site of virus replication during the remainder of the incubation period.

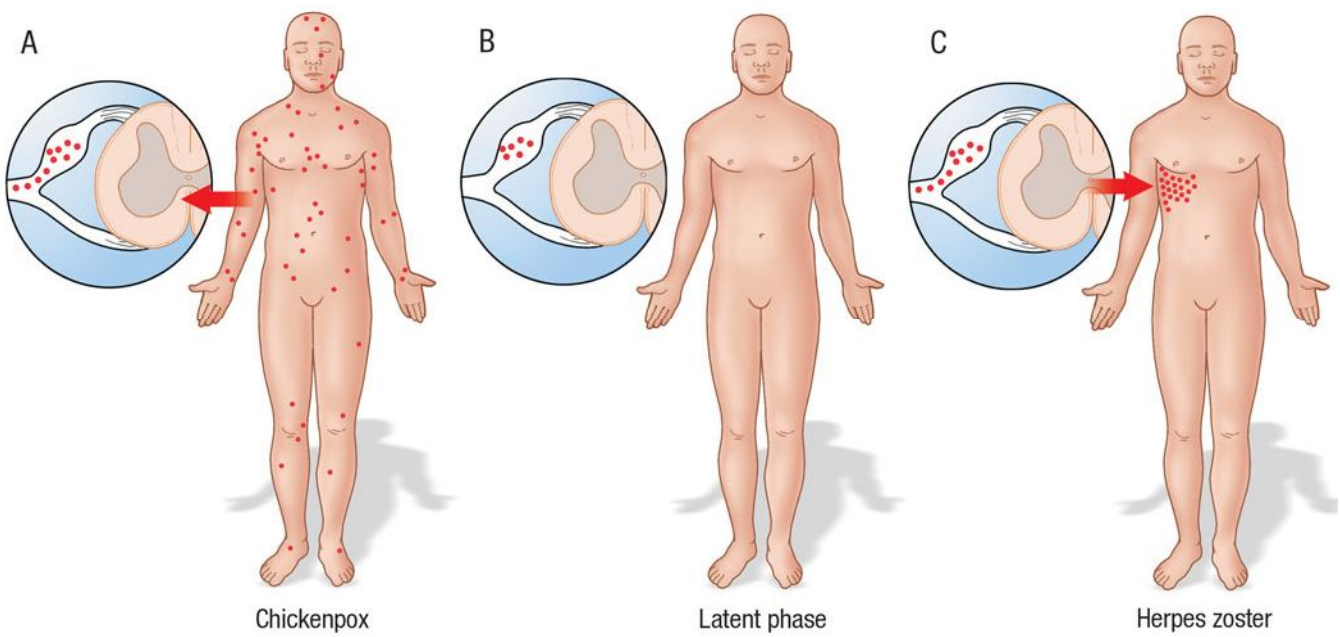


▲ **FIGURE 194-1** **A.** The epidemiology of herpes zoster and postherpetic neuralgia. The annual incidence of herpes zoster per 1000 persons in a general medical practice. **B.** The percentage of patients with pain persisting after the onset of the herpes zoster rash. These data are from the placebo recipients in one large, double-blind treatment study. **C.** The proportion of patients with postherpetic neuralgia according to age. (From Kost RG, Straus SE: Postherpetic neuralgia: Pathogenesis, treatment, and prevention. *N Engl J Med* **335**:32, 1996, with permission.)

The incubating infection is partially contained by innate host defenses (e.g., interferon, natural killer cells) and by developing VZV-specific immune responses. In most individuals, virus replication eventually overwhelms these developing host defenses, so that approximately 2 weeks after infection, a much larger (secondary) viremia and associated symptoms and lesions occur. Skin lesions appear in successive crops, reflecting a cyclic viremia, which in the normal host is terminated after approximately 3 days by VZV-specific humeral and cellular immune responses. Virus circulates in mononuclear leukocytes, primarily lymphocytes. Even in uncomplicated varicella, the secondary viremia results in the sub-clinical infection of many organs in addition to the skin. Effective host immune responses terminate viremia and limit the progression of varicella lesions in the skin and other organs. Humeral immunity to VZV protects against varicella. People with detectable serum antibody do not usually become ill after exogenous exposure. Cell-mediated immunity to VZV also develops during the course of varicella, persists for many years, and protects against severe infections.[24]

Pathogenesis of Herpes Zoster

During the course of varicella, VZV passes from lesions in the skin and mucosal surfaces into the contiguous endings of sensory nerves and is transported centripetally up the sensory fibers to the sensory ganglia. In the ganglia, the virus establishes a latent infection that persists for life. Herpes zoster occurs most often in dermatomes in which the rash of varicella achieves the highest density—those innervated by the first (ophthalmic) division of the trigeminal nerve and by spinal sensory ganglia from T1 to L2 (Fig. 194-2).



▲ **FIGURE 194-2** Varicella and herpes zoster. **A.** During primary varicella-zoster virus (VZV) infection (varicella or chickenpox), virus infects sensory ganglia. **B.** VZV persists in a latent phase within ganglia for the life of the individual. **C.** With diminished immune function, VZV re-activates within sensory ganglia, descends through sensory nerves, and replicates in skin.

Although the latent virus in the ganglia retains its potential for full infectivity, re-activation is sporadic and infrequent, and infectious virus does not appear to be present during latency. The mechanisms involved in re-activation of latent VZV are unclear, but re-activation has been associated with immunosuppression; emotional stress; irradiation of the spinal column; tumor involvement of the cord, dorsal root ganglion, or adjacent structures; local trauma; surgical manipulation of the spine; and frontal sinusitis (as a precipitant of ophthalmic zoster). Most important, though, is the decline in VZV-specific cellular immunity that occurs with increasing age.[25]

VZV may also re-activate without producing overt disease. The small quantity of viral antigens released during such contained re-activations would be expected to stimulate and sustain host immunity to VZV.[26]

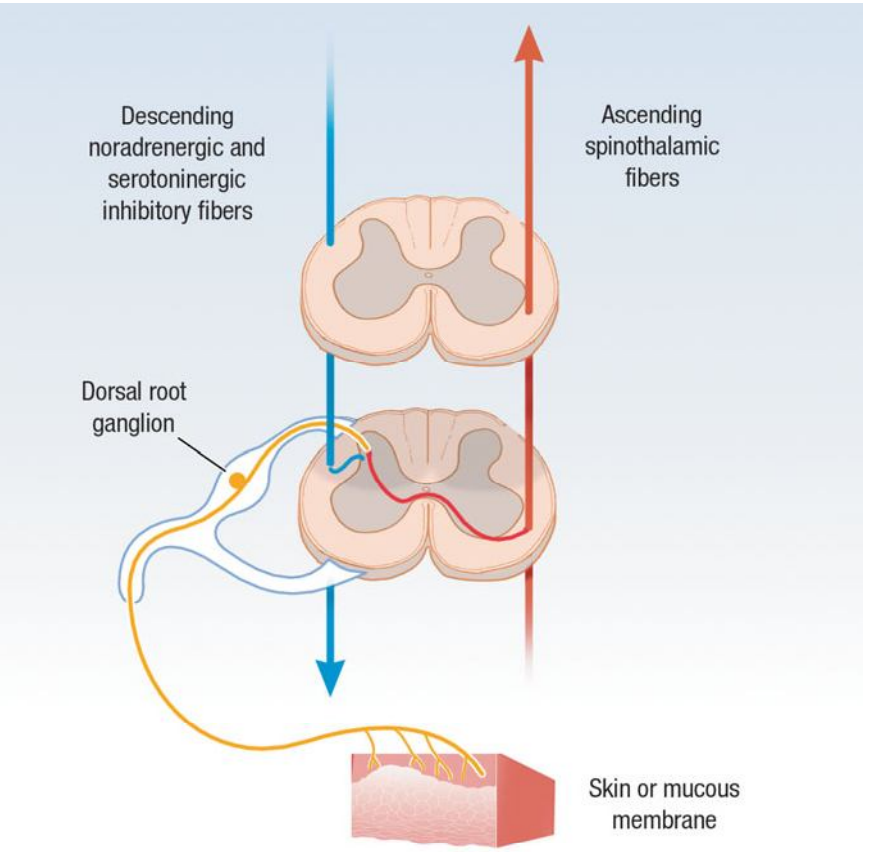
When VZV-specific cellular immunity falls below some critical level, re-activated virus can no longer be contained.[11] Virus multiplies and spreads within the ganglion, causing neuronal necrosis and intense inflammation, a process that is often accompanied by severe neuralgia.[27] Infectious VZV then spreads antidromically down the sensory nerve, causing intense neuritis, and is released from the sensory nerve endings in the skin, where it produces the characteristic cluster of zoster vesicles. Spread of the ganglionic infection proximally along the posterior nerve root to the meninges and cord results in local leptomeningitis, cerebrospinal fluid pleocytosis, and segmental myelitis. Infection of motor neurons in the anterior horn and inflammation of the anterior nerve root account for the local palsies that may accompany the cutaneous eruption, and extension of infection within the central nervous system (CNS) may result in rare complications of herpes zoster (e.g., meningoencephalitis, transverse myelitis).

Pathogenesis of Pain in Herpes Zoster and Postherpetic Neuralgia

Pain is a major symptom of herpes zoster. It often precedes and generally accompanies the rash, and it frequently persists after the rash has healed—a complication known as *postherpetic neuralgia* (PHN). A number of different but overlapping mechanisms appear to be involved in the pathogenesis of pain in herpes zoster and PHN (Fig. 194-3).[28,29]

Injury to the peripheral nerve and to neurons in the ganglion triggers afferent pain signals. Inflammation in the skin triggers nociceptive signals that further amplify cutaneous pain. The abundant release of excitatory amino acids and neuropeptides induced by the sustained barrage of afferent impulses during the prodrome and acute phase of herpes zoster may cause excitotoxic injury and the loss of inhibitory interneurons in the spinal dorsal horn. Damage to neurons in the spinal cord and ganglion, and to the peripheral nerve, is important in the pathogenesis of PHN. Damaged primary afferent nerves may become spontaneously active and hypersensitive to peripheral stimuli, and also to sympathetic stimulation. Excessive nociceptor activity and ectopic impulse generation may, in turn, sensitize CNS neurons, augmenting and prolonging central responses to innocuous as well as noxious stimuli. Clinically, these mechanisms result in allodynia [pain and/or unpleasant sensations elicited by stimuli that are normally not painful (e.g., light touch)] with little or no sensory loss.

The anatomic and functional changes responsible for PHN appear to be established early in the course of herpes zoster. This would explain the correlation of initial pain severity and the presence of prodromal pain with the subsequent development of PHN, and the failure of antiviral therapy to fully prevent PHN (see Treatment).



▲ **FIGURE 194-3** Pathway of normal pain perception. Noxious stimuli activate free nerve endings in the skin to generate signals that are conveyed through unmyelinated C fibers (*red*) and small Aδ fibers to the neuronal bodies in the segmental dorsal root ganglia, then proximally to the dorsal horn of the spinal cord, where they form synapses with second-order neurons. Spinal cord neurons are subject to powerful descending inhibitory signals from the brain (*blue*), mediated by the biogenic amines serotonin and norepinephrine. Drugs that potentiate the central effects of biogenic amines, such as tricyclic antidepressant drugs, may act by enhancing these descending pathways. Endogenous opiates also contribute to descending inhibitory input. The net result of peripheral afferent input and descending inhibitory input is projected cephalad, joining other ascending fibers in the contralateral spinothalamic tract (*orange*). Information from the spinothalamic tract is integrated with input from brainstem and cortical areas for the perception of specific aspects of pain as well as more general affective components of pain perception.

CLINICAL FINDINGS

Clinical Findings of Varicella

PRODROME OF VARICELLA In young children, prodromal symptoms are uncom-

▲ **FIGURE 194-4** Varicella. **A.** A full spectrum of lesions—that is, erythematous papules, vesicles ("dewdrops on rose petals"), crusts, and erosions at sites of excoriation—is seen in a child with a typical case of varicella. **B.** A wider range of lesions, including many large pustules, is seen in a 21-year-old woman who was febrile as well as "toxic" and had varicella pneumonitis.

mon. In older children and adults, the rash is often preceded by 2 to 3 days of fever, chills, malaise, headache, anorexia, severe backache, and, in some patients, sore throat and dry cough.

RASH OF VARICELLA In unvaccinated persons, the rash begins on the face and scalp and spreads rapidly to the trunk, with relative sparing of the extremities (Fig. 194-4). New lesions appear in successive crops, but their distribution remains central. The rash tends to be denser in the small of the back and between the shoulder blades than on the scapulae and buttocks and more profuse on the medial than on the lateral aspects of the limbs. It is not uncommon to have a few lesions on the palms and soles, and vesicles often appear earlier and in larger numbers in areas of inflammation, such as diaper rash or sunburn.

A striking feature of varicella lesions is their rapid progression, over as little as 12 hours, from rose-colored macules to papules, vesicles, pustules, and crusts (see Fig. 194-4). The typical vesicle of varicella is 2 to 3 mm in diameter and elliptical, with its long axis parallel to the folds of the skin. The early vesicle is superficial and thin-walled, and it is surrounded by an irregular area of erythema, which gives the lesions the appearance of a "dewdrop on a rose petal." The vesicular fluid soon becomes cloudy with the influx of inflammatory cells, which convert the vesicle to a pustule (see Fig. 194-4). The lesion then dries, beginning in the center, first producing an umbilicated pustule and then a crust. Crusts fall off spontaneously in 1 to 3 weeks, leaving shallow pink depressions that gradually disappear. Scarring is rare unless the lesions were traumatized by the patient or superinfected with bacteria. Healing lesions may leave hypopigmented spots that persist for weeks to months.

Vesicles also develop in the mucous membranes of the mouth, nose, pharynx, larynx, trachea, gastrointestinal tract, urinary tract, and vagina. These mucosal vesicles rupture so rapidly that the vesicular stage may be missed. Instead, one sees shallow ulcers 2 to 3 mm in diameter.

A distinctive feature of varicella is the simultaneous presence, in any one area of the skin, of lesions in all stages of development. Careful prospective studies have shown that the average number of lesions in healthy children ranges from 250 to 500; secondary cases resulting from household exposure are more severe than primary cases resulting from exposure at school, presumably because more intense and prolonged exposure at home results in a higher virus inoculum.

Fever usually persists as long as new lesions continue to appear, and its height is generally proportional to the severity of the rash. It may be absent in mild cases or rise to 40.5°C (105°F) in severe cases with extensive rash. Prolonged fever or recurrence of fever after defervescence may signify a secondary bacterial infection or another complication. The most distressing symptom is pruritus, which is usually present throughout the vesicular stage.

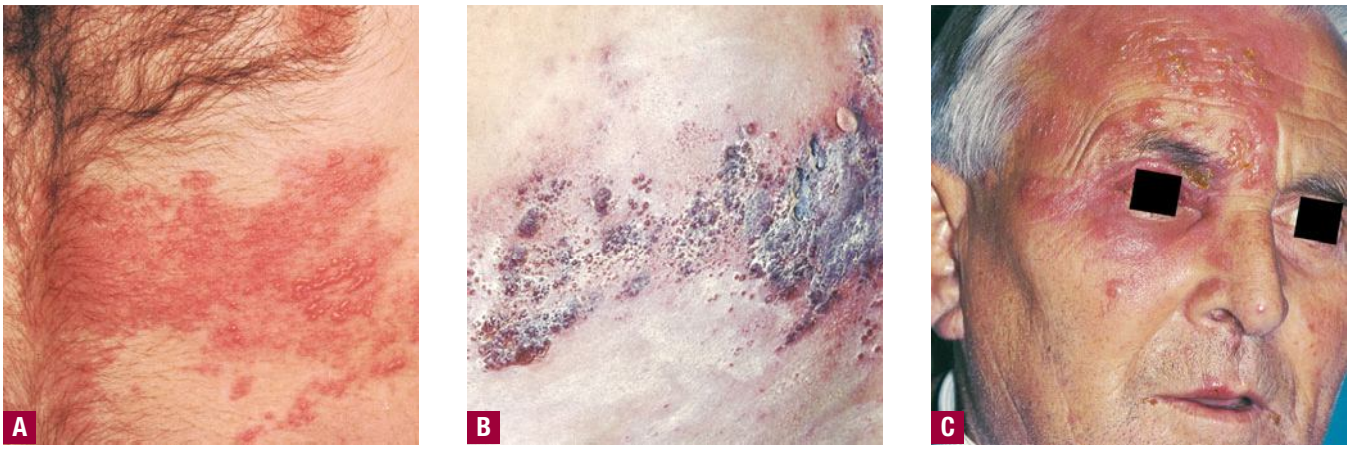
The varicella vaccine alters the natural history of the rash. A small percentage of vaccinees develop breakthrough varicella after exposure to people with active VZV infections. The usual breakthrough rash is predominately maculopapular with fewer lesions (i.e., less than 60) and fewer vesicles than the rash of natural varicella. The incidence and severity of fever is also less than that in natural varicella.[30]

Clinical Findings of Herpes Zoster

PRODROME OF HERPES ZOSTER Pain and paresthesia in the involved dermatome often precede the eruption by several days and vary from superficial itching, tingling, or burning to severe, deep, boring, or lancinating pain. The pain may be constant or intermittent, and it is often accompanied by tenderness and hyperesthesia of the skin in the involved dermatome. The pre-eruptive pain of herpes zoster may simulate pleurisy, myocardial infarction, duodenal ulcer, cholecystitis, biliary or renal colic, appendicitis, prolapsed intervertebral disk, or early glaucoma, and this may lead to serious misdiagnosis and misdirected interventions. Prodromal pain is uncommon in immunocompetent persons younger than 30 years of age, but it occurs in the majority of persons with herpes zoster over the age of 60 years. A few patients experience acute segmental neuralgia without ever developing a cutaneous eruption—a condition known as *zoster sine herpete*.

RASH OF HERPES ZOSTER The most distinctive feature of herpes zoster is the localization and distribution of the rash, which is nearly always unilateral and is generally limited to the area of skin innervated by a single sensory ganglion (Fig. 194-5). The area supplied by the trigeminal nerve, particularly the ophthalmic division, and the trunk from T3 to L2 are most frequently affected; the thoracic region alone accounts for more than one-half of all reported cases, and lesions rarely occur distal to the elbows or knees.[11,15]

Although the individual lesions of herpes zoster and varicella are indistinguishable, those of herpes zoster tend to evolve more slowly and usually consist of closely grouped vesicles on an erythematous base, rather than the more discrete, randomly distributed vesicles of varicella. This difference reflects intraneural spread of virus to the skin in herpes zoster, as opposed to viremic spread in varicella. Herpes zoster lesions begin as erythematous macules and papules that often first appear where superficial branches of the affected sensory nerve are given off, for example, the posterior primary division and the lateral and anterior branches of the anterior primary division of spinal nerves. Vesicles form within 12 to 24 hours and evolve into pustules by the third day. These dry and crust in 7 to 10



▲ **FIGURE 194-5** Herpes zoster. **A.** Early involvement of a thoracic dermatome with erythema within the dermatome and areas of grouped vesicle formation. **B.** Later involvement with crusted sites on the back, where the eruption first appeared, and many confluent hemorrhagic vesicles and bullae on the lateral chest wall, where the eruption appeared more recently; some vesicles are also seen outside the involved dermatome, representing hematogenous dissemination, a not uncommon occurrence. **C.** Ophthalmic zoster. Note the involvement of the tip of the nose, which frequently signals involvement of the eye.

days. The crusts generally persist for 2 to 3 weeks (see Fig. 194-5B). In normal individuals, new lesions continue to appear for 1 to 4 days (occasionally for as long as 7 days). The rash is most severe and lasts longest in older people, and is least severe and of shortest duration in children.

Between 10 percent and 15 percent of reported cases of herpes zoster involve the ophthalmic division of the trigeminal nerve (see Fig. 194-5C).[31] The rash of ophthalmic zoster may extend from the level of the eye to the vertex of the skull, but it terminates sharply at the midline of the forehead. When only the supratrochlear and supraorbital branches are involved, the eye is usually spared. Involvement of the nasociliary branch, which innervates the eye as well as the tip and side of the nose, provides VZV with direct access to intraocular structures. Thus, when ophthalmic zoster involves the tip and the side of the nose, careful attention must be given to the condition of the eye. The eye is involved in 30 percent to 40 percent of patients with ophthalmic zoster. Corneal sensation is generally impaired and when impairment is severe, it may lead to neurotrophic keratitis and chronic ulceration.

Herpes zoster affecting the second and third divisions of the trigeminal nerve (Fig. 194-6) as well as other cranial nerves may produce symptoms and lesions in the mouth, ears, pharynx, or larynx. The so-called *Ramsay Hunt syndrome* (facial palsy, in combination with herpes zoster of the external ear or tympanic membrane, with or without tinnitus, vertigo, and deafness), results from involvement of the facial and auditory nerves.

PAIN OF HERPES ZOSTER Although the rash is important, pain is the cardinal problem posed by herpes zoster, especially in the elderly. Most patients experience dermatomal pain or discomfort during the acute phase (30 days from rash onset) that ranges from mild to severe. Patients describe their pain or discomfort as burning, deep aching, tingling, itching, or stabbing. For some patients, the pain intensity is so great that words such as *horrible* or *excruciating* are used to describe the experience. Acute herpes zoster pain is associated with decreased physical functioning, emotional distress, and decreased social functioning.[32]

HERPES ZOSTER IN THE IMMUNOCOMPROMISED HOST Except for PHN, most serious complications of herpes zoster occur in immunocompromised persons. These complications include necrosis of skin and scarring (Fig. 194-7) and cutaneous dissemination with an incidence as high as 25 percent to 50 percent. Approximately 10 percent of patients with cutaneous dissemination also manifest widespread (Fig. 194-8), often fatal, visceral dissemination, particularly to the lungs, liver, and brain.[33]

HIV-infected patients are fairly unique in their tendency to suffer multiple recurrences of herpes zoster as their HIV infection progresses; herpes zoster may recur in the same or different dermatomes or in several contiguous or non-contiguous dermatomes. Herpes zoster in patients with acquired immunodeficiency syndrome (AIDS) may be severe, with cutaneous and visceral dissemination. Patients with AIDS may also develop chronic verrucous, hyperkeratotic (Fig. 194-9), or ecthymatous cutaneous lesions caused by acyclovir-resistant VZV.

DIAGNOSIS OF VARICELLA

Varicella can usually be diagnosed readily on the basis of the appearance and evolution of its characteristic rash (see Fig. 194-4), particularly when there is a history of exposure within the preceding 2 to 3 weeks.

▲ **FIGURE 194-7** **A.** Acute, necrotic herpes zoster involving the first and second distributions of the fifth cranial nerve in a woman with lymphoma receiving cytotoxic chemotherapy. **B.** Dense scar formation and temporal muscle wasting several weeks later. ◀ **FIGURE 194-9** Chronic verrucous lesions of herpes zoster despite long-term acyclovir treatment in a patient with advanced acquired immunodeficiency syndrome. (Used with permission from David Paar, MD.)

Disseminated herpes zoster may be mistaken for varicella when there is widespread dissemination of VZV from a small, painless area of herpes zoster or from the affected sensory ganglion in the absence of an obvious dermatomal eruption. This is not infrequent in profoundly immunosuppressed, seropositive persons (see Fig. 194-7).

Disseminated HSV infections may resemble varicella; however, there is often an obvious concentration of lesions at and surrounding the site of the primary or recurrent infection (e.g., the mouth or external genitalia), and there may be marked toxicity and encephalitis.

The remaining differential diagnoses of varicelliform rashes are listed in Box 194-1. The character, distribution, and evolution of the lesions, together with a careful epidemiologic history, usually differentiate these diseases from varicella. When any doubt exists, the clinical impression should receive laboratory confirmation.

DIAGNOSIS OF HERPES ZOSTER

In the pre-eruptive stage, the prodromal pain of herpes zoster is often confused with other causes of localized pain. Once the eruption appears, the character and dermatomal location of the rash, coupled with dermatomal pain or discomfort, usually makes the diagnosis obvious (see Figs. 194-5 and 194-6).

A cluster of vesicles, particularly near the mouth or genitals, may represent herpes zoster, but it may also be a recurrent HSV infection.[12] Zosteriform herpes simplex is often impossible to distinguish from herpes zoster on clinical grounds. A history of multiple recurrences at the same site is common in herpes simplex

but does not occur in herpes zoster in the absence of profound and clinically obvious immune deficiency.

Box 194-1 lists other considerations in the differential diagnosis of herpes zoster.

LABORATORY TESTS

The lesions of varicella and herpes zoster are indistinguishable by histopathology (Fig. 194-10). The presence of multinucleated giant cells and epithelial cells containing acidophilic intranuclear inclusion bodies (see Fig. 194-10B) distinguishes the cutaneous lesions produced by VZV from all other vesicular eruptions (e.g., those caused by variola and other poxviruses, and by coxsackie viruses and echoviruses) except those produced by HSV (see Fig. 193-9 in Chap. 193). These cells can be demonstrated in Tzanck smears prepared at the bedside; material is scraped from the base of an early vesicle, spread on a glass slide, fixed in acetone or methanol, and stained with hematoxylin-eosin, Giemsa, Papanicolaou, or Paragon multiple stain.

Punch biopsies provide more reliable material for histologic examination than Tzanck smears and facilitate diagnosis in the prevesicular stage and in atypical lesions such as the chronic verrucous lesions produced by acyclovir-resistant VZV in patients with AIDS (see Fig. 194-9).

The definitive diagnosis of VZV infection, as well as the differentiation of VZV from HSV, is accomplished by the isolation of virus in cell cultures inoculated with vesicle fluid, blood, cerebrospinal fluid or infected tissue, or by the direct identification of VZV antigens or nucleic acids in these specimens. Virus isolation is the only technique that yields infectious VZV for further analysis, such as determination of its sensitivity to antiviral drugs; however, VZV is extremely labile, and only 30 percent to 60 percent of cultures from proven cases are generally positive. To maximize virus recovery, specimens should be inoculated into cell culture immediately. It is important to select new vesicles containing clear fluid for aspiration, because the probability of isolating VZV diminishes rapidly as lesions become pustular. VZV is almost never isolated from crusts.

VZV can be isolated and propagated in vitro in monolayer cultures of a variety of human (and certain simian) cells. The cytopathic effects induced by the replicating virus in such cell cultures are characterized by the formation of acidophilic intranuclear inclusion bodies and multinucleated giant cells similar to those seen in the cutaneous lesions of the disease. These changes are indistinguishable from those produced by HSV, but whereas HSV rapidly spreads to infect the remaining cells in the culture, the cytopathic effect of VZV remains focal. Cytopathic effects of VZV are generally not apparent until several days after specimen inoculation. Modifications of the cell culture assay in which vesicle fluid or lesion scrapings are centrifuged onto cells growing on coverslips at the bottom of thin glass-walled "shell" vials followed 24 to 72 hours later by fixation and staining with fluorescein- or enzyme-labeled monoclonal antibodies to VZV proteins, can confirm the presence of VZV relatively quickly, well before cytopathic effects are evident in conventional cell cultures.[34]

Immunofluorescent or immunoperoxidase staining of cellular material from fresh vesicles or prevesicular lesions has become the diagnostic method of choice in many centers; it can detect VZV significantly more often and faster than virus culture, even relatively late in the disease when cultures are no longer positive.[34] Enzyme immunoassays provide another rapid and sensitive method for antigen detection.

Detection of VZV DNA in clinical specimens after amplifications by polymerase chain reaction provides the greatest assay sensitivity, very high specificity, and rapid turn-around time. It has revolutionized the diagnosis of VZV infections.[34,35]

Serologic tests permit the retrospective diagnosis of varicella and herpes zoster when acute and convalescent sera are available for comparison.[34] These assays can also identify susceptible individuals who may be candidates for isolation or prophylaxis. The technique most commonly used is a solid-phase enzyme-linked immunosorbent assay. This assay, however, often lacks sensitivity and specificity and does not detect antibody in people who are immune, and sometimes yield false-positive results in susceptible individuals. Several more sensitive techniques have been developed to measure humoral responses to VZV. These include an immunofluorescence assay for antibody to VZV-induced membrane antigens (fluorescent antibody to membrane antigen) that reliably distinguishes immune from susceptible adults and a latex agglutination test that is comparable in sensitivity and specificity to fluorescent antibody to membrane antigen assays but is much simpler to perform.[36]

COMPLICATIONS

Complications of Varicella

In the normal child, varicella is rarely complicated. The most common complication is the secondary bacterial infection of skin lesions, usually by staphylococci or streptococci, which may produce impetigo, furuncles, cellulitis, erysipelas, and, rarely, gangrene.[37] These local infections often lead to scarring and, rarely, to septicemia with metastatic infection of other organs. Bullous lesions may develop when vesicles are superinfected by staphylococci that produce exfoliative toxins. Invasive group A streptococcal infections are particularly virulent. In the absence of varicella vaccination, up to one-third of invasive group A streptococcal infections are associated with varicella; they usually occur within 2 weeks of the onset of the varicella rash.[38] Widespread varicella vaccination appears to have markedly reduced the percentage of invasive group A streptococcal hospitalizations associated with varicella in the United States.[39]

Secondary bacterial pneumonia, otitis media, and suppurative meningitis are rare complications and typically respond to appropriate antibiotic therapy. However, bacterial superinfection is common and potentially life-threatening in leukopenic patients. Other complications reflect a basic defect in the capacity of the host to limit VZV replication and dissemination.[40]

In adults, fever and constitutional symptoms are more prominent and prolonged, the rash of varicella is more profuse, and complications are more frequent.[40] High rates of complications have been reported in adults not born in the United States (i.e., adults born in Mexico).[41] Primary varicella pneumonia is the major complication of adult varicella. Some patients are virtually asymptomatic, but others develop severe respiratory embarrassment, with cough, dyspnea, tachypnea, high fever, pleuritic chest pain, cyanosis, and hemoptysis 1 to 6 days after onset of the rash. The severity of the symptoms usually exceeds the physical findings, but the roentgenogram typically reveals diffuse, peribronchial nodular densities throughout both lung fields with a tendency to concentrate in the perihilar regions and at the bases. The mortality in adults with frank varicella pneumonia has been estimated to be between 10 percent and 30 percent, but it is less than 10 percent if immunocompromised patients are excluded.[42]

TABLE 194–1
Complications of Herpes Zoster

CUTANEOUS	VISCERAL	NEUROLOGIC
• Bacterial superinfection	• Pneumonitis	• Postherpetic neuralgia
• Scarring	• Hepatitis	• Meningoencephalitis
• Zoster gangrenosum	• Esophagitis	• Transverse myelitis
• Cutaneous dissemination	• Gastritis	• Peripheral nerve palsies
	• Pericarditis	• Motor
	• Cystitis	• Autonomic
	• Arthritis	• Cranial nerve palsies
		• Sensory loss
		• Deafness
		• Ocular complications
		• Granulomatous angiitis (causing contralateral hemiparesis)

Varicella during pregnancy is a threat to both mother and fetus.[43] Disseminated infection and varicella pneumonia may result in maternal death, but neither the incidence nor the severity of varicella pneumonia appear to be significantly increased by pregnancy. The fetus may die as a consequence of premature labor or maternal death caused by severe varicella pneumonia, but varicella during pregnancy does not, otherwise, substantially increase fetal mortality. Nevertheless, even in uncomplicated varicella, maternal viremia can result in intrauterine (congenital) VZV infection, and a characteristic constellation of congenital abnormalities.[43] Perinatal varicella (i.e., varicella occurring within 10 days of birth) is more serious than varicella in infants infected even a few weeks later.

The morbidity and mortality of varicella are markedly increased in immunocompromised patients. In these patients, continued virus replication and dissemination result in a prolonged high-level viremia, a more extensive rash, a longer period of new vesicle formation, and clinically significant visceral dissemination. Immunosuppressed and glucocorticoid-treated patients may develop pneumonia, hepatitis, encephalitis, and hemorrhagic complications of varicella, which range in severity from mild febrile purpura to severe and often fatal purpura fulminans and "malignant" varicella.

CNS complications of varicella occur in fewer than 1 in 1000 cases; they include several distinct syndromes. Varicella-associated Reye syndrome (acute encephalopathy with fatty degeneration of the liver) typically occurs 2 to 7 days after the appearance of the rash. In the past, from 15 percent to 40 percent of all cases of Reye syndrome occurred in association with varicella, particularly when aspirin was administered for fever, with mortality as high as 40 percent.[44] Acute cerebellar ataxia is more common than the other neurologic complications of varicella, occurring in 1 in 4000 cases, and is more benign.[45] Encephalitis is much less common, occurring in 1 in 33,000 cases, but it frequently causes death or permanent neurologic sequelae. The pathogenesis of cerebellar ataxia and encephalitis remains obscure, but in many cases it is possible to detect VZV antigens, VZV antibodies, and VZV DNA in the cerebrospinal fluid of patients, suggesting direct infection of the CNS.[35]

Although elevated aminotransferase levels are common, clinical hepatitis is rare except as a complication of progressive varicella. Other rare complications of varicella include myocarditis, glomerulonephritis, orchitis, pancreatitis, gastritis and ulcerative lesions of the bowel, arthritis, Henoch-Schönlein vasculitis, optic neuritis, keratitis, and iritis. The pathogenesis of many of these complications has not been delineated, but direct parenchymal or endovascular VZV infection, or vasculitis induced by VZV antigen-antibody complexes, appear to be responsible in most cases.

Complications of Herpes Zoster (Table 194-1)

The sequelae of herpes zoster include cutaneous, ocular, neurologic, and visceral complications. Most complications of herpes zoster are associated with the spread of VZV from the initially involved sensory ganglion, nerve, or skin, either via the bloodstream or by direct neural extension. The rash may disseminate after the initial dermatomal eruption has become apparent. When immunocompetent patients are carefully examined, it is

not uncommon to have at least a few vesicles in areas distant from the involved and immediately adjacent dermatomes. The disseminated lesions usually appear within a week of the onset of the segmental eruption and, if few in number, are easily overlooked. More extensive dissemination (with 25 to 50 lesions or more), producing a varicella-like eruption (generalized herpes zoster; see Fig. 194-7), occurs in 2 percent to 10 percent of unselected patients with localized zoster, most of whom have immunologic defects as a result of acquired immunodeficiency, as seen with HIV infection, underlying malignancy (particularly lymphomas), or immunosuppressive therapy. If the rash spreads widely from a small, painless area of herpes zoster, the initial dermatomal presentation may go unnoticed, and the ensuing disseminated eruption may be mistaken for varicella.

When the dermatomal rash is particularly extensive, as it often is in severely immunocompromised patients, there may be superficial gangrene with delayed healing and subsequent scarring (see Fig. 194-7B). Secondary bacterial infection may also delay healing and cause scarring.

The eye is involved in 20 percent to 70 percent of patients with ophthalmic zoster, with a wide range of possible complications.[31] VZV is also the principle cause of acute retinal necrosis, a fulminant sight-threatening disease observed primarily in otherwise healthy individuals.[46]

Herpes zoster may be attended by a variety of neurologic complications (see Table 194-1), of which PHN is the most common and important.[47] PHN has been variably defined as any pain after rash healing or any pain 1 month, 3 months, 4 months, or 6 months after rash onset, with most recent definitions focusing on 90 to 120 days after rash onset.[48,49] In clinic and community studies, the overall incidence of PHN is 8 percent to 15 percent, depending on the definition (see Fig. 194-1).[28,50,51] Age is the most significant risk factor for PHN (see Fig. 194-1). Clinically significant pain lasting 3 months or more is rare in immunocompetent persons younger than 50 years of age, but complicates 12 percent to 15 percent of cases of herpes zoster in persons 60 years of age and older.[14] Other risk factors for PHN include the presence of prodromal pain, severe pain during the acute phase of herpes zoster, greater rash severity, more extensive sensory abnormalities in the affected dermatome and, possibly, ophthalmic (as opposed to thoracic or abdominal) herpes zoster.[52] Increasing age, greater acute pain severity, presence of prodromal pain, and greater rash severity have each been reported to be independent predictors of PHN.[49] The positive predictive value of each factor alone was low, but, together, the positive predictive value was almost 50 percent. Conversely, 90 percent to 95 percent of patients with herpes zoster who had none of these risk factors developed PHN. PHN usually remits spontaneously over several months but, as with PHN itself, the risk of long-lasting PHN also increases with increasing age.

Patients with PHN may suffer from constant pain (described as *burning, aching, throbbing*), intermittent pain (*stabbing, shooting*), and/or stimulus-evoked pain, including allodynia (*tender, burning, stabbing*). Allodynia (pain elicited by stimuli that are normally not painful) is a particularly disabling component of the disease that is present in approximately 90 percent of patients with PHN. Patients with allodynia may suffer severe pain after even the lightest touch of the affected skin by things as trivial as a breeze or a piece of clothing. These subtypes of pain may produce disordered sleep, depression, anorexia, weight loss, chronic fatigue, and social isolation, and they often interfere with dressing, bathing, general activity, traveling, shopping, cooking, and housework.

TREATMENT

Antiviral Agents

The nucleoside analogues acyclovir, famciclovir, valacyclovir, and brivudin and the pyrophosphate analog foscarnet show efficacy in treating VZV infections. Acyclovir is a guanosine analog that is selectively phosphorylated by VZV thymidine kinases (it is a poor substrate for cellular thymidine kinase) and thus is concentrated in infected cells. Cellular enzymes then convert acyclovir monophosphate to acyclovir triphosphate, which interferes with viral DNA synthesis by inhibiting viral DNA polymerase. VZV is approximately 10-fold less sensitive to acyclovir than HSV (see Chap. 232).

Two prodrugs, valacyclovir and famciclovir, are better and more reliably absorbed than acyclovir after oral administration. Thus, they produce much higher blood levels of antiviral activity and permit less frequent dosing than acyclovir.

Because of their superior pharmacokinetics and the lower sensitivity of VZV compared with HSV, famciclovir, or valacyclovir are preferred to acyclovir for oral therapy of VZV infections. Acyclovir-resistant varicella and herpes zoster have been documented in patients with advanced AIDS (see Fig. 194-9). Because of the mechanism of acyclovir resistance in VZV (mutations in the viral thymidine kinase gene), these infections are cross-resistant to ganciclovir, valacyclovir, famciclovir, and penciclovir. They usually respond to foscarnet, 40 mg intravenously every 8 hours; however, the infections commonly recur after treatment has ended.

Treatment of Varicella

TOPICAL THERAPY In normal children, varicella is generally benign and self-limited. Cool compresses or calamine lotion locally, oral antihistamines, and tepid baths with baking soda or colloidal oatmeal (3 cups per tub of water) may relieve itching. Creams and lotions containing glucocorticoids and occlusive ointments should not be used. Antipyretics may be needed, but salicylates must be avoided because of their association with Reye syndrome.[44] Minor bacterial infections are treated with warm soaks. Bacterial cellulitis requires systemic antimicrobial therapy that is effective against *Staphylococcus aureus* and group A β-hemolytic streptococcus.

ANTIVIRAL THERAPY ***Normal Children.*** (Table 194-2) A large randomized, controlled trial of acyclovir treatment of healthy children 2 to 12 years of age found that early treatment (within 24 hours of the appearance of rash) with oral acyclovir (20 mg/kg four times a day for 5 days) modestly reduced the maximum number of lesions, the time to cessation of new lesion formation, and the duration of the rash, fever, and constitutional symptoms when compared with placebo.[53] Treatment initiated more than 24 hours after rash onset was not effective. Because varicella is a relatively benign infection in children and the clinical benefits of treatment are modest, it does not require routine acyclovir treatment.[54] However, many have favored its use when cost is not a concern, when it can be begun in time to benefit the patient (within 24 hours of rash onset), and when there is a perceived need to speed resolution of the infection so that parents can comfortably return to work. Because secondary cases among susceptible children in the household are generally more severe

TABLE 194–2
Treatment of Varicella in the Normal and Immunocompromised Patient

PATIENT GROUP	REGIMEN
Normal	
Neonate	Acyclovir, 500 mg/m^2 q8h × 10 days
Child	Symptomatic treatment alone, or acyclovir, 20 mg/kg PO qid × 5 days
Adolescent, adult, or glucocorticoids used	Acyclovir, 800 mg PO 5×/day × 7 days
Pneumonia, pregnancy	Acyclovir, 800 mg PO 5×/day × 7 days, or acyclovir, 10 mg/kg IV q8h × 7 days
Immunocompromised	
Mild varicella or mild compromise	Acyclovir, 800 mg PO 5×/day × 7–10 days
Severe varicella or severe compromise	Acyclovir, 10 mg/kg IV q8h × 7 days or longer
Acyclovir resistant (advanced acquired immunodeficiency syndrome)	Foscarnet, 40 mg/kg IV q8h until healed

than the index cases, and because early initiation of treatment is more readily accomplished in secondary cases, treatment with acyclovir seems reasonable for such secondary cases.

Normal Adolescents and Adults. A randomized, controlled trial of acyclovir treatment of healthy adolescents 13 to 18 years of age found that early treatment with oral acyclovir (800 mg five times a day for 5 days) reduced the maximum number of lesions and time to cessation of new lesion formation compared with placebo.[55] A randomized, placebo-controlled trial of oral acyclovir in healthy young adults with varicella showed that early treatment (within 24 hours of rash onset) with oral acyclovir (800 mg five times a day for 7 days) significantly reduced the time to crusting of lesions, the extent of disease, and duration of symptoms and fever.[42] Thus, routine treatment of varicella in adults seems reasonable. Although not tested, it is likely that famciclovir, 500 mg orally every 8 hours, or valacyclovir, 1000 mg orally every 8 hours, would be convenient and appropriate substitutes for acyclovir in normal adolescents and adults. Many physicians do not prescribe oral acyclovir in uncomplicated varicella during pregnancy because the risk to the fetus of treatment is unknown. Other physicians recommend oral acyclovir for infections in the third trimester when organogenesis is complete, when there may be a heightened risk of varicella pneumonia, and when infection can be spread to the newborn. Intravenous acyclovir is often considered for pregnant women with varicella who have extensive cutaneous and/or systemic disease.

Complications of Varicella in Normal Persons. Uncontrolled trials in immunocompetent adults with varicella pneumonia suggest that early treatment (within 36 hours of hospitalization) with intravenous acyclovir (10 mg/kg every 8 hours) may reduce fever and tachypnea and improve oxygenation.[56] Other serious complications of varicella in the immunocompetent host, such as encephalitis, meningoencephalitis, myelitis, and ocular complications, should be treated with intravenous acyclovir.

Immunocompromised Patients. Controlled trials in immunocompromised patients with varicella demonstrated that treatment with intravenous acyclovir decreased the incidence of life-threatening visceral complications when treatment was initiated within 72 hours of rash onset.[57] Immune compromise, however, is a continuum ranging from minimal to severe. Intravenous acyclovir has been the standard of care for varicella in patients with substantial immunodeficiency. Although oral therapy with famciclovir or valacyclovir might suffice for patients with mild degrees of immune impairment, there are no controlled clinical trials to guide the decision.

Treatment of Herpes Zoster

TOPICAL THERAPY During the acute phase of herpes zoster, the application of cool compresses, calamine lotion, cornstarch, or baking soda may help to alleviate local symptoms and hasten the drying of vesicular lesions. Occlusive ointments should be avoided, and creams or lotions containing glucocorticoids should not be used. Bacterial superinfection of local lesions is uncommon and should be treated with warm soaks; bacterial cellulitis requires systemic antibiotic therapy. Topical treatment of the herpes zoster rash with antiviral agents is not effective.

ANTIVIRAL THERAPY The major goals of therapy in patients with herpes zoster are to (1) limit the extent, duration, and severity of pain and rash in the primary dermatome; (2) prevent disease elsewhere; and (3) prevent PHN.

Normal Patients. Table 194-3 lists the current recommendations for treatment of herpes zoster. Randomized controlled trials indicate that oral acyclovir (800 mg five times a day for 7 days), famciclovir (500 mg every 8 hours for 7 days), and valacyclovir (1 g three times a day for 7 days) reduce time to rash healing, and the duration and severity of acute pain in older adults with herpes zoster who are treated within 72 hours of rash onset. In some studies, the duration of chronic pain was also reduced, but the U.S. Food and Drug Administration (FDA) has not approved these agents for the prevention of PHN.[28,58,59] Randomized controlled trials comparing acyclovir with valacyclovir, acyclovir with famciclovir, and valacyclovir with famciclovir demonstrated equivalent results in rash healing, acute pain, and the duration of chronic pain.[60–62] All three drugs are acceptable

TABLE 194-3
Treatment of Herpes Zoster in the Normal Immunocompromised Patient

PATIENT GROUP	REGIMEN
Normal	
Age < 50 yr	Symptomatic treatment only, or acyclovir, 800 mg/PO 5×/day × 7 days
Age ≥ 50 yr, or with ophthalmic involvement	Acyclovir, 800 mg PO 5×/day × 7 days, or valacyclovir, 1 g PO q8h × 7 days, or famciclovir, 500 mg PO q8h × 7 days
Immunocompromised	
Mild compromise, or human immunodeficiency virus	Acyclovir, 800 mg PO 5×/day × 7–10 days, or valacyclovir or famciclovir
Severe compromise	Acyclovir, 10 mg/kg IV q8h × 7–10 days
Acyclovir resistant (advanced acquired immunodeficiency syndrome)	Foscarnet, 40 mg/kg IV q8h until healed

agents for older adults, with cost and dosing schedule determining the choice of agent. However, the reduced sensitivity of VZV compared with HSV, and the higher and more reliable blood levels of antiviral activity achieved, make famciclovir or valacyclovir preferable to acyclovir for oral treatment of herpes zoster.

Because of the lower risk of PHN, antiviral therapy is less valuable or necessary for treatment of uncomplicated herpes zoster in healthy people younger than 50 years of age. The use of antiviral agents is unproven if treatment is initiated more than 72 hours after rash onset. Nevertheless, we believe that it is prudent to initiate antiviral therapy even if more than 72 hours have elapsed after rash onset in patients who have ophthalmic zoster or who continue to have new vesicle formation.[59]

Ophthalmic zoster represents a special therapeutic challenge because of the risk of ocular complications. Examination by an ophthalmologist should be sought in most cases. Oral acyclovir has been shown in a randomized, controlled trial to be effective in preventing ocular complications of ophthalmic zoster.[63] Famciclovir and valacyclovir appear to have efficacy comparable to that of acyclovir in the treatment of ophthalmic zoster, and are preferred for the reasons cited above.[64,65]

Immunocompromised Patients. A randomized, double-blind, placebo-controlled trial in immunocompromised patients with herpes zoster showed that intravenous acyclovir (500 mg/m^2 every 8 hours for 7 days) halted progression of the disease, both in patients with localized herpes zoster and in patients with cutaneous dissemination before treatment.[66] Acyclovir accelerated the rate of clearance of virus from vesicles and markedly reduced the incidence of visceral and progressive cutaneous dissemination. Pain subsided faster in acyclovir recipients, and fewer reported PHN, but these differences were not statistically significant. Clinical trials comparing intravenous acyclovir with intravenous vidarabine for the treatment of herpes zoster in immunocompromised patients showed that acyclovir was significantly more effective and less toxic.[33,66] In patients with mild immunocompromise and localized herpes zoster, oral acyclovir, valacyclovir, or famciclovir usually suffices.[67,68] A randomized, controlled trial of oral famciclovir versus oral acyclovir in patients with localized herpes zoster after bone marrow or organ transplantation or cancer chemotherapy showed that the two treatments were equivalent in rash healing and loss of acute pain and that both were well tolerated.[68]

ANTI-INFLAMMATORY THERAPY The possibility that PHN might be caused by inflammation of the sensory ganglion and contiguous neural structures provided the rationale for the use of glucocorticoids during the acute phase of herpes zoster in an attempt to further reduce acute pain and prevent PHN. Randomized controlled trials, however, showed that the addition of glucocorticoids to acyclovir did not change the incidence of chronic pain.[69,70] However, glucocorticoids did reduce acute pain in most trials, and in one trial of acyclovir and prednisone, the time to uninterrupted sleep, return to baseline daily activity, and cessation of analgesic therapy was reduced in patients who received glucocorticoids.[70] Consequently, some experts advocate oral glucocorticoids for otherwise healthy older adults whose rash is complicated by moderate to severe pain and who have no contraindications to glucocorticoids. Others believe that the common adverse effects of glucocorticoids argue against their routine use in older patients with herpes zoster. The authors agree and do not recommend the use of glucocorticoids in this setting. Glucocorticoids, in combination with effective antiviral therapy, may improve motor outcomes and acute pain in VZV-induced facial paralysis and cranial polyneuritis, where compression of affected nerves may contribute to disability.

ANALGESICS Greater severity of acute pain is a risk factor for PHN, and acute pain may contribute to central sensitization and the genesis of chronic pain. Therefore, aggressive pain control is both reasonable and humane. The severity of acute herpes zoster pain should be determined using simple standardized pain scales. Clinicians should prescribe nonopiate or opiate analgesics with the goal of limiting the severity of pain to less than 3 or 4 on a 0 to 10 scale, and to a level that does not interfere with sleep. The choice, dosage, and schedule of drugs are governed by the patient's pain severity, underlying conditions, and response to specific drugs. If pain control remains inadequate, regional or local anesthetic nerve blocks should be considered for acute pain control.[71] Although carefully managed opiates, anticonvulsants, and tricyclic antidepressants (TCAs) have demonstrated efficacy in established PHN, their effectiveness when administered during the acute phase of herpes zoster in reducing the incidence, duration, or severity of PHN is not known. This needs to be evaluated in rigorous clinical trials. A randomized controlled trial demonstrated that a single epidural injection of corticosteroids and local anesthetics in the acute phase of herpes zoster did not prevent the subsequent development of PHN.[71]

Treatment of Postherpetic Neuralgia

Once established, PHN is difficult to treat.[28] Fortunately, it resolves spontaneously in most patients, although this often requires several months (see Fig. 194-1). Clinicians have advocated a wide range of treatments, including many oral and topical medications, epidural injection of local anesthetic and glucocorticoids, acupuncture, biofeedback, subcutaneous injections of triamcinolone, trans-epidermal electric nerve stimulation, spinal cord stimulators, and systemic administration of a variety of compounds, but most have not been validated by controlled trials. However, the topical 5 percent lidocaine patch, gabapentin, pregabalin, opioids, and TCAs have been shown in randomized, controlled trials to be effective in patients with PHN. On average, these agents provide adequate pain relief (defined as reduction of pain to below 4 on a 0 to 10 point scale or by 50 percent on a visual analog or Likert scale) in 30 percent to 60 percent of patients. These modalities are now recommended as first-line, evidence-based pharmacotherapy for PHN in practice management guidelines.[72,73]

TOPICAL THERAPY Topical anesthesia delivered by means of a 5 percent lidocaine patch has been shown in controlled clinical trials to produce significant pain relief in patients with PHN. The 10 cm × 14 cm lidocaine patch contains 5 percent lidocaine base, adhesive, and other ingredients on a polyester backing. It is easy to use and is not associated with systemic lidocaine toxicity.[74] Up to three patches are applied over the affected area for 12 hours a day. The disadvantages of the patch are application site reactions, such as skin redness or rash, and substantial cost. EMLA (eutectic mixture of local anesthetics) cream applied once a day over the affected area under an occlusive dressing is an alternative method of delivering topical anesthesia.

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide), an extract of hot chili peppers, is a chemical known to deplete substance P, an important endogenous neuropeptide that acts as a chemomediator of nociceptive impulses from the

periphery to the CNS. A small clinical trial of topical capsaicin for 4 weeks in patients with PHN demonstrated significant effects of this therapy on pain, with 75 percent of patients experiencing substantial pain relief.[75] Unfortunately, the ointment burns too much to be tolerated by many patients. In the authors' experience, capsaicin is rarely effective in patients with PHN.

ORAL AGENTS Gabapentin has been shown to produce moderate or greater pain relief in 41 percent to 43 percent of patients with PHN compared to 12 percent to 23 percent in patients receiving placebo.[76,77] Frequent adverse effects of gabapentin include somnolence, dizziness, and peripheral edema. Pregabalin has been shown to produce 50 percent or greater pain relief in 50 percent of patients with PHN compared to 20 percent in placebo recipients.[78] Dizziness, somnolence, and peripheral edema were the most common adverse effects reported with this medication.[78,79] Pregabalin has a less complicated dose titration schedule and a faster onset of action than gabapentin.

TCAs have been shown to produce moderate to good pain relief in 44 percent to 67 percent of elderly patients with PHN in several randomized, controlled trials.[72,73] Nortriptyline and desipramine are preferred alternatives to amitriptyline because they cause fewer cardiac adverse effects, sedation, cognitive impairment, orthostatic hypotension, and constipation in the elderly.[80]

Treatment with scheduled opioids may also reduce PHN. In a randomized, placebo-controlled crossover trial of sustained-release oxycodone in patients with PHN, patients reported significant pain relief when treated with opioid compared to placebo.[81] In a crossover study in patients with PHN, both controlled-release morphine and TCAs provided significant pain relief compared to placebo.[82] In this trial, patients preferred treatment with opioid analgesics to either TCAs or placebo despite a greater incidence of adverse effects and more drop-outs during opioid treatment. In a randomized controlled trial, combination therapy with morphine and gabapentin produced greater pain relief than each agent alone and placebo but with greater adverse effects.[83]

PREVENTION

Prevention of Varicella

VARICELLA VACCINE Several studies conducted in Europe, Japan, and the United States from the early 1970s through the early 1990s demonstrated that live attenuated (Oka strain) VZV vaccines were immunogenic and efficacious in protecting susceptible children against varicella. Although breakthrough cases of varicella were observed after subsequent exposure to wild-type VZV, they were relatively mild.[84] Similar results were obtained in adults when two doses were given 4 to 8 weeks apart. Vaccinated children and adults developed breakthrough varicella caused by wild-type VZV at a rate of 1 percent to 3 percent per year compared to an attack rate of 8 percent to 13 percent per year in unvaccinated children. On the basis of these data, the FDA licensed the Oka/Merck varicella vaccine in the United States in 1995.

The Advisory Committee on Immunization Practices (ACIP) and the American Academy of Pediatrics recommend varicella vaccine for (1) routine childhood immunization, one dose at 12 to 18 months of age; (2) susceptible, immunocompetent children older than 13 years of age, adolescents, and adults, using two doses, 4 to 8 weeks apart; (3) susceptible individuals at high risk for exposure or transmission, including susceptible health care workers, family of immunosuppressed individuals, teachers of children, day care workers, residents and staff in institutional settings, nonpregnant women of childbearing age, and college students; (4) post-exposure prevention and outbreak control; and (5) day care and school entry.[85] The ACIP issued expanded recommendations for varicella vaccine in 2005 to promote wider use for adolescents and adults, in HIV-infected children, and a second dose for outbreak control. These recommendations are under review by the CDC and Department of Health and Human Services (http://www.cdc.gov/vaccines/vpd-vac/varicella/default.htm).

The immunity to varicella induced by varicella vaccine is not as solid as that induced by wild-type VZV infection, and the duration of vaccine-induced immunity is not yet known. However, a high percentage of children followed long-term have remained seropositive.[86] Recent experience in clinical practice indicates that vaccine efficacy in children is modestly lower than that reported in clinical trials, and outbreaks of breakthrough varicella in schools and day care centers do occur.[87–90] In a prospective, population-based study, vaccine effectiveness for prevention of all disease was 78.9 percent (95 percent confidence interval; 69.7 percent to 85.3 percent); for prevention of moderate disease, it was 92 percent (50 to 500 lesions); and for prevention of severe disease and physician visits, it was 100 percent.[89] Interestingly, cases of breakthrough varicella in household settings were half as contagious as cases of varicella in unvaccinated persons, although the minority of breakthrough cases with 50 lesions or more were as contagious as cases in unvaccinated persons. In adults, approximately 20 percent of vaccinees lose detectable antibodies to VZV over time, but continue to be partially protected—breakthrough varicella is characterized by mild disease rather than severe varicella.[87–90]

In 2006, the ACIP recommended routine administration of a second "booster" dose of the varicella vaccine to increase the proportion of the population protected and the duration of immunity.[91] The second dose may be especially important because of the approval by the FDA in 2005 of a combined measles, mumps, rubella and varicella vaccine for routine immunization of children 12 months to 12 years of age.

More than 15,000 adverse events after varicella vaccination were reported to the FDA's Vaccine Adverse Event Reporting System and the CDC from March 1995 through December 2001, over 95 percent of which were non-serious events, mainly minor rashes and injection site reactions.[92] Serious adverse events were rare and, in the majority, a causal relationship between the reported serious adverse event and varicella vaccine could not be established.

Herpes zoster has been reported in vaccinees, but it occurred at a significantly lower frequency than herpes zoster in persons of similar age following varicella caused by wild-type VZV. Cases of laboratory-confirmed herpes zoster in vaccinees from several studies included some cases caused by re-activation of the vaccine virus and others caused by re-activation of wild-type virus acquired before vaccination as a consequence of unrecognized varicella.

POST-EXPOSURE PROPHYLAXIS AND INFECTION CONTROL Patients with varicella and herpes zoster may transmit VZV to susceptible individuals. No preventive measures are recommended for a normal child who has been exposed to varicella or herpes zoster. On the other hand, it is desirable to prevent or modify varicella in high-risk immunocompromised individuals.

Passive immunization with VZIG was an effective preventive strategy but the production of VZIG has been discontinued in the United States. An in-

TABLE 194-4
Criteria for the Use of Investigational Varicella-Zoster Immune Globulin for the Prophylaxis of Varicella

- Immunocompromised patients.
- Neonates whose mothers have signs and symptoms of varicella around the time of delivery (i.e., 5 days before to 2 days after).
- Premature infants born at ≥ 28 wk of gestation who are exposed during the neonatal period and whose mothers do not have evidence of immunity.
- Premature infants born at < 28 wk of gestation or who weigh ≤ 1000 g at birth and were exposed during the neonatal period, regardless of maternal history of varicella disease, or vaccination. Pregnant women.

vestigational VZIG, VariZIG, is available under an investigational new drug application submitted to the FDA. The investigational VariZIG is a purified human immune globulin preparation made from plasma containing high levels of anti-varicella antibodies (immunoglobulin class G). This product can be requested for patients who have been exposed to varicella and who are at increased risk for severe disease and complications.[93] The patient groups recommended by ACIP to receive VariZIG are listed in Table 194-4.

Active immunization with the live attenuated varicella vaccine is also effective in preventing illness or modifying varicella severity in children if used within 3 days after exposure.[94] Whereas protection afforded by zoster immune globulin is transient, varicella vaccine induces long-lasting (active) immunity to VZV and protection against subsequent exposures.

Chemoprophylaxis with acyclovir also has been studied in susceptible children after household exposure to varicella. Children who received post-exposure treatment with acyclovir experienced fewer and less severe cases of varicella than children in the control group.[95] However, appropriate timing is critical, but poorly defined immunity to varicella may not be achieved, especially with early post-exposure treatment, and there are always fears that resistant strains will be selected by promiscuous application of this approach. Hence, post-exposure antiviral chemotherapy is not recommended for routine use in children.

Infection control practices for VZV increase in importance with the age and compromised immune status of the exposed, susceptible individual. There is no need to prevent exposure of susceptible normal children to VZV, but careful isolation procedures should be enforced to prevent infection of susceptible immunocompromised patients, newborn infants, and adults, particularly women of childbearing age. Exposure of susceptible immunocompromised patients to VZV warrants reduction in the dosage of glucocorticoids and other immunosuppressive drugs, and administration of investigational VariZIG. Hospital and long-term care facility personnel without a clear history of varicella or herpes zoster should be tested for antibody to VZV so that appropriate leave from work can be instituted after VZV exposure. In hospitals, airborne and contact precautions are recommended until all lesions are crusted for patients with varicella, immunocompromised patients with localized herpes zoster, and any patient with disseminated herpes zoster.[96] Contact precautions are recommended for immunocompetent patients with localized herpes zoster.

Prevention of Herpes Zoster: Zoster Vaccine

Until universal varicella vaccination greatly reduces the number of people latently infected with wild-type VZV, prevention of herpes zoster must be aimed at preventing re-activation and spread of the latent virus. Long-term suppressive acyclovir treatment is only practical in immunocompromised patients at proven risk of developing herpes zoster within a defined time period, for example, in the year after bone marrow or solid organ transplantation. Other strategies must be devised for the general population.

One approach to the prevention of herpes zoster is the stimulation of immunity to VZV, which wanes in the elderly and in other high-risk individuals.[25] Studies of healthy adults older than 55 years of age with a history of varicella have demonstrated an increase in VZV-specific T lymphocytes and humoral immunity after vaccination with live attenuated VZV vaccine that is similar to the increase observed after an episode of herpes zoster.[97] These findings suggest that vaccination of older persons may be useful in preventing herpes zoster and its complications. A recent Veterans Affairs Cooperative Study tested the hypothesis that vaccination against VZV would decrease the incidence and/or severity of herpes zoster and PHN among older adults.[14] The study enrolled 38,546 adults 60 years of age or older in a randomized, double-blind, placebo-controlled trial of a live attenuated (Oka/Merck) VZV vaccine of much greater potency than the currently licensed varicella vaccine. A total of 957 confirmed cases of herpes zoster (315 among vaccine recipients and 642 among placebo recipients) and 107 cases of PHN (27 among vaccine recipients and 80 among placebo recipients) were included in the efficacy analysis. The zoster vaccine reduced the burden of illness due to herpes zoster by 61.1 percent ($p < 0.001$), reduced the incidence of PHN by 66.5 percent ($p < 0.001$), and reduced the incidence of herpes zoster by 51.3 percent ($p < 0.001$). Reactions at the injection site were more frequent among vaccine recipients but were generally mild. This landmark study showed that the zoster vaccine markedly reduced morbidity from herpes zoster and PHN among older adults. The FDA licensed the zoster vaccine for the prevention of herpes zoster in adults 60 years of age and older in 2006. With the development of the varicella and zoster vaccines, antiviral therapy, and neuropathic pain treatments, clinicians now have multiple effective tools to markedly reduce human suffering from varicella and herpes zoster.

CHAPTER 195

Poxvirus Infections

Wynnis Tom
Sheila Fallon Friedlander

POXVIRUSES

The poxviruses are double-stranded DNA viruses that replicate in the cytoplasm of host cells (Table 195-1). They are the largest animal viruses and can be seen with light microscopy.[1] The poxviruses that cause significant disease in humans are reviewed here. Their effects on hosts range from systemic disease to localized infection to epithelial cell proliferation alone.

ORTHOPOXVIRUS INFECTIONS

Smallpox (Variola)

Variola virus is the pathogen responsible for smallpox, a disease that devastated humankind in catastrophic epidemics for over 3000 years. This poxvirus killed and scarred millions of people in both the Old and New Worlds, affecting entire populations on every continent.

The important discovery of vaccination by Edward Jenner changed the history of this disease. It could now be prevented, and an intensive global effort at vaccination and tracking of cases led to its eradication in 1980.[2] Smallpox was thought to have become a disease of historical interest. Threats of bioterrorism in recent years, however, have renewed the need for knowledge about smallpox and its features, as well as the development of improved vaccines and treatments for use should the disease arise again.

EPIDEMIOLOGY Unlike other diseases caused by members of the family Poxviridae, smallpox affects only humans and thus cannot be acquired from another species. Transmission in the majority of cases is via respiratory droplets and requires close contact. Outbreaks occur in the winter and early spring seasons when conditions of low humidity and low temperature favor survival of the aerosolized virus.[3] Smallpox is less infectious than other diseases spread by the respiratory route, including measles, varicella, and influenza. Secondary attack rates for unvaccinated contacts are estimated to range from 37 percent to 88 percent.[4] Secondary cases are often limited to family members or health care workers. Spread of smallpox is enhanced when there are large quantities of virus in the aerosolized droplets, an increased number and extent of exposures between infected individuals and contacts, and a higher population density. The very young, elderly, and pregnant women are more susceptible to infection.[5] Individuals with more severe clinical disease are reported to be more infectious, but these same people also tend to be toxemic and confined to bed.

Because no significant sub-clinical carrier state exists, eradication was possible and was accomplished in 1980. After its eradication, the responsible virus was supposed to be limited to two laboratories in the United States and the former Soviet Union. Of concern is that these or other unreported stocks of virus may be in the hands of countries or groups with terrorist relationships and could be aerosolized for use as a biologic weapon (see Chap. 213). The possibility of genetically altering smallpox or similar viruses to increase virulence further heightens concerns regarding the misuse of this virus.[6] Routine vaccination of civilians was discontinued in the United States in 1972 and worldwide in the 1980s. Only a small group of U.S. civilians, along with military personnel, have been vaccinated since that time to serve as first-line responders in a possible outbreak. Those who were vaccinated before 1972 have uncertain levels of immunity.[7] Given this, the majority of the population would be susceptible to smallpox disease.

ETIOLOGY AND PATHOGENESIS Smallpox is caused by the variola virus, a linear, double-stranded DNA virus of the genus *Orthopoxvirus*. Variola virus measures approximately 300 by 250 by 200 nm and has an oval or brick-shaped appearance on electron microscopy (see eFig. 195-0.1 in on-line edition). Strains of the virus fall into two main groups, variola major and minor. Although their genomes share approximately 98 percent homology, their virulence is markedly different, with 30 percent or higher mortality associated with the major type and less than 1 percent mortality associated with the minor type.[2,8]

Humans are the only known natural reservoir of variola virus. The disease process begins on close, prolonged exposure to an infected individual. The usual portal of entry is the oropharyn-

POXVIRUSES AT A GLANCE

- Poxviruses are the largest animal viruses; they can cause disease of varying severity in humans.
- Smallpox is the only poxvirus for which humans are the sole reservoir, which allowed its eradication.
- The smallpox vaccine virus, vaccinia, has its own adverse effects.
- Monkeypox is a zoonotic infection endemic in Africa, but it has recently appeared in the Western Hemisphere.
- Milker's nodule and orf mainly cause localized cutaneous infections.
- Molluscum contagiosum is generally a benign cutaneous disease most frequently seen in children and immunocompromised individuals.
- Histopathologic features of poxviral cutaneous lesions include the presence of intracytoplasmic eosinophilic inclusion bodies.

SMALLPOX AT A GLANCE

- Smallpox is an illness with mortality rates of over 30 percent in its major form.
- It is transmitted mainly by the respiratory route; viremia leads to cutaneous and visceral involvement.
- The eruption consists of papules that progress simultaneously to vesicular and pustular lesions in a centrifugal pattern.
- The disease has not been seen since 1978, but the potential use of aerosolized variola virus for bioterrorism is of significant concern.
- Smallpox vaccination has been reinstituted on a selective basis for response in the case of an outbreak.

TABLE 195-1
Poxviruses with Humans as Hosts

Genus	Species	Hosts	Main Portal of Entry	Clinical Features
Orthopoxvirus	Variola virus	Humans	Respiratory tract	High fever and myalgias precede an oropharyngeal enanthem and centrifugal exanthem. Simultaneous progression of skin lesions from macules to papulovesicles, pustules, and crusts, resulting in significant scars. Last reported case in 1978 but a concern for use in bioterrorism.
	Vaccinia virus	Humans	Skin	Used as vaccine for protection against smallpox and monkeypox. Vaccination site progresses from papule to vesicle, pustule, and crust, leaving scar. Adverse events occur when virus spreads locally or in a generalized manner, more severe in individuals with disruption of the skin barrier or immunocompromise.
	Monkeypox virus	Rodents, humans, monkeys, anteaters	Skin	Clinical presentation similar to that of smallpox but more prominent lymphadenopathy and lower mortality.
	Cowpox virus	Rodents, cats, humans, cattle	Skin	Contact with infected animal host gives rise to papule that becomes vesicular, hemorrhagic, pustular, and ulcerative; resulting eschar heals over 3–4 wk with scarring. Pustular stage often is umbilicated with surrounding zone of erythema and edema. Constitutional symptoms and lymphangitis common. Can be extensive or severe if skin barrier disrupted.
Parapoxvirus	Orf virus	Sheep, goats, humans	Skin	Contact with infected animal or fomite leads to papule(s) that forms pustules or nodules with central umbilication and surrounding gray-white or violaceous ring and outer zone of erythema; lesion usually occurs on hand. Lesions become weepy then dry and crust. Healing occurs over 4–8 wk, usually without scarring. Constitutional symptoms and lymphangitis occur less commonly.
	Paravaccinia virus	Cattle, humans	Skin	Transmitted on contact with infected teats or mouths of cattle. Clinical findings and course similar to those of orf; differentiated by their different animal hosts.
	Bovine papular stomatitis virus	Cattle, humans	Skin	Transmitted by contact with infected mouths of cattle. Clinical findings and course similar to those of orf and paravaccinia.
Molluscipoxvirus	Molluscum contagiosum virus	Humans, chimpanzees (one report)	Skin	Discrete firm, dome-shaped papules with central umbilication. Can be extensive in individuals with atopic dermatitis or immunocompromise. Most cases self-resolve in 9–12 mo but lesions often treated to speed resolution; can be persistent/refractory in immunocompromised individuals.
Yatapoxvirus	Tanapox virus	Humans, monkeys	Possibly skin	Uncertain mode of transmission, possible mosquito vector from infected monkeys to humans. Short fever precedes eruption of one to multiple pruritic, indurated papules with surrounding edema. Become necrotic and/or ulcerative then heal within 6 wk with scarring.

geal or respiratory tract, either by inhalation of aerosolized droplets or direct contact with infected mucous membranes.[9] After entry, the virus attaches to respiratory epithelial cells, travels to regional lymph nodes, and replicates at these sites. Transient primary viremia with uptake of the virus by macrophages occurs, and the variola virus spreads to the reticuloendothelial organs, where asymptomatic replication continues. A massive secondary viremia follows and causes the onset of symptoms (the prodromal period). The virus spreads to the skin and mucosa, along with other organs and tissues such as the liver and kidneys.[10] Variola virus is transmissible beginning in the late prodromal phase through aerosolization of viral particles from the oropharynx. It is most infectious during the first 7 to 10 days after onset of the viral rash and remains transmissible until the scabs fall off of skin lesions.[10,11]

Variola virus is less commonly spread via accidental inoculation in the skin, through the conjunctiva, and through contact with infected body fluids or highly contaminated fomites. Rarely, it has been transmitted transplacentally and by long-range airborne or suspended viral particles in enclosed areas.[6]

CLINICAL FINDINGS ***History.*** The infected individual remains asymptomatic during the incubation period of viral replication. A prodrome of high fever [39°C to 41°C (102.2°F to 105.8°F)], chills, myalgias, and severe headache develops within 7 to 17 days of exposure. Average incubation is 12 days for variola major and a few days longer for variola minor. The person usually is severely ill and bedridden during the prodromal period, which lasts 2 to 4 days. Children may develop seizures.[4,9]

Cutaneous Lesions. Evanescent, non-specific urticarial or morbilliform lesions can develop during the prodrome. These occur mainly in previously vaccinated individuals at the vaccination site and the axillae, popliteal, and groin areas.[2] Approximately 1 day after the onset of fever, an enanthem develops. These earliest viral lesions are red macules on the mouth, tongue, and oropharynx that subsequently vesiculate and ulcerate, releasing high concentrations of transmissible virus particles in the respiratory secretions. A skin rash (exanthem) erupts two to several days after the onset of fever, at about the same time the mucosal lesions ulcerate. The fever usually declines with appearance of the rash.[6,12] The exanthem varies depending on viral dose and strain, vaccination status, level of immunity, and nutritional status.[5] The outbreak is categorized into two clinical forms, variola major and variola minor.

Forms of variola major are more common than variola minor. One classification divides variola major into five clinical types.[13] Ordinary smallpox is the most common type and accounts for over 90 percent of cases of smallpox in unvaccinated individuals and 70 percent in those who have been vaccinated. Skin lesions begin as macules on the face and upper extremities that then spread quickly to the trunk and lower extremities. Involvement of all parts of the body, including palms and soles, occurs within 24 to 48 hours. The macules become raised papules within 1 day and then form vesicles, often with central umbilication, after 4 to 5 days (see eFig. 195-0.2 in on-line edition). Fever recurs as the lesions become firm pustules around day 7 (Fig. 195-1) and persists until all lesions have crusted and scabbed at day 14 (Fig. 195-2). Scabs separate by 3 to 4 weeks after the onset of the rash. Key features of smallpox skin lesions are their prominence peripherally on the face and extremities and their simultaneous progression in a centrifugal pattern, with all lesions in any one area exhibiting the same morphology.[9,14] After their resolution, pitted scars ("pockmarks") are often left behind and can be disfiguring (Fig. 195-3). Scarring is most common on the face, where there are larger and more numerous sebaceous glands, which are particularly susceptible to infection and destruction by variola virus.[2]

Modified smallpox has as severe a prodromal illness as ordinary smallpox, but the clinical course of cutaneous lesions is accelerated. Lesions are fewer in number and tend not to progress to vesicles or pustules, crusting by day 10. This form occurs mainly in vaccinated individuals and does not cause death. Flat smallpox (also called *malignant smallpox*) is an uncommon form of variola major in which the macules barely raise. It usually occurs in children and unvaccinated individuals lacking cellular immunity. Those affected become severely ill with toxic fever, and most die with hemorrhagic lesions and pneumonia.[4] The hemorrhagic, or fulminant, type of variola major is equally common in unvaccinated and vaccinated persons. It is divided into two forms, early and late. The early form consists of petechial hemorrhages into the skin or mucous membranes during the prodromal period. Massive hemorrhage from mucosal surfaces leads to death within 8 days of onset, before any appearance of the typical rash of smallpox, with a case fatality of 100 percent. Women, especially if pregnant, are more susceptible to this form. In the late form, hemor-

▲ **FIGURE 195-1** Pustular smallpox lesions with characteristic highest density on the face and extremities. (From the Centers for Disease Control and Prevention Public Health Image Library, Atlanta, GA.)

▲ **FIGURE 195-3** Scars and pockmarks remain after the crusts have fallen off. (From the Centers for Disease Control and Prevention Public Health Image Library, Atlanta, GA, and contributed by J. Noble, Jr., MD.)

▲ **FIGURE 195-2** Crusted lesions on the foot at day 21 of the rash of smallpox. (From the Centers for Disease Control and Prevention Public Health Image Library, Atlanta, GA, and contributed by Paul B. Dean, MD.)

rhage appears after onset of the typical rash, death occurs by 12 days after onset, and men and women are equally affected.[15] The last type of variola major is variola sine eruption, in which vaccinated individuals come in contact with affected individuals and develop fever and other symptoms (e.g., headache, conjunctivitis) but no rash. In this case, the illness lasts 48 hours or less. Serologic studies do show a rise in antibody titers against smallpox virus.[4,13]

Variola minor is clinically indistinguishable from cases of modified smallpox and from cases of ordinary smallpox in which lesions are discrete rather than confluent. At times, the lesions are nonumbilicated. In the pre-eradication period, the diagnosis of variola minor was given only after assessment of the severity of an outbreak, if the case fatality rate was low (1 percent or less).[8] Molecular virologic differentiation between major and minor viral strains is now available.

Related Physical Findings. Variola virus spreads via the blood to affect other non-cutaneous systems. It can infect the metaphysis of growing bones and lead to arthritis in up to 2 percent of affected children. Osteomyelitis occurs less frequently than arthritis. Swelling of the eyelids and a mild conjunctivitis are common findings. Cough and bronchitis may be seen in some cases of smallpox. A degree of encephalopathy often occurs, with symptoms ranging from headache and hallucinations to delirium and psychosis.[2] Gross hematuria can occur with the hemorrhagic type of variola major.[15]

LABORATORY TESTS The white blood cell count may increase as the skin lesions of smallpox become pustules. Severe thrombocytopenia occurs in both early and late hemorrhagic smallpox. A marked decrease in the level of factor V (accelerator globulin) and increase in thrombin time are noted in the early form, likely from disseminated intravascular coagulation. The late form has a smaller degree of these coagulation disturbances.[2]

Histopathology. Skin biopsy specimens from early papules show edema and dilation of the capillaries of the papillary dermis with a perivascular infiltrate of lymphocytes, histiocytes, and plasma cells. Next, the cells of the epidermis become vacuolated and swollen and undergo ballooning degeneration. These vesicles have characteristic intracytoplasmic inclusion bodies called *Guarnieri bodies*. Pustules form with migration of polymorphonuclear cells into the vesicles. Eventually the pustule becomes a crust, with new epithelium growing to repair the surface. Mucous membrane lesions show similar changes but also have extensive necrosis of the epithelial cells leading to rapid ulceration rather than vesiculation.[16]

Special Tests. For diagnosis, specimens (skin lesions, tonsillar swab, blood, skin biopsy) should be collected by someone recently vaccinated and sent to designated high-containment facilities.

Scrapings of skin lesions can be examined via electron microscopy to assess for the typical oval or brick shape of orthopoxviruses. Serologic testing for orthopoxviruses with paired samples can be performed; this identifies the presence of a member of the genus but is not specific for variola virus. Polymerase chain reaction (PCR) methods are used to definitively identify variola virus and can also characterize the viral strain. Variola virus can be cultured in several commonly used cell lines and can be identified by the formation of characteristic pocks on chorioallantoic membranes of chicken embryos.[6,17]

DIFFERENTIAL DIAGNOSIS The exanthem of smallpox is most often confused with that of varicella (chickenpox). Smallpox lesions are centrifugal with simultaneous progression of all lesions. In contrast, varicella lesions have a more truncal (centripetal) distribution, the vesicles are more superficial, and lesions are present at different stages. Varicella also has a shorter disease course, with only a 1- to 2-day prodrome and with all lesions crusting in 4 to 6 days from their initial appearance.[10] Human monkeypox clinically resembles smallpox but often manifests lymphadenopathy. It is a zoonotic disease and is not spread as easily between persons. The morbilliform prodromal rash of smallpox can be confused with measles or coxsackievirus infections. Secondary syphilis should be considered, especially when there are lesions on the palms and soles, but these lesions do not progress. Other eruptions in the differential diagnosis are listed in Box 195-1. The lesions of hemorrhagic smallpox can be similar to those of meningococcemia, severe acute leukemia, and other acute hemorrhagic eruptions such as those associated with coagulopathies.

Box 195-1

Differential Diagnosis of Smallpox and Monkeypox

Most Likely

- Papulovesicular eruption
  - Varicella
  - Disseminated zoster
  - Generalized vaccinia
- Prodromal morbilliform eruption
  - Measles
  - Drug eruption
- Hemorrhagic lesions (smallpox only)
  - Meningococcemia
  - Disseminated intravascular coagulation
- Mucosal lesions
  - Hand-foot-and-mouth disease
  - Stevens-Johnson syndrome

Consider

- Papulovesicular eruption
  - Kaposi varicelliform eruption
  - Eczema vaccinatum
  - Extensive molluscum contagiosum (human immunodeficiency virus infection)
  - Drug eruption
  - Bullous impetigo
  - Pityriasis lichenoides et varioliformis acuta
  - Rickettsialpox
- Prodromal morbilliform eruption
  - Coxsackievirus infection
  - Other viral infections
- Hemorrhagic lesions (smallpox only)
  - Acute leukemia
- Mucosal lesions
  - Oral herpes simplex

Always Rule Out

- Papulovesicular eruption
  - Secondary syphilis
- Hemorrhagic lesions (smallpox only)
  - Acquired coagulopathy
- Mucosal lesions
  - Stevens-Johnson syndrome

COMPLICATIONS Secondary bacterial infection occurs commonly at skin lesions (5 percent of affected individuals) as well as at regional lymph nodes. A temperature spike occurring 3 to 5 days after the start of the prodrome may indicate secondary infection.[12] Keratitis and corneal ulceration, common in malnourished individuals, result in blindness in 1 percent of cases. Either variola virus or bacterial superinfection can lead to respiratory complications, including pneumonia, at day 8 to 10 of illness. Both arthritis and osteomyelitis can lead to limb deformities, including bone shortening, subluxation, and flail joints. Orchitis is less common and usually unilateral. Encephalitis is reported in 0.2 percent of cases.[2]

PROGNOSIS AND CLINICAL COURSE The most common form of variola major, common smallpox, is associated with a mortality rate ranging from less than 10 percent when lesions are discrete to 50 percent to 75 percent when lesions are confluent. Death often occurs between days 10 and 16 of illness. Modified smallpox is associated with less than 10 percent mortality. In contrast, flat smallpox has a case fatality rate of over 90 percent, and hemorrhagic forms have nearly 100 percent mortality. The overall mortality rate for variola major is 30 percent, compared to less than 1 percent for variola minor.[13] Those who survive either disease have lifetime immunity. Death from smallpox is thought to be secondary to toxemia associated with immune complexes and variola antigens along with hypotension/shock and multiorgan failure. Encephalitis is an important factor in death from variola minor but not from variola major.[2,4]

TREATMENT There is no specific treatment for smallpox. A patient suspected of having the disease should be isolated in a negative-pressure room and given supportive care. Precautions should be taken to prevent secondary infection and appropriate antibiotics administered should it occur. Research on antiviral agents is ongoing. Intravenous cidofovir, a nucleotide analog approved for treatment of cytomegalovirus infection, is available from the Centers for Disease Control and Prevention (CDC, Atlanta, GA) through an Investigational New Drug protocol. It has been found to have activity against variola, vaccinia, and other orthopoxviruses in in vitro and animal studies, but clinical data are not yet available.[18] Topical idoxuridine may be used to treat corneal lesions, although its efficacy has not been proven.

PREVENTION Because of the development of lifelong immunity after recovery from natural smallpox infection, the first efforts at prevention were to introduce crusts or fluid from lesions to unaffected individuals to induce mild disease. This process of variolation did reduce morbidity and mortality but also caused full infection and spread in some cases. In 1796, Dr. Edward Jenner developed vaccination, using the cowpox virus to introduce cross-immunity against the variola virus. Vaccinia virus later became the virus used. Vaccination is 90 percent to 96 percent effective in preventing smallpox disease when given before exposure to variola virus. For post-exposure prophylaxis, smallpox vaccination within 2 to 3 days of exposure can protect against severe disease. Vaccination within 4 to 5 days may protect against death.[2,19] Vaccination does not give lifelong immunity, however. The duration and degree of protection over time are subjects of debate. Most estimates suggest that primary vaccination gives full protection for 3 to 5 years and some but declining immunity at 10 years and after. Revaccination may give significant protection for at least 30 years.[11,20]

Vaccinia and Smallpox Vaccination

The vaccinia virus is also of the genus Orthopoxvirus. Its origins are unknown, but it is most similar to the cowpox virus in this family. In the nineteenth century, it replaced cowpox as the virus for smallpox vaccination. Discussion here focuses on its features as the smallpox vaccine, because it is not known to cause natural infection. Because of its significant homology with other poxviruses, vaccinia virus provides not only protection against smallpox but also cross-protection against closely related orthopoxviruses such as monkeypox, camelpox, and cowpox.[2]

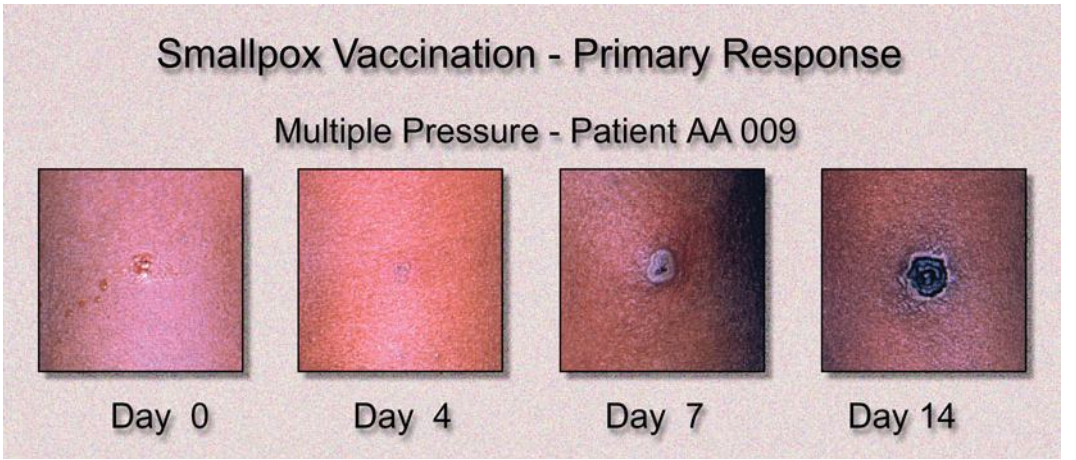
EPIDEMIOLOGY Eradication of smallpox was made possible by intensive tracking of cases of infection with ring vaccination of primary and secondary contacts. The last known case of natural infection was one of variola minor in Somalia in 1977. One final case of accidental laboratory infection occurred in 1978, and the World Health Organization declared eradication in 1980. Routine vaccination of civilians was discontinued in the United States in 1972 and worldwide in the 1980s; vaccination of U.S. military personnel ceased in 1990. With the postal anthrax and World Trade Center attacks in 2001 and other threats of bioterrorism, vaccination was reinitiated in the United States in late 2002 for the military and a small group of voluntary public health and health care workers who would be first-line responders in a possible outbreak.[21]

Vaccination made eradication of smallpox possible, but given that vaccinia is a live virus, it does carry its own set of adverse effects. Most adverse events can occur at any age, but infants and children younger than the age of 5 years are particularly affected. Adverse reactions are 10 times more common in primary vaccination than in revaccination. Individuals with atopic dermatitis can acquire a severe eruption, eczema vaccinatum, from contacts more often than from direct vaccination.[4]

ETIOLOGY AND PATHOGENESIS Smallpox vaccination involves the introduction of vaccinia virus into the outer layers of the intact skin. There are many strains of the virus, with the less pathogenic New York City Board of Health and Lister-Elstree strains being used during the global smallpox eradication campaign. The currently licensed vaccine in the United States is a lyophilized, calf-lymph vaccine (Dryvax, Wyeth Laboratories, Marietta, PA) produced from the New York City Board of Health vaccinia strain.[11] After injection of vaccine into the skin by a bifurcated needle (see eFig. 195-3.1 in on-line edition), the virus rapidly multiplies locally and occasionally in regional lymph nodes. Viable, transmissible vaccinia virus is present at the resulting skin lesion until the lesion scabs and separates. The infection heals with scarring at the injection site. It is usually limited by the host response with the development of antibody- and cell-mediated immunity.[10] Adverse events and complications occur when the virus spreads outside of the local area, either by transfer or a host inability to contain the response.

CLINICAL FINDINGS ***History.*** Soreness is almost universal at the vaccination site. Systemic symptoms can occur and are considered normal reactions. These include fever [higher than 37.7°C (99.9°F), more common in children], chills, headache, myalgias, and malaise. They generally peak at days 8 to 10 and last 1 to 3 days. Approximately 30 percent of vaccinees feel too ill to carry out normal activities.[22]

Cutaneous Lesions. The normal local skin reaction to vaccination begins 3 to 5 days after administration with a papule that then develops into a vesicle (Jennerian vesicle) followed by a pustule around day 7 to 9. It crusts and scabs over at day 10 to 14, with the scab detaching at day 17 to 21 and leaving a residual scar (Fig. 195-4). A robust take, in which the local reaction is 10 centimeters or larger in diameter, occurs in 2 percent to 16 percent of first-time vaccinees (see eFig. 195-4.1 in on-line edition). This can be mistaken for bacterial cellulitis, but it occurs 8 to 10 days after vaccination and self-improves without antibiotic therapy in 24 to 72 hours.[23] In contrast, secondary bacterial infections



▲ **FIGURE 195-4** Normal progression seen at the smallpox vaccination site. (From the Centers for Disease Control and Prevention, Atlanta, GA.)

usually occur within the first 5 days or 30 days after vaccination.

Previously vaccinated individuals have a milder reaction with an accelerated time course. Those with substantial residual immunity may have only erythema with revaccination. Minor local reactions that can occur near the primary site include nearby satellite lesions that progress at the same rate, lymphadenopathy/lymphangitis, and intense surrounding erythema or edema.[11] Vaccinia can be inadvertently inoculated into other body sites (see eFig. 195-4.2 in on-line edition), and secondary reactions such as erythema multiforme can occur (see eFig. 195-4.3 in on-line edition) (see next section).

Adverse Reactions. Adverse cutaneous reactions associated with smallpox vaccination can be localized or generalized. Secondary bacterial infection, usually by staphylococci and group A streptococci, can occur at the primary site. Accidental vaccinia is the autoinoculation of vaccinia virus from the vaccination site to another area. It is the most common adverse event seen and accounts for about half of all such events. The most common sites of transfer are the eyelids (see eFig. 195-4.2 in on-line edition), nose, mouth, and genitalia. Lesions are seen at these areas 7 to 10 days after vaccination, and they usually follow the time course of the original primary lesion. The lesions may be more attenuated if autoinoculation occurs more than 5 days after vaccination as the host immune response is developing.[24] Accidental inoculation to the eyes can lead to conjunctivitis, keratitis, or iritis.

Generalized adverse eruptions can be non-specific, immune-mediated reactions, including morbilliform and roseola-like rashes. Hypersensitivity reactions such as erythema multiforme can also develop (see eFig. 195-4.3 in on-line edition). These rashes typically self-resolve over several days. In rare cases Stevens-Johnson syndrome can develop and require hospitalization and supportive care. Vaccination can also lead to generalized vaccinia, in which macular, papular, or, less commonly, vesicular lesions can be disseminated to normal skin without evidence of autoinoculation. Generalized vaccinia can be limited or extensive and can occur anywhere on the body (Fig. 195-5). It is thought be caused by spread of vaccinia virus via the bloodstream and usually occurs 6 to 9 days after primary vaccination. The lesions progress as do other vaccinial lesions. The condition is self-limited in immunocompetent individuals but is often more severe in the setting of immunodeficiency.[25]

Eczema vaccinatum is the localized or generalized spread of vaccinia virus in individuals affected with atopic dermatitis or, less frequently, other chronic dermatoses. The individual feels ill with fever, malaise, and lymphadenopathy. It can occur in the primary vaccinee with onset usually at the same time or soon after the appearance of lesions at the vaccination site. Papules, pustules, or vesicles can occur anywhere on the body but have a predilection for areas with prior lesions of atopic dermatitis. Lesions can range from several to hundreds; the most serious cases result in substantial loss of the skin barrier. The severity of eczema vaccinatum is independent of the severity or activity of the atopic dermatitis or other underlying skin disease. It can also be acquired by secondary transmission, usually by children in contact with a recently vaccinated family member (Fig. 195-6).[9,26]

Vaccination of individuals with severe impairment of the immune system leads to progressive vaccinia, also called *vaccinia necrosa* and *vaccinia gangrenosa*. In these individuals, the primary lesion at the site of vaccination does not heal but instead enlarges and progresses to a painless ulcer with central necrosis (see eFig. 195-6.1 in on-line edition). Viral replication is not halted and viremia occurs, with similar metastatic lesions developing at distant sites on the skin, bone, and/or viscera. Most cases have occurred in individuals with defective cell-mediated immunity, but cases have also been described in those with humoral defects.[4] The degree of immune impairment may correlate with the risk for development of progressive vaccinia, but the precise protective level is unknown.[23]

▲ **FIGURE 195-5** Generalized vaccinia in an 8-month-old infant. (From the Centers for Disease Control and Prevention Public Health Image Library, Atlanta, GA, and contributed by Allen W. Mathies, MD, of the California Emergency Preparedness Office, Immunization Branch.)

◀ **FIGURE 195-6** Eczema vaccinatum with lesions in areas of active dermatitis.

Related Physical Findings. In addition to the skin, other organ systems can be affected by smallpox vaccination. Central nervous system complications occur in previously healthy individuals. Postvaccinial encephalopathy most commonly affects children younger than 2 years of age, causing cerebral edema without inflammation. Symptoms develop abruptly 6 to 10 days after vaccination and can include fever, headache, seizures, hemiplegia, aphasia, and transient amnesia. Postvaccinial encephalitis and encephalomyelitis occur 11 to 15 days after vaccination, with fever, malaise, vomiting, and headache that progress to confusion, seizures, amnesia, spinal cord signs, and coma.[27] These complications are thought to be autoimmune reactions, because vaccinia virus is not found in sampled cerebrospinal fluid or tissue. Higher rates of central nervous system complications are seen with non–New York City Board of Health vaccinia strains. Other neurologic events reported to occur in temporal association with smallpox vaccination include transverse myelitis, paralysis, seizures, and polyneuritis, but causality has not been established.[2,28]

Cardiac events, including myopericarditis, can also occur. Since reinitiation of smallpox vaccination in the United States in 2002, ischemic cardiac events as well as nonischemic dilated cardiomyopathy have been reported for the first time. The rate of myopericarditis among U.S. military vaccinees is elevated 3.6-fold compared to the rate in unvaccinated personnel, which suggests but does not prove causality.[29] Whether the ischemic and dilated cardiomyopathy conditions are caused by smallpox vaccination or are coincidental occurrences is not yet clear.[9]

LABORATORY TESTS Neutralizing antibodies and cellular immunity start to become detectable around day 7 of vaccination. Vaccinia virus can be detected at the primary vaccination site and sites of accidental vaccinia, generalized vaccinia, eczema vaccinatum, and progressive vaccinia.

COMPLICATIONS Vaccinia keratitis can cause corneal ulceration with scarring and visual loss. Eczema vaccinatum can be so severe that the affected individual loses a substantial amount of the cutaneous barrier, much like a burn victim. Individuals with postvaccinial encephalopathy, encephalitis, or encephalomyelitis may recover in approximately 2 weeks, but one-fourth of survivors are left with residual sequelae (mental impairment, paralysis).[30]

Smallpox vaccination of a woman during pregnancy can rarely lead to fetal, or congenital, vaccinia, with about 50 cases reported in the literature. Transmission to the fetus can occur at any time during the pregnancy and results in lesions on the skin, mucous membranes, and placenta. The appearance can be similar to that of generalized vaccinia or progressive vaccinia, and lesions can be extensive (see eFig. 195-6.2 in on-line edition). It is unknown whether infection is through the blood or by direct contact with infected amniotic fluid. No reliable intrauterine diagnostic test exists to confirm fetal infection.[28]

PROGNOSIS AND CLINICAL COURSE Potentially fatal adverse reactions from smallpox vaccination include eczema vaccinatum, progressive vaccinia, and postvaccinial central nervous system disease. Progressive vaccinia is universally fatal if untreated. Central nervous system complications have a 15 percent to 25 percent case fatality rate. Most fatal cases from secondary transmission occur in infants younger than 1 year of age and are from contact eczema vaccinatum. Fetal vaccinia often results in fetal or neonatal death.[9,30]

Myopericarditis was reported in the pre-eradication era and was thought to cause the rare cases of cardiac-associated deaths after vaccination. It has also been reported since reinstitution of vaccination in the United States in 2002, but no deaths have occurred to date. Several ischemic cardiac deaths have occurred.[31]

TREATMENT Symptomatic treatment alone is needed for the normal systemic symptoms and minor local events (robust take, lymphangitis, intense erythema or edema) occurring after vaccination. Secondary infections should be treated with appropriate antimicrobial therapy. Uncomplicated cases of accidental vaccinia do not require therapy. Extensive cases can be treated by administration of vaccinia immune globulin (VIG) or cidofovir to speed recovery. VIG is a sterile solution of the immunoglobulin fraction of plasma from persons vaccinated with the smallpox (vaccinia) vaccine. Topical antiviral medications can be used in moderate to severe cases of ocular vaccinia. Vidarabine ointment has been effective in the past, but supplies are likely very limited because it is no longer manufactured. Trifluridine eyedrops can be tried, but there are no clinical data regarding successful treatment. It should not be administered for longer than 14 days, because it can cause a reversible superficial punctate keratopathy. VIG can exacerbate vaccinia keratitis and should not be used in cases of isolated keratitis.[23]

Generalized vaccinia usually requires only symptomatic treatment, but if it is severe, such as in those with immunodeficiency, VIG may be of benefit. With severe eczema vaccinatum in which there is significant loss of the skin barrier, meticulous skin care with volume and electrolyte repletion is needed. Early treatment with VIG has been shown to reduce mortality from eczema vaccinatum (fatality rate was reduced from 30 percent to 40 percent to 7 percent).[23] VIG administration and care in

an intensive care unit also reduced the case fatality rate of progressive vaccinia from 100 percent to 20 percent to 30 percent.[30] Treatment for neurologic complications is supportive care; there is no evidence that VIG is effective in these cases. Given the rarity of fetal vaccinia, inadvertent vaccination during pregnancy is not ordinarily a reason for termination. There is also no indication for prophylactic administration of VIG to the pregnant woman, but it might be considered for a viable infant born with vaccinial lesions.[25,32]

PREVENTION The vaccination site should be covered with gauze and an overlying semi-permeable membrane bandage. Taking contact precautions and washing the hands frequently when caring for the site should be emphasized.

A higher proportion of persons are at risk for adverse vaccine reactions today than during the era of routine smallpox vaccination. Atopic dermatitis as well as immunocompromise have increased in prevalence.[33] To reduce the incidence of adverse events, smallpox vaccination in the United States is currently limited to the select groups discussed earlier (see Epidemiology). There are no absolute contraindications to vaccination should an actual outbreak occur. Current recommendations and contraindications in the absence of a known exposure risk are listed in Box 195-2. More detailed guidelines are available from the CDC.

Safer vaccines are under research and development to prevent the adverse effects and complications of smallpox vaccination. Tissue and cell-culture vaccines, including ACAM1000 and ACAM2000 (Acambis, Cambridge, MA) and cell-cultured smallpox vaccine (DynPort, Frederick, MD), are in clinical trial. Production involves the sterile growth of cell lines that host the vaccinia virus. By increasing purity and reducing contamination, these vaccines may help avoid the allergic and autoimmune reactions thought to stem from the nonvaccinia material in calf-lymph vaccines. These reactions include hypersensitivity reactions, erythema multiforme, and possibly the encephalitic and cardiac reactions. Because they are similar in immunogenicity to Dryvax, however, they are not necessarily safer with regard to vaccinia-associated adverse events.[20]

A second strategy is the development of vaccines using strains of vaccinia attenuated by serial passage through nonhuman tissue. This leads to a reduced capacity for replication and potentially reduced adverse effects. The modified vaccinia Ankara strain is produced by passage through chick embryo fibroblasts. No significant complications were reported with its use in Germany and Turkey in the 1970s to help people at high risk for side effects (such as those with atopic dermatitis/eczema, etc.) tolerate the standard smallpox vaccine; efficacy against actual disease, however, was never proven. The LC16m8 vaccine also uses an attenuated vaccinia strain, with passage of the Lister vaccinia strain through rabbit kidney cells. Studies in Japan in the 1960s and 1970s found it to have less local and systemic reactogenicity but similar protective immunity to conventional smallpox vaccines. Further clinical study of modified vaccinia Ankara and Lc16m8 vaccines is under way.[6,9] Finally, advances in modern molecular immunology have introduced the idea of subunit vaccines with genes or proteins from vaccinia virus. These are under laboratory investigation as future vaccine candidates.[10,34]

Box 195-2

Vaccination Against Smallpox Using Vaccinia Virus

INDICATIONS

- Pre-exposure prevention of smallpox
- Post-exposure prophylaxis against severe disease and death

CONTRAINDICATIONS

- Contraindications in the pre-exposure setting
  - Presence of atopic dermatitis or other eruptions with disruption of the skin barrier
  - Immunosuppression, including human immunodeficiency virus infection/acquired immunodeficiency syndrome, inherited and acquired cellular immunodeficiencies, and severe autoimmune disease
  - Known heart disease or significant cardiac risk factors
  - Serious allergy to components of the vaccine diluent (polymyxin, neomycin, streptomycin, chlortetracycline)
  - Age younger than 12 mo
  - Pregnancy or breast-feeding
- Contraindications in the post-exposure setting
  - No absolute contraindications in the case of an actual smallpox outbreak

Monkeypox

In contrast to smallpox, which was described in writings as far back as 340 A.D., monkeypox is a more recently recognized disease. It was first identified in 1958 as an illness of cynomolgus monkeys, hence its name. Monkeypox was first documented to cause human illness in 1970 in Zaire (the present Democratic Republic of the Congo), when an illness similar to smallpox was noted after eradication of the latter.

EPIDEMIOLOGY Human monkeypox is a disease acquired mainly from infected animals. It is endemic in the rain forest countries of central and west Africa, occurring in sporadic outbreaks. The majority of cases are in children. Despite its recent recognition, monkeypox has presumably caused illness for thousands for years.[35] Transmission is mainly during handling of infected animals or contact with the animals' body fluids. Person-to-person spread via respiratory droplets and close contact can occur as with smallpox, but usually in a limited manner. Outbreaks in the Democratic Republic of the Congo in 1996 to 1997 showed sustained human-to-human transmission for the first time. This may reflect decreased immunity with the discontinuation of smallpox vaccination.[36] In spring 2003, the first cases of human monkeypox in the Western hemisphere occurred in the Midwest region of the United States (72 reported cases, 37 laboratory confirmed). All cases are thought to be associated with contact with ill pet prairie dogs previously housed with African rodents imported from Ghana.[37]

The longest documented chain of person-to-person transmission is eight generations, which suggests that monkeypox has little potential for the type of epidemic spread seen with smallpox.[36] Possible genetic alteration to produce greater virulence or transmissibility is a concern, however.

ETIOLOGY AND PATHOGENESIS Monkeypox is caused by the monkeypox virus, a zoonotic virus. Like variola and vaccinia viruses, it is also of the genus Orthopoxvirus and has an oval or brick shape on electron microscopy. The monkeypox viral genome is 96 percent identical to that of the variola virus at the central region which encodes essential enzymes and structural proteins. The end regions that encode virulence and host-range factors are substantially different, and the range of hosts for the monkeypox virus is much wider than that for variola virus.[37] In addition to humans, hosts for monkeypox include cynomolgus and other monkeys, other

primates (apes, gorillas, chimpanzees, orangutans), and nonprimate animals such as rabbits, mice, guinea pigs, and giant anteaters. The natural reservoir is unknown but is thought to be wild rodents such as the squirrel.[1,38]

Monkeypox is mainly transmitted through abraded skin after a bite or scratch from an infected animal or by contact with their infected body fluids. The virus multiplies locally at the site of injury, then is rapidly transported to regional lymph nodes, where multiplication continues. Invasion of the bloodstream disseminates the virus to distant sites. The monkeypox virus is also transmissible from person to person via aerosolization of the virus or contact with lesions or body fluids during the first week of the rash. It may rarely be transmitted by contaminated fomites.[39]

CLINICAL FINDINGS ***History.*** Sub-clinical cases of monkeypox can occur in individuals with and without prior smallpox vaccination. In those with illness, symptoms manifest after a 10- to 14-day incubation period. A prodrome of fever, chills, malaise, headache, myalgias, and back pain occurs, lasting 2 to 3 days. Some individuals experience sore throat, cough, or shortness of breath. Diarrhea and abdominal pain may also be reported.[2,36]

Cutaneous Lesions. Usually 1 to 3 days after the onset of fever, a rash develops, initially consisting of monomorphic macules and papules. Most commonly, the eruption begins on the face and/or trunk, with the lesions spreading in a centrifugal pattern to become generalized. They then progress over 14 to 21 days to vesicles and pustules that umbilicate, crust, and desquamate (see eFigs. 195-6.3 and 195-6.4 in on-line edition). Dyspigmented and pitted scars result. Monkeypox lesions can involve the oral and genital mucous membranes.[35] No hemorrhagic form of monkeypox like that of smallpox has been described in humans.

In the outbreak in the United States, only one case, a child, had a generalized rash as extensive as that seen in cases in Africa. The other affected individuals had only localized lesions, mostly on the hands, associated with direct contact with the infected animals (Fig. 195-7 and see eFig. 195-7.1 in on-line edition). This may reflect infection with a less virulent viral strain than those in Africa.[36]

Related Physical Findings. Significant lymphadenopathy develops 1 to 2 days before the onset of the rash, usually in submandibular, cervical, or inguinal areas (Fig. 195-8). Conjunctivitis and keratitis may occur. Confusion and seizures are rare.[40,41]

▲ **FIGURE 195-7** The primary inoculation site of monkeypox virus in a 3-year-old child, 14 days after being bitten by a prairie dog. (Used with permission from the Marshfield Clinic, Marshfield, WI.)

LABORATORY TESTS Leukocytosis, elevated transaminase levels, and low blood urea nitrogen level are often seen. Lymphocytosis and thrombocytopenia occur with less frequency.[42]

Histopathology. On examination of skin biopsy specimens, the features are indistinguishable from those of smallpox. There is similar dermal papillary edema, acute inflammation, and ballooning degeneration of keratinocytes (Fig. 195-9). Cytoplasmic eosinophilic inclusion bodies (Guarnieri bodies) are also seen (see eFig. 195-9.1 in on-line edition). Focal necrosis may occur.[40]

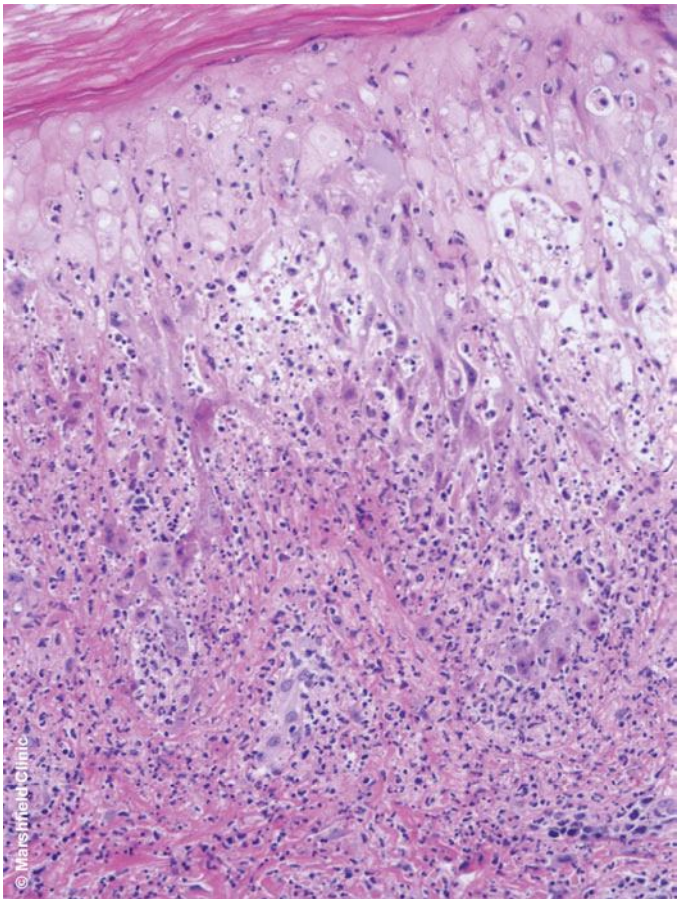
▲ **FIGURE 195-8** Significant postauricular lymphadenopathy with pustular skin lesions in a 2-year-old girl with monkeypox. (Used with permission from the Armed Forces Institute of Pathology, Washington, DC, http://www.afip.org/Departments/infectious/index.html.)

Special Tests. Electron microscopy of material from scabs or fluid from skin lesions can be used to determine the presence of an orthopoxvirus, but it cannot distinguish among them. Assays for specific antibodies against monkeypox can differentiate it from other poxviruses. Monkeypox virus has good growth in RK13 cells and causes pocks on chorioallantoic membranes at 39°C (102.2°F). Isolation of the virus on mammalian cell culture and characterization by PCR and sequencing can definitively identify monkeypox virus.[17,38]

DIFFERENTIAL DIAGNOSIS The features of monkeypox are clinically similar to but less severe than those of ordinary smallpox (variola major). Lymphadenopathy is a distinctive hallmark of monkeypox not usually seen in smallpox. It is observed in 90 percent of cases in which the individual has never received the smallpox vaccine and in approximately 53 percent of those who have been vaccinated.[2] Varicella has a milder and shorter viral prodrome, with pleomorphic lesions evolving in a centripetal distribution. Lymphadenopathy is also infrequent with varicella. Orf and bovine stomatitis, caused by poxviruses of the genus Parapoxviridae, can produce similar skin lesions but these are localized. Also in the differential diagnosis are drug eruptions, eczema herpeticum, and rickettsialpox (see Box 195-1). Persons with human immunodeficiency virus infection may develop extensive molluscum lesions that can look similar.

COMPLICATIONS Secondary skin and soft tissue infections may occur (approximately 20 percent of cases). Affected individuals may also develop pneumonitis (12 percent), encephalitis (fewer than 1 percent), and ocular complications, including scarring with corneal lesions.[35]

PROGNOSIS AND CLINICAL COURSE The scars left by the rash may improve over time. In Africa, mortality ranges from 1 percent to 10 percent and mainly occurs in children. Death is generally in the second week of disease and is secondary to bacterial superinfection, gastrointesti-



▲ **FIGURE 195-9** Histopathologic features of a monkeypox lesion, including dermal papillary edema, acute inflammation, and ballooning degeneration of keratinocytes. (Hematoxylin and eosin stain.) (Used with permission from the Marshfield Clinic, Marshfield, WI.)

nal complications, or pulmonary complications. These are likely compounded by poor nutrition and inaccessibility of medical care.[2,37] All affected individuals recovered without any deaths during the outbreak in the United States in 2003.[43]

TREATMENT There is no specific treatment for monkeypox. Symptomatic treatment should be instituted. Cidofovir may be considered in severe cases, but there are no available data on its clinical efficacy in humans. VIG administration can also be considered in severe cases, but its benefits are unknown.

PREVENTION Global eradication of monkeypox is more difficult than smallpox eradication, because the wide range of hosts for monkeypox virus allows it to maintain an animal reservoir while sporadically causing human disease. Vaccination with the current calf-lymph–derived smallpox vaccines (vaccinia virus) has been found to be effective in preventing human monkeypox. Observation of cases in Africa shows 85 percent protection against monkeypox. Cases of monkeypox are milder and even sub-clinical when they occur in vaccinated individuals.[40]

The CDC currently recommends pre-exposure vaccination for investigators of animal or human monkeypox cases and health care providers who may care for or be in close contact with patients with monkeypox, provided they have no contraindication to smallpox vaccination (Box 195-3). The role of post-exposure vaccination is less clear, but it is recommended for those within 4 days of direct exposure to monkeypox virus and should be considered up to 14 days after exposure, including in children under the age of 12 months, pregnant women, and people with skin conditions. Those with impaired immune systems or life-threatening allergy to latex or vaccine components should not receive the current Dryvax vaccine even if exposed to monkeypox, but VIG can be considered for post-exposure prophylaxis.[35,36]

The newer smallpox vaccines under research and development are also being studied for efficacy against monkeypox virus and may in the future allow prevention of human monkeypox with fewer adverse effects.

Box 195-3

Vaccination Against Human Monkeypox Using Vaccinia Virus

INDICATIONS

- Pre-exposure vaccination for investigators of animal or human monkeypox cases and health care providers who may care for or be in close contact with patients with monkeypox
- Post-exposure vaccination for those within 4 days of direct exposure to monkeypox virus, should be considered up to 14 days after exposure

CONTRAINDICATIONS

- Contraindications in the pre-exposure setting
  - Presence of atopic dermatitis or other eruptions with disruption of the skin barrier
  - Immunosuppression, including human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS), inherited and acquired cellular immunodeficiencies, and severe autoimmune disease
  - Known heart disease or significant cardiac risk factors
  - Serious allergy to components of the vaccine diluent (polymyxin, neomycin, streptomycin, chlortetracycline)
  - Age younger than 12 mo
  - Pregnancy or breast-feeding
- Contraindications in the post-exposure setting
  - Immunosuppression, including HIV/AIDS, inherited and acquired cellular immunodeficiencies, and severe autoimmune disease
  - Life-threatening allergy to components of the vaccine diluent (polymyxin, neomycin, streptomycin, chlortetracycline)

PARAPOXVIRUS INFECTIONS

Unlike the orthopoxviruses, members of the genus *Parapoxviridae* tend to cause localized disease in healthy individuals.

Milker's Nodule

EPIDEMIOLOGY Milker's nodule, also called *paravaccinia* and *pseudocowpox*, occurs worldwide but is prevalent only in individuals in close contact with cattle. It is an occupational disease of milkers, veterinarians, and workers in the meat industry. Most cases are in newly em-

ployed milkers who have not developed immunity.[1] Cases are mostly sporadic, but small epidemics have been reported. No natural cases of human-to-human transmission have been reported, only experimentally transmitted cases in the laboratory setting.[44]

ETIOLOGY AND PATHOGENESIS Milker's nodule is caused by the paravaccinia virus (also called *pseudocowpox virus*), a member of the genus *Parapoxviridae*. It is a 260- by 160-nm cylindrical virus with spirally arranged tubules. The virus typically is found at the teats and mouth of cattle but may also be on the trunk and legs. Humans are accidental hosts on contact with infected animals or contaminated fresh meat. Paravaccinia virus is transferred by direct inoculation into the skin, often through a break in the skin barrier.[45] Cases of transmission from contaminated fomites to individuals with burn injury have been reported.[46]

CLINICAL FINDINGS ***History.*** The incubation period for milker's nodule is 4 to 7 days. In a minority of cases, the infected individual develops mild systemic symptoms such as a transient low-grade fever.[47]

Cutaneous Lesions. The sites of inoculation of paravaccinia virus are usually the hands and, on occasion, the face. After the incubation period, skin lesions develop. One to several lesions usually appear, but they may occasionally be numerous. Lesions begin as red and occasionally pruritic macules that become raised papules (see eFig. 195-9.2 in on-line edition). They can then form papulovesicles with a target-like appearance—a red center surrounded by a white or gray ring and outer red halo. The lesions then develop into bluish or violaceous tender nodules. Some ulcerate or have a central depression (Fig. 195-10), which results in formation of eschars with crust. Lesions often take 4 to 8 weeks, and sometimes longer, to heal.[44,45]

Related Physical Findings. Lymphangitis is often present in the skin surrounding the primary lesion(s). Lymphadenopathy is not common.

LABORATORY TESTS ***Histopathology.*** The histopathologic findings of milker's nodule depend on the stage of the lesion. Early lesions show vacuolization and ballooning of cells in the upper third of the epidermis, which sometimes leads to multilocular vesicles. Intracytoplasmic inclusion bodies may be seen, with rare intranuclear inclusions. Epidermal necrosis may be observed focally with ulceration and crust as the lesion progresses. Neutrophils are seen in the epidermis and superficial papillary dermis with epidermal necrosis. Mature lesions have finger-like epidermal projections, papillary dermal edema, and a mixed inflammatory infiltrate that includes lymphocytes, histiocytes, and eosinophils. Regressing lesions have decreasing acanthosis and inflammation.[44,48]

▲ **FIGURE 195-10** **A.** Firm, eroded milker's nodule. **B.** Multiple lesions at the site of a second-degree scalding burn sustained in a milking barn.

Special Tests. Electron microscopy of blister fluid or crusts can identify the characteristic cylindrical shape of parapoxviruses. Paravaccinia virus is slow-growing on tissue culture.

Viral DNA hybridization or PCR procedures may be used to distinguish paravaccinia virus from other parapoxviruses.[49]

DIFFERENTIAL DIAGNOSIS Milker's nodules appear very similar to the lesions of orf, another parapoxvirus. Attention to clinical history usually allows differentiation, with cattle the source of infection for milker's nodules and sheep or goats for orf. Tissue cultures can aid in diagnosis if needed. Bovine papular stomatitis virus causes disease in cattle with lesions around the animal's mouth. Transmission to people produces lesions similar to milker's nodules, and some think these may actually be the same virus.[50] Milker's nodules must also be differentiated from cowpox. Cowpox is very rare in humans. It has a longer incubation period, causes more pain and lymphadenopathy, and has led to death in persons with immunocompromise or atopic dermatitis. Large lesions of milker's nodule can be confused with anthrax, pyogenic granuloma, giant herpetic lesions, and keratoacanthoma (Box 195-4).

Box 195-4

Differential Diagnosis of Milker's Nodule and Orf

Most Likely

- Few to multiple lesions
  - Bovine papular stomatitis
  - Cowpox
  - Herpetic whitlow
- Solitary lesion
  - Pyogenic granuloma
  - Pyoderma

Consider

- Few to multiple lesions
  - Atypical mycobacterial infection
  - Sporotrichosis
- Solitary lesion
  - Tularemia
  - Giant herpetic lesion
  - Giant molluscum
  - Erysipeloid

Always Rule Out

- Few to multiple lesions
  - Anthrax
  - Primary inoculation tuberculosis
- Solitary lesion
  - Keratoacanthoma
  - Syphilitic chancre

COMPLICATIONS Secondary bacterial infection can occur but is rare. Erythema multiforme, morbilliform eruptions, and erythema nodosum have been reported in cases of milker's nodule.

PROGNOSIS AND CLINICAL COURSE Milker's nodule is a self-limited illness. Most cases heal without scarring. Infection produces lifelong immunity.

TREATMENT Because the disease is self-limited, treatment, if needed, is symptomatic. Surgical curettage of large lesions may help speed healing.[47,51]

PREVENTION There is no cross-immunity between orthopoxviruses and parapoxvi-

TABLE 195-2
Clinical Manifestation of Orf

Time after Exposure	Clinical Manifestations	Laboratory Analysis	Other Notes
3–7 days	One to four papules on hand (typically only one lesion): begin as a red maculopapular lesion ↓ Vesicle ↓	Can confirm by histology, viral culture, increase in serologic titers, or complement fixation. Electron microscopy of lesional skin shows brick-shaped viral particles (200–380 nm in length); intranuclear inclusions are occasionally seen.	Systemic symptoms are rare, but may include lymphadenopathy and lymphangitis, fever, rigors, drenching sweat, malaise, and urticaria.
10–14 days	Target lesion, with red center, white middle ring, and red halo ↓		
14–21 days	Acute weeping stage ↓		Lesions are relatively painless.
21–28 days	Regenerative dry stage with black dots ↓		
28–35 days	Papillomatous stage ↓		
35 days	Regressive stage with dry crust and eventual shedding of the scab		Typically no scarring occurs.

From Diven DG: Poxvirus, in *Mucocutaneous Manifestations of Viral Disease,* edited by Tyring SK. New York, Infarma Healthcare, 2002:39, with permission.

ruses, and thus smallpox vaccination (vaccinia virus) has no effect on this illness. Prevention mainly consists of isolation of infected animals and contact precautions.[52]

Orf

Contagious pustular dermatosis, infectious pustular dermatitis, scabby mouth disease, and sore mouth disease are all synonyms for orf, a self-limited zoonotic viral infection that usually involves the hands of people handling infected animals. The offending Orf virus is a member of the *Parapoxvirus* genus. It is an endemic disease in sheep and goats that usually affects the area around the lips and nostrils of the animal, as well as the teats of ewes suckling young. It is transmitted to humans through contact with infected tissue or fomites, and human infections have been noted after vaccination of sheep herds.[53,54] Orf shares clinical characteristics with other infectious diseases and may be mistaken for more serious and life-threatening disorders such as tularemia, anthrax, and erysipeloid. Although clinical appearance and history of ruminant exposure are usually diagnostic, real-time PCR testing, which is available through the CDC, is the most rapid and accurate way to make the diagnosis when clinical uncertainty exists.[54]

EPIDEMIOLOGY Human disease is more commonly seen in farmers and shepherds, but anyone who has contact with small ruminants is at risk. Although sheep and goats are the more common sources of infection, the virus has also been found in camels, mountain goats, gazelles, and musk oxen. Disease can occur after contact with animals or fomites such as barn doors, feeding troughs, wire fencing, and bottles. The virus is quite hardy and can survive heating, drying, and certain solvents such as ether and chloroform. Vaccination of animals with unattenuated virus leads to milder disease in the animal but can result in infection of humans exposed to the vaccinated animal.[53]

ETIOLOGY AND PATHOGENESIS Orf virus is the prototypic species of the genetically heterogeneous Parapoxvirus genus.[55] It is an ovoid cross-hatched particle of approximately 250 by 160 nm with a twine-like structure. Electron microscopic analysis can distinguish this parapoxvirus from orthopoxviruses such as variola (smallpox). Virulence proteins elaborated by the virus aid in evading host immunity.

CLINICAL FINDINGS ***Cutaneous Lesions.*** Five to 6 days after inoculation, a slightly elevated red papule appears, followed by vesiculation (Table 195-2). This evolves into a targetoid nodule with a red center, white ring, and peripheral rim of erythema (Fig. 195-11). A weeping stage (see eFig. 195-11.1 in on-line edition) is followed by a dry stage and finally a dry crust and scab, which resolves without scarring in most cases. Multiple lesions are sometimes present, and giant lesions occasionally occur.[56]

Related Physical Findings. Systemic findings are uncommon in immunocompetent individuals but can include lymphadenopathy and lymphangitis. Rarely fever and malaise may occur.

LABORATORY TESTS ***Histopathology.*** In the target stage, intranuclear and intracytoplasmic inclusions are present in vacuolated epidermal cells, with an accumulation of neutrophils, basophils, dendritic cells, and lymphocytes (see eFig. 195-11.2 in on-line edition). Papillomatosis and acanthosis subsequently develop, and marked finger-like downward projections of the epidermis may be seen (see eFig. 195-11.3 in on-line edition).

Special Tests. Electron microscopy may be helpful in distinguishing between

▲ **FIGURE 195-11** The target phase of orf shows a white circle with central and peripheral erythema.

parapoxviruses and other types of poxviruses but is not diagnostic for orf; similar limitations exist with serologic testing. Tissue culture is possible but time consuming. The most rapid and sensitive means of making the diagnosis is PCR testing, and real-time PCR procedures, in particular, appear extremely sensitive.[54]

DIFFERENTIAL DIAGNOSIS A variety of bacterial and infectious diseases can present with findings similar to those of orf (see Box 195-4). Exposure history is important, because many of these disorders (milker's nodules, cowpox, monkeypox, etc.) are associated with exposures to animals other than sheep or goats.[49] The lesion of anthrax is more hemorrhagic with rapid progression to an eschar. Tularemia and syphilis lead to chancres. Sporotrichosis begins as a single necrotic nodule but is followed by multiple nodules arising in a linear fashion along the lymphatics. Primary inoculated tuberculosis and atypical mycobacterial infection can give rise to ulcerative lesions that may take months to years to heal.

COMPLICATIONS Secondary bacterial infection, swelling, lymphadenitis, and fever can occur. Erythema multiforme,[57] vesicular eruptions,[58] and secondary spread within active atopic dermatitis skin lesions have been reported.[58] Bullous pemphigoid has also rarely been reported after orf infection.[59]

PROGNOSIS AND CLINICAL COURSE Orf is usually a self-limited disease that resolves within 4 to 6 weeks. Typically scarring does not occur. Immunocompromised individuals can develop progressive destructive lesions that may require interventions such as débridement or antiviral therapy such as cidofovir cream.[60,61]

TREATMENT Supportive care is the most appropriate intervention for immunocompetent patients. Application of compresses, culture of lesion specimens, and antibiotic coverage may be appropriate if secondary bacterial infection is suspected. Immunocompromised patients may require medical intervention (see Prognosis and Clinical Course).

PREVENTION Barrier precautions such as use of gloves and good hand hygiene are recommended. Patients with an impaired skin barrier from either abrasions or intrinsic skin disease (e.g., atopic dermatitis) should be particularly vigilant regarding avoidance of contact with infected animals or potential fomites.

MOLLUSCIPOXVIRUS INFECTION: MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum (MC) is a benign but nonetheless frequently troublesome viral infection that generally affects young children. It is characterized by smooth, dome-shaped discrete papules that occasionally develop surrounding areas of scale and erythema (molluscum dermatitis). Patients and families are bothered by this infection because of its often prolonged course, because it may persist for months to years. MC is a greater concern in immunocompromised individuals and those with atopic dermatitis, in whom the extent and duration of infection may be more extreme. Sexually transmitted disease occurs in adults but is extremely unlikely in children.

Epidemiology

MC virus (MCV) infection occurs worldwide and appears specific to humans. The prevalence of MCV infection has risen significantly in the past several decades, with an 11-fold increase noted in one U.S. study of patient visits for this disorder over a two-decade span.[62] This rise appears to parallel the overall increase in sexually transmitted diseases. Although a prevalence rate of less than 5 percent in U.S. children is often cited,[63] the rate varies by location, and it is thought that sub-clinical infection may be more common than overt disease. A representative Australian study documented an overall seropositivity rate of 23 percent, which supports the view that sub-clinical or mild unrecognized disease exists in the population. Human immunodeficiency virus–infected individuals are at higher risk for extensive prolonged disease, and individuals with atopic conditions appear more likely to have increased numbers of lesions and experience a more prolonged disease course.[63]

Transmission may occur via direct skin or mucous membrane contact, or via fomites. Bath towels, swimming pools, and Turkish baths have all been reported as sources of infection, and individuals involved in close contact sports (e.g., wrestling) also appear at higher risk.[64,65] Autoinoculation and koebnerization also play a role in the spread of lesions.

Etiology and Pathogenesis

MCV is a large, brick-shaped Poxvirus that replicates within the cytoplasm of cells. It shares a number of genomic similarities with other poxviruses, and approximately two-thirds of the viral genes are similar to those of vaccinia and variola virus.[68] There are four subtypes of MCV, but they all appear identical clinically. Ninety-eight percent of disease in the United States is caused by MCV genotype 1.[67,68] Serial transmission of the virus has not yet been achieved in culture. An incubation period of 2 to 7 weeks has been observed.

Virus replicates within the cytoplasm of epithelial cells, and infected cells replicate at twice the baseline rate. There are many MCV genes that may contribute to an impaired immune response to this virus, including (1) a homolog of a major histocompatibility class 1 heavy chain, which may interfere with antigen presentation; (2) a chemokine homolog that may inhibit inflammation; and (3) a glutathione peroxidase homolog that may protect the virus from oxidative damage by peroxides.[66,69]

Clinical Findings

CUTANEOUS LESIONS MC often presents with extremely small pink, pearly, or flesh-colored papules that then enlarge, occasionally reaching sizes of up to 3 cm ("giant molluscum"). As they enlarge, a dome-shaped, opalescent morphology may become more apparent. The lesions may have a central dell or umbilication (Fig. 195-12A), within which a white curd-like substance can be seen that can be expressed with pressure.[70] Most patients develop multiple papules, often in intertriginous sites, such as the axillae, popliteal fossae, and groin. Genital and perianal lesions can develop in children and are only rarely associated with sexual transmission in this population.[62]

Lesions may be grouped in clusters or appear in a linear array. The latter often results from koebnerization, or development of lesions at sites of trauma. Erythema and eczematous changes may occur around lesions; this is termed *molluscum dermatitis*. Papules may become erythematous (see Fig. 195-12B), which is believed to be an immune response to the infection. Patients with acquired immunodeficiency syndrome may develop large and extensive lesions involving both genital and extragenital sites.[70]

◀ **FIGURE 195-12** Molluscum contagiosum. **A.** Discrete, solid, skin-colored papules, 1 mm to 2 mm in diameter, with central umbilication. **B.** Multiple, scattered, and discrete lesions, some of which are inflamed.

Special Tests

Diagnosis is usually straightforward. Evaluation of the central contents using a crush preparation and Giemsa staining can be carried out when necessary (Fig. 195-13), and histopathologic evaluation can be performed as needed.

Histopathologic examination reveals a hypertrophied and hyperplastic epidermis. Above the basal layer, enlarged cells containing large intracytoplasmic inclusions (Henderson-Paterson bodies) can be seen (Fig. 195-14). These increase in size as the cells reach the horny layer.

Differential Diagnosis

The differential diagnosis includes verrucae, pyogenic granulomas, amelanotic melanoma, basal cell carcinomas, and appendageal tumors. Fungal infections such as cryptococcosis, histoplasmosis, and penicilliosis must be considered in immunocompromised hosts (Box 195-5).

Complications

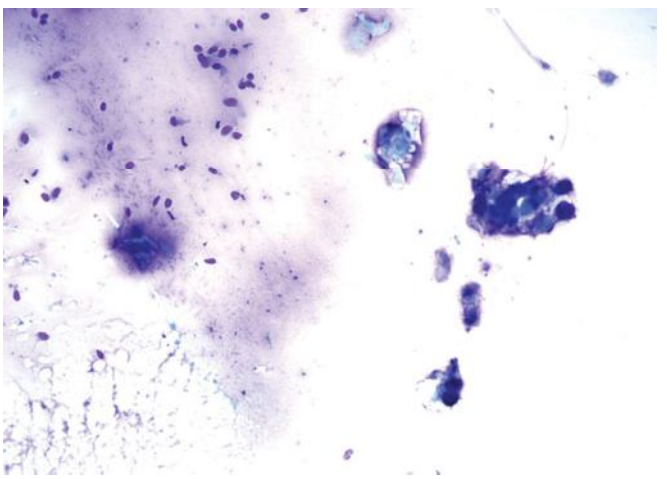
Although many patients are asymptomatic, pruritus is sometimes a significant problem, particularly in those patients with underlying atopic dermatitis. Chronic conjunctivitis and punctate keratitis may develop in patients with eyelid lesions. Secondary bacterial infection can occur, particularly if patients scratch their lesions.

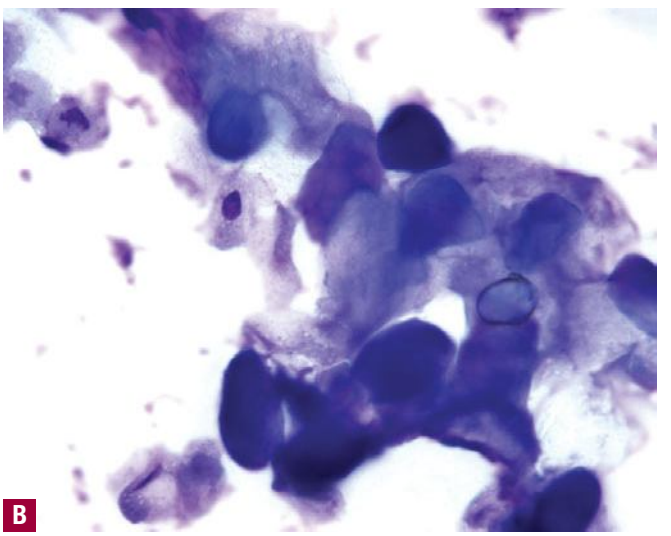
Prognosis and Clinical Course

Spontaneous clearance occurs, but often over a prolonged period of months to years. Most families prefer treatment if lesions persist more than a month or two.

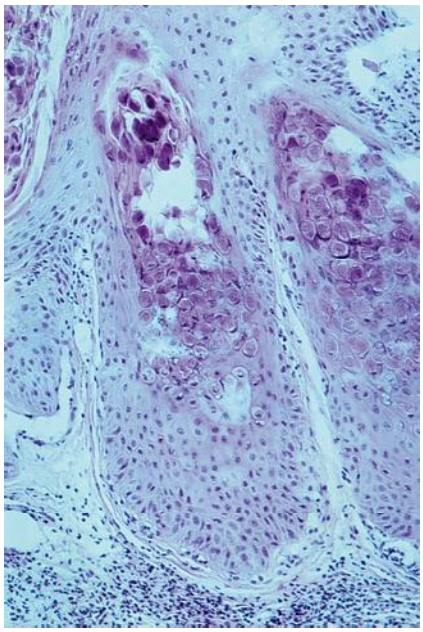
Treatment

It is important to discuss the risks and benefits of individual therapies with families before embarking on treatment for this essentially benign condition, which will generally resolve without complication in the immunocompetent individual (Table 195-3). Many experts use cantharidin 0.7 percent or 0.9 percent liquid for treatment of MC. This extract of the blister beetle, *Cantharis vesicatoria,* induces vesiculation at the dermoepidermal junction when applied topically to the skin. It must be applied with care and washed off 2 to 6 hours later. Use on the face or genital areas is not recommended, and





▲ **FIGURE 195-13** Microscopic preparation (Giemsa stain) of cellular material from the area of central umbilication (**A**) shows intracytoplasmic molluscum inclusion bodies (**B**).



▲ **FIGURE 195-14** Molluscum contagiosum. Histopathologic examination of a skin biopsy specimen shows downgrowth of infected epidermal cells bearing large eosinophilic cytoplasmic inclusion bodies (Henderson-Paterson bodies). (Hematoxylin and eosin stain.)

families must be counseled regarding the small risk of extreme reaction or scarring.

Other traditional therapies have included curettage and cryotherapy; however, both of these treatments are painful. The use of topical anesthetic agents may ameliorate some of the associated pain, but patients generally find topical cantharidin treatment the most efficient and least painful. Other topical therapeutic modalities include retinoid creams, imiquimod cream, salicylic acid, cidofovir, and silver nitrate paste and tape stripping. Oral cimetidine has also been used with success.[71] However, a Cochrane Database analysis of treatments for molluscum contagiosum, which identified only five therapeutic studies of high quality, found that no single intervention is convincingly effective for the treatment of molluscum contagiosum.[72]

Prevention

Prevention of spread may be enhanced by avoiding trauma to the sites of involvement as well as avoiding scratching, with the use of antipruritics as necessary. Autoinoculation may be decreased by treating all existing lesions.

TABLE 195-3
Treatment of Molluscum Contagiosum

		Considerations	Level of Evidence[a]
Watchful waiting	Spontaneous resolution occurs over months to years in immunocompetent individuals.	Risk of autoinoculation, associated dermatitis, secondary bacterial infection	3
Topical therapies	Cantharidin (0.7% or 0.9%)	Rarely severe blistering and scarring of concern	2, 3
	Podophyllin (10%–25% resin) (0.3% or 0.5% cream)	Rarely severe blistering and scarring of concern	1, 2, 3
	Cryotherapy/liquid nitrogen	Painful	3
	Curettage	Painful, scarring possible	3
	Imiquimod cream (5%)	Irritation common	1, 2, 3
	Topical retinoids	Irritation common	3
	Silver nitrate paste		2
	Trichloroacetic acid (25%–35%)	Rarely severe blistering and scarring of concern	2, 3
	Topical cidofovir (1%, 3% gel; 1%, 3% cream)	Expensive	2, 3
Systemic therapies	Oral cimetidine (40 mg/kg/day)		2, 3
	Oral cidofovir	Recommended only for immunocompromised individuals, expensive	3
	Subcutaneous interferon-α	Recommended only for immunocompromised individuals	3

CHAPTER 196

Warts

Elliot J. Androphy
Douglas R. Lowy

Warts, or verrucae, are benign proliferations of the skin and mucosa that are caused by infection with papillomaviruses (PVs). These viruses do not produce acute signs or symptoms but induce a slow, focal expansion of epithelial cells. Lesions may remain subclinical for long periods or may grow to large fulminating masses that persist for months or even years. A subset of human PVs (HPVs) is known to cause benign warts that may undergo neoplastic transformation.

ETIOLOGY

PVs comprise a large family of small DNA viruses found in humans and many other species.[1] PVs are highly host-specific, meaning that those from one species do not induce papillomas in heterologous species, so HPVs infect only humans. Rabbit, bovine, and canine PVs have been used in animal models of viral infection because biologic experiments cannot be performed in humans using HPVs.

The PV genome is present within the viral particle as a single covalently closed circle of double-stranded DNA. Each genome is composed of approximately 8000 nucleotide base pairs, which is approximately one-twentieth the size of a herpesvirus genome. Recombinant DNA technology has enabled the molecular cloning of the complete viral genome from clinical lesions, and the entire nucleotide sequence for many human and animal PVs is known. Comparison of these DNA sequences reveals that they share a similar genetic organization (Fig. 196-1) and are predicted to encode eight to nine related protein products.[2] PV proteins are labeled as E (early) and L (late).[3] The E proteins are necessary for viral DNA replication and are not incorporated into the infectious virus particle. Because the E genes do not encode a DNA polymerase or thymidine kinase, PVs are not susceptible to inhibition by acyclovir or similar nucleoside analogues. Rather, these viruses use host cell enzymes and factors to replicate their genomes. The L1 and L2 genes encode the structural proteins that form the outer protein shell or capsid of the infectious viral particle, which is called the *virion*. The spherical virion measures approximately 55 nm in diameter and packages the viral DNA (Fig. 196-2).

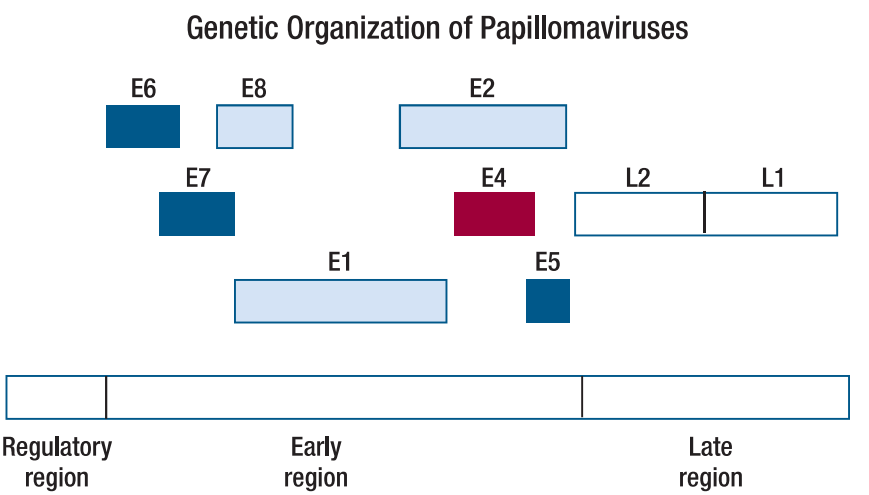
HUMAN PAPILLOMAVIRUS TYPES

More than 100 HPV types have been sequenced; the actual number of genotypes is even higher.[1,4] The degree of relatedness of their DNA sequence distinguishes between HPV types. The polymerase chain reaction (PCR), which is a highly sensitive, specific, and rapid technique to amplify and sequence any viral DNA isolate, readily allows HPV types to be defined by DNA sequence homology.[5] Fresh tissue is not required, as PCR can be applied to specifically amplify HPV DNA in paraffin-embedded tissue blocks that are decades old.[6] By convention, two HPV isolates are the same type when a highly conserved sequence within their L1 genes is at least 90 percent identical.[7] A sub-type has 91 percent to 98 percent identity, whereas a natural variant has less than 2 percent divergence to a known type in this region of L1. A new HPV sub-type is defined when its DNA sequence is less than 90 percent homologous to all other known HPVs.[4]

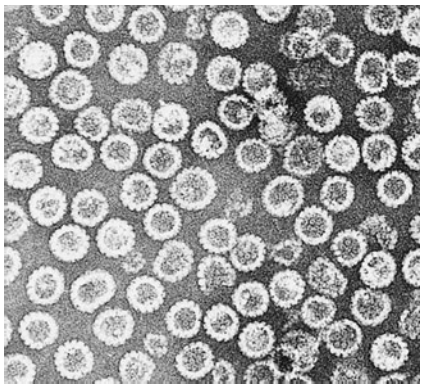
Often associated with distinct regional predilection, histopathology, and biology, HPVs are categorized as cutaneous (non-genital) types such as HPV-1, -2, -3, and -4; genital-mucosal types such as HPV-6, -11, -16, and -18; and those usually isolated from epidermodysplasia verruciformis (EV) such as HPV-5 and -8 (Table 196-1). PVs have also been classified by phylogenetic organization based on their DNA homology.[8,9] The α virus genus includes a large set of

PAPILLOMAVIRUS INFECTIONS AT A GLANCE

- Very common infection of skin and mucosa of children and adults.
- Papules of variable size often with filiform scale with local symptoms.
- Caused by human papillomaviruses (HPVs), a subset of which are associated with cervical, penile, anal, and other epithelial malignancies.
- Treatment requires physical destruction of infected epithelial cells.
- A prophylactic vaccine effectively protects from infection with HPVs most commonly identified in cervical cancer and genital warts.



▲ **FIGURE 196-1** All PV genomes are composed of approximately 8000 nucleotide base pairs, represented as a linear sequence but actually a closed circle of double-stranded DNA. The boxes depict the viral genes, each of which encodes a protein. The regulatory region is a DNA segment that does not encode proteins, but participates in regulating the expression of the viral genes and the replication of the viral DNA. In general, E6, E7, and E5 represent transforming genes; E1 and E2 coordinate replication and expression of the viral genome; and the L1 and L2 proteins form the viral capsid. E4 encodes a protein that may be involved in the release of the virus from the cell's keratin framework.



▲ **FIGURE 196-2** Transmission electron micrograph of human papillomavirus-16 virus-like particles composed of the viral L1 and L2 capsid proteins. The L1 and L2 proteins have been expressed in cultured cells and have self-assembled into 55-nm particles that are similar morphologically to infectious virus, except that they do not contain the viral DNA. The particles in the electron micrograph have been purified from the cells. (Micrograph used with permission from Heather Greenstone.)

cutaneous and genital-mucosal types, and the β genus is primarily comprised of EV types. Other genus classifications include more distantly related human and animal PV species. HPVs closely related by DNA sequence tend to induce similar lesions. Examples include highly related types such as 3 and 10, which induce flat warts; types 6 and 11, which induce genital-mucosal warts (condylomata acuminata); and types 5 and 8, which induce scaly lesions in EV.

Another important distinction is that specific HPV genotypes have malignant potential. This was first noted in EV, in which warts that contain HPV types such as 5 and 8 have a high rate of malignant degeneration, whereas those induced by other HPV types, even in the same patient, tend to remain benign.[10] Similarly, the majority of cervical carcinomas contain HPV-16, -18, or other so-called *high-risk* types, whereas the *low-risk* HPV-6 and -11, which are found in benign cervical disease, are identified in < 1 percent of cervical malignancies.[11]

PATHOGENESIS

HPV infection occurs through inoculation of virus into the viable epidermis through defects in the epithelium. Maceration of the skin is probably an important predisposing factor, as suggested by the increased incidence of plantar warts in swimmers who frequent public pools. Although the cellular receptor(s) for HPV has not been identified, cell surface heparan sulfate, which is encoded by proteoglycans and binds PV particles with high affinity, is required for entry.[12,13] To establish persistent infection, it is probably necessary to enter an epidermal basal cell that is either a stem cell or is converted by the virus to one with stem cell–like properties. It is believed that a single copy or at most a few copies of the viral genome are maintained as an extrachromosomal plasmid within the infected epithelial basal cells. When these cells divide, the viral genome is also replicated and partitioned to each progeny cell, then transported within the replicated cells as they migrate upward to form the differentiating layers.

After experimental PV inoculation, a verruca usually appears within 2 to 9 months. This observation implies a relatively long period of sub-clinical infection and may represent an inapparent source of infectious virus. The rough surface of a wart may disrupt adjacent skin and enable inoculation of virus into adjacent sites, with the development of new warts over a period of weeks to months. Each new lesion results either from the initial exposure or spread from other warts. There is no convincing evidence for blood-borne dissemination. Autoinoculation of virus into apposed skin is commonly seen on adjacent digits (Fig. 196-3) and in the anogenital region.

HPV DNA has been detected in normal-appearing mucosa and in normal-appearing skin adjacent to treatment sites of recurrent genital warts.[14] Whether this HPV DNA represents sub-clinical states rather than true "latency" (i.e., non-replicating and transcriptionally inactive virus) is unknown. Whether HPV DNA persists in the epithelium after successful treatment of immunocompetent individuals remains an unresolved question. However, the fact that HPV DNA becomes undetectable, even by very sensitive techniques, in the majority of cervical HPV infections implies that viral cure after treatment is possible and may be common.

Viral RNA expression (transcription) is extremely low until the upper Malpighian layer, just before the granular layer, where viral DNA synthesis typically results in hundreds of copies of viral genomes per cell. The viral capsid proteins (L1 and L2; see Figs. 196-1 and 196-2) are synthesized and assembled into virions in the nuclei of the cells at this upper level. The newly synthesized viral DNA is packaged into the virions in the nuclei of these differentiated Malpighian cells. A viral protein called *E1-E4* (the product of a spliced RNA from the E1 and E4 genes) may induce collapse of the cytoplasmic keratin filament network.[15] This is postulated to facilitate release of the virions from the cross-linked cytoskeleton of keratinocytes so that virus can be inoculated into another site or desquamated into the environment.

TABLE 196-1
Clinical Associations of Human Papillomavirus (HPV) Types

HPV Type	Most Common Clinical Lesion	Less Frequent Lesion	Potential Oncogenicity
1	Deep plantar/palmar warts	Common warts	
2, 4, 27, 29	Common warts	Plantar, palmar, and mosaic warts	
3, 10, 28, 49	Flat warts	Flat warts in EV	HPV-10 rare in cervical and vulvar carcinomas
7	Butcher's warts		
13, 32	Oral focal epithelial hyperplasia		
5, 8, 9, 12, 14, 15, 17, 19–26, 36, 47, 50	EV, warts in immunosuppression	Normal skin (?)	HPV-5, -8, -9 isolated from SCCs
6, 11	Anogenital warts, cervical condylomata	Bowenoid papulosis, common warts; respiratory papillomatosis, common warts	Buschke-Löwenstein tumor; rare in penile, vulvar cervical, and other urogenital tumors; "low risk"
16, 18, 31, 33–35, 39, 40, 51–60	Cervical condylomata; anogenital warts; bowenoid papulosis	Common warts	Genital and cervical dysplasias and carcinomas; rare in cutaneous SCC; "high risk"

EV = epidermodysplasia verruciformis; SSC = squamous cell carcinoma.

▲ **FIGURE 196-3** **A.** Common wart, periungual. Multiple, confluent, keratotic papules are apparent around the proximal periphery of the fingernails. **B.** Common wart, verruca plantaris. **C.** Common wart, mosaic plantar. A large hyperkeratotic plaque is seen on the heel, made up of multiple small coalescing warts.

PVs do not bud from the nuclear or plasma membrane, as do many viruses such as herpes simplex or human immunodeficiency virus (HIV). Therefore, they do not possess a lipoprotein envelope that causes susceptibility to rapid inactivation by environmental conditions such as freezing, heating, or dehydration with alcohol. In contrast, PV virions are resistant to desiccation[16] and to the detergent nonoxynol-9, although exposure of virions to formalin, strong detergents such as sodium dodecyl sulfate,[17] or prolonged high temperature can reduce their infectivity. PVs can remain infectious for years when stored in glycerol at room temperature. Indeed, L1 and L2 form a tightly packed, very stable protein capsid (see Fig. 196-2).

The relative abundance of these stable virus particles in a wart varies with the clinical setting and the HPV type. Newer lesions tend to contain more virions than do older verrucae. Plantar warts containing HPV-1 have a high number of virions; anogenital verrucae typically have trace quantities of mature virus particles; common warts usually have intermediate numbers.

Because the viral episomes are at low copy and the L1 and L2 proteins are not expressed in the lower epithelial levels in warts, it is assumed that the state of differentiation of the infected epithelial cell influences viral transcription, signals initiation of viral DNA synthesis, and permits virion assembly. The propagation of limited amounts of HPVs in cultured cells is a consequence of the ability to reproduce the milieu required for physiologic differentiation.[18,19] Further support for the belief that the production of virus particles depends on the state of epithelial differentiation is the fact that virion production decreases as benign papillomas progress toward dysplasia. Capsid proteins are virtually never observed in HPV-induced malignancies. Although it is possible to isolate infectious HPVs from cultured epithelial cells, the process is time-consuming, technically challenging, expensive, and limited to research laboratories. Therefore, laboratory culture for detection of HPV is not a practical diagnostic test.

Because viral replication occurs in upper levels of the epithelium composed of non-replicating keratinocytes, PVs must block terminal differentiation and stimulate cell division to provide the enzymes and co-factors necessary for replication of viral DNA. Experimental evidence from cell culture systems has shown that PV proteins can alter cell proliferation and inhibit cell death via apoptosis. These experimental systems have been used to examine and compare the in vitro activities of genital-mucosal HPVs. Their relative activity varies with the HPV type. In one assay, keratinocytes or cervical cells were grown as a stratified epithelium on a raft that provided an air-media interface.[20] The introduction of high-risk HPV-16 or -18 DNA induced a disorganized pattern of differentiation with suprabasal mitotic figures resembling squamous cell carcinoma (SCC) in situ, whereas the cells retained a normal pattern of stratification with the use of low-risk HPV-6 or -11 DNA.[21,22] In another cell culture model, introduction of HPV-16 or -18 DNA or the high-risk HPV-16 or -18 E6 and E7 genes into primary human keratinocytes allowed resistance to calcium-induced differentiation and conferred the ability to be continuously passaged and avoid replicative senescence.[23,24] Low-risk HPVs were much less active.[25] The high-risk E6 and E7 genes are preferentially retained and expressed in cervical cancers, implying that these assays measure a property that is closely related to the oncogenic potential of these viruses in cervical infection. Thus, for the genital-mucosal HPVs, there is an excellent correlation between their ability to induce cell transformation in vitro and their association with malignancy.

The E5, E6, and E7 proteins (see Fig. 196-1) have different mechanisms to activate cell growth and inhibit apoptosis.[26,27] High-risk E6 and E7 bind to and cause the degradation of the tumor suppressor p53 and the retinoblastoma proteins, respectively, and thereby relieve infected cells from the normal growth inhibitory activities of these cellular factors. Nonetheless, the E6 proteins from some HPV types, including those associated with malignancies in EV and immunosuppression, do not directly bind p53, although they may prolong the life span of infected cells by an alternate mechanism,[28] such as inactivation of the pro-apoptotic protein Bak.[29,30] Studies demonstrate that E6 and E7 must have other targets in the cell.[31] For instance, high-risk E6 stimulates expression of hTERT, the catalytic subunit of telomerase.[32,33] This enzyme protects the ends of chromosomes, and its expression blocks cell senescence in culture. Telomerase is expressed in stem cells and many cancers. The viral E5 proteins appear to activate growth factor receptors. In the bovine PV, which induces fibropapillomas, E5 appears to preferentially activate the receptors for platelet-derived growth factor, whereas

HPV-16 E5 may stimulate the epidermal growth factor receptor.[34,35]

EPIDEMIOLOGY

Acquisition of HPV depends on several factors, including the location of lesions, the quantity of infectious virus present, the degree and nature of the contact, and the general and HPV-specific immunologic status of the exposed individual. The roles of immunity and genetic susceptibility to PV infection are incompletely understood.[36,37] The decrease in the frequency of warts with age implies that resistance to infection develops over time, and much of this resistance may be immunologic. In experimental PV infection in animals, resistance to virus challenge correlates with the presence of neutralizing anti-capsid antibodies, and serum or immunoglobulin G from resistant animals can provide protection through passive transfer.[38,39] It is therefore likely that neutralizing antibodies account for at least some of the resistance to re-infection. Serum antibodies to viral capsids are detectable in some patients with current warts or a history of warts. These antibodies, as well as other host factors, may help to limit the spread of warts to new sites. Although humoral immunity may contribute to resistance to acquisition of infection, host cellular immune reactivity plays an important role in wart regression. Individuals with impaired cell-mediated immunity are particularly susceptible to persistent HPV infection, and their infections are notoriously resistant to treatment. Warts are common in renal and solid organ transplant patients on immunosuppressive therapy, which may contribute to their increased risk of cutaneous malignancy.[40,41] Although there are instances in which treatment of one or a few warts leads to resolution of many or all warts in nonimmunosuppressed patients, this outcome is the exception rather than the rule.

The source or reservoir for HPV is believed to be individuals with clinical and sub-clinical infection, as well as virus present in the environment. Using sensitive PCR detection, there is considerable evidence that HPV DNA, including novel types and those found in EV, is often resident at extremely low levels in normal skin and hair follicles of immunocompetent individuals.[14,42] This contrasts with the large amounts of virus readily detected in EV lesions. Studies to identify the HPV genotype in EV wart lesions are limited to research laboratories. When ultra-sensitive techniques are used to identify HPV DNA in a lesion not known to be caused by HPV, additional evidence should be sought before concluding that the virus has contributed to the development of the lesion. Approximately 50 percent of EV cases are inherited, usually with an autosomal recessive pattern. Mutations in the EVER genes are reported to be present in a subset of EV individuals.[43,44]

Non-genital warts occur most frequently in children and young adults, in whom the incidence may exceed 10 percent.[45,46] The age-specific incidence of non-genital warts differs from that of anogenital warts, which are uncommon in children. Anogenital warts behave as a sexually transmitted condition, and partners can transmit the virus with high efficiency.[47] Penile lesions occur frequently in the sexual contacts of women with cervical intraepithelial neoplasia, but not all pearly penile papules are caused by HPV.[48,49]

Although genital warts in children may be a consequence of sexual abuse, such warts in infants and children commonly result from virus inoculation at birth or from incidental spread from cutaneous warts (see Chap. 105). In contrast to anogenital lesions in adults, a significant proportion of genital warts in children contain HPV types that are usually isolated from non-genital warts.[50–52]

The majority of respiratory (laryngeal) papillomas occur in infants and young children. Oral and respiratory warts in adults are usually the consequence of oral-genital contact. The HPVs isolated from respiratory tract papillomas are often the same types as those of genital warts, especially HPV-6 and -11,[53] and respiratory papillomatosis in young children is thought to result from seeding of the larynx and oropharynx during parturition.[54] Although the epidemiologic correlation of condyloma in mothers of infants with respiratory papillomas has been documented,[55] cervical and genital warts are common in the childbearing age bracket, and respiratory papillomatosis of infants is rare. Because Cesarean section has attendant risk and is not fully protective, this is not routinely recommended for expectant mothers. Instead, treatment efforts should be aimed at reducing HPV infection before delivery.

In addition to causing lesions on the external genitalia, genital-mucosal HPV types also infect the uterine cervix.[56,57] This sexually transmitted infection, which may involve low- or high-risk HPV types, is especially common in sexually active women younger than 25 years of age. The majority of HPV DNA–positive cervical infections are transient and remain histologically normal. Thus, even normal-appearing genital skin or mucosa may represent a reservoir for contagion. Studies of large populations throughout the world have clearly documented the natural history of cervical infection and the association of high-risk HPV with cervical cancer. Persistence of HPV DNA strongly correlates with an increased risk for progression to cervical dysplasia and invasive cancer. High-risk HPV DNA has also been detected in clinically normal penile skin, although less is known of the epidemiology of genital HPV infection in men.[58]

CLINICAL FINDINGS

History

The typical history is of a newly acquired, slowly expanding, persistent, and often scaly lesion of the skin. Over several weeks to months, the appearance of additional nearby lesions is suggestive of local spread and the diagnosis of HPV infection.

Cutaneous Lesions

Warts are described by their clinical location or morphology. As shown in Figs. 196-3 to 196-8, the cutaneous manifestations of warts are varied. Common warts (verruca vulgaris) are scaly, rough, spiny papules or nodules that can be found on any cutaneous surface (see Table 196-1). They often occur as single or grouped papules on the hands and fingers (see Figs. 196-3A to 196-5). Verrucae may also be filiform (see Fig. 196-6) or appear as cutaneous horns. Flat

▲ **FIGURE 196-4** Common wart. Large hyperkeratotic nodules are seen on the lower lip.

▲ **FIGURE 196-5** Common wart. A giant wart is seen on the dorsum of the hand in a renal transplant recipient; the lesions were resistant to treatment, but resolved spontaneously when immunosuppressive therapy was discontinued.

warts, (verruca plana), are 1 to 4 mm, slightly elevated, flat-topped papules that have minimal scale (see Fig. 196-8). These are most frequent on the face, hands, and lower legs. Plantar and palmar warts are thick, endophytic, and hyperkeratotic papules, which may be painful with pressure (see Fig. 196-3B,C). Punctate black dots ("seeds") that become evident after shaving away of the outer keratinous surface represent thrombosed capillaries in the papilloma. Mosaic warts result from coalescence of plantar or palmar warts into large plaques (see Fig. 196-3C). Some individuals with an apparently normal immunologic state develop exuberant warts of the palms or soles that are refractory to treatment. Butcher's warts are verrucous papules, usually multiple, on the dorsal, palmar, or periungual hands and fingers of meat cutters, and may be infected with HPV-7.

Anogenital warts (also known as *condylomata acuminata*, *genital warts*, or *venereal warts*) consist of epidermal and dermal papules or nodules on the perineum, genitalia, crural folds, and anus (Fig. 196-9A–C). They vary in size and can form large, exophytic, cauliflower-like masses, especially in the moist environment of the perineum. Discrete 1- to 3-mm sessile warts may occur on the penile shaft. Lesions that resemble common warts also occur in this region but are unusual. Warts may extend internally into the vagina, urethra, and peri-rectal epithelium.

▲ **FIGURE 196-6** Common warts. Filiform warts on the chin and lips of a child.

▲ **FIGURE 196-7** The large, scaly, and horny warts contain human papillomavirus (HPV)-2. The smaller, flatter, less scaly papules are warts that contain HPV-3.

Bowenoid papulosis is a clinicopathologic entity in which HPVs have been identified.[59] Papules, often multiple, appear as 2- to 3-mm lesions on the external male and female genitalia (see Fig. 75-20; Chap. 75). Histologically, there is cellular atypia resembling Bowen's disease or SCC in situ. These lesions are usually infected with HPV-16, which suggests that bowenoid papulosis may represent a precursor of penile and vulvar cancer. However, the rate of transition to frank malignancy is much lower for the external genitalia than for the cervix. These small papules should be treated because they may represent a reservoir for the transmission of potentially oncogenic HPVs.

Epidermodysplasia Verruciformis

EV usually manifests in childhood with persistent and often widespread warts that do not regress due to unique susceptibility to specific HPV types. Individual lesions typically have either the appearance of flat warts or flat, scaly,

▲ **FIGURE 196-8** Plane warts, verruca plana. **A.** Multiple pinkish flat warts on the face of an 11-year-old girl. **B.** Many flat-topped papules occur in a linear configuration as a result of autoinoculation.

red-brown macules that resemble lesions of pityriasis versicolor (Fig. 196-10). The presence of warts on large areas of the body is suggestive but not necessary to consider this diagnosis. Involvement of the cervical and oropharynx is rare. Failure to clear lesions despite adequate treatment is another indication of potential EV. Because warts in EV almost always recur after treatment, this implies a failure to mount an effective immune response to the HPV infection. Individuals with EV do not usually have frequent bacterial or other viral infections. Immunocompromised individuals, such as those with HIV infection, may have multiple warts that contain EV types and are difficult to eradicate, but this susceptibility is acquired.[60,61] SCCs in EV and immunosuppression usually arise in pityriasis-like lesions on sun-exposed areas (Fig. 196-11). Regional and distant metastases may occur. Although pityriasis-like lesions caused by any EV type may be at increased risk of becoming malignant,

This progressed to so-called *oral florid papillomatosis*.

this is high for those caused by HPV-5 and -8.

Extracutaneous (Mucosal) Infections

Oral warts are small, slightly elevated, soft, often pink or white papules that may be found on the buccal, gingival, labial mucosa, tongue, or hard palate (see Fig. 196-9D). Verrucous, horny papillomas may occur on the palate. Mucosal lesions of the oropharynx, termed *focal epithelial hyperplasia*, also contain HPVs. In oral florid papillomatosis, multiple large verrucae appear within the oral cavity (see Fig. 196-9D). Progression to verrucous carcinoma may occur. Oral warts may result from genital contact. Warts may also occur in the urethra, usually when meatal warts are present. They may spread to the urinary bladder.

In respiratory (laryngeal) papillomatosis, multiple warts usually involve the larynx and may extend to the oropharynx and bronchopulmonary epithelia. Presenting symptoms commonly include hoarseness and stridor. Cases typically occur in infants or young children (in whom the lesions may block the airway), but the condition may develop at any age. These HPV-associated papillomas may spontaneously remit, especially at puberty, but recurrences are frequent.

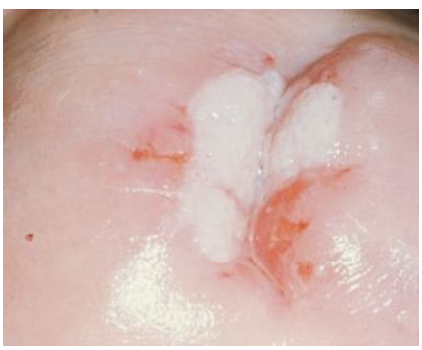
▲ **FIGURE 196-10** Epidermodysplasia verruciformis. Plane wart–like lesions on the dorsa of the hands and forearms, associated with human papillomavirus-5 and -8. The lesions are numerous, flat, reddish, and partly confluent.

▲ **FIGURE 196-11** Invasive cancer in an epidermodysplasia verruciformis patient infected with numerous human papillomavirus (HPV) types, including HPV-5, -8, -9, -14, and others. In the tumor cells, DNA HPV-5 was detected in a high copy number. This large squamous cell carcinoma did not metastasize and did not recur after surgery. There are numerous actinic keratoses on the forehead.

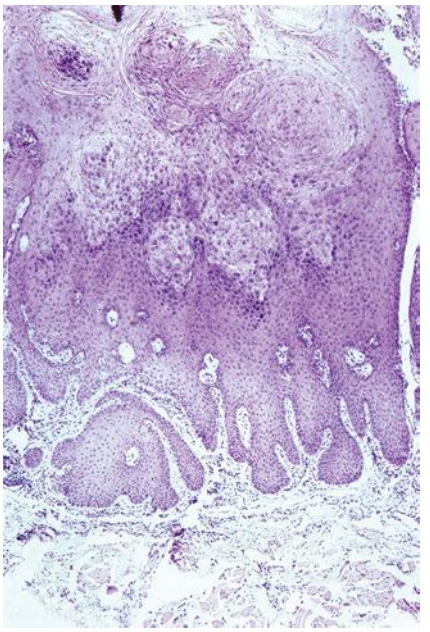
Cervical lesions are usually flat or slightly elevated, and visualization may require colposcopy and enhancement after acetic acid application, which makes them appear as white patches (Fig. 196-12).

Histopathology

Verrucae consist of an acanthotic epidermis with papillomatosis, hyperkeratosis, and parakeratosis (Fig. 196-13). The elongated rete ridges often point toward the center of a wart. The dermal capillary vessels are prominent and may be thrombosed. Mononuclear cells may be present. Large keratinocytes with an eccentric, pyknotic nucleus surrounded by a perinuclear halo (koilocytotic cells or koilocytes) are characteristic of HPV-associated papillomas. Koilocytes visualized in a Papanicolaou (Pap) smear represent a hallmark of HPV infection.



▲ **FIGURE 196-12** Colposcopic view of cervical condyloma after treatment with acetic acid for visualization as white, elevated patch.



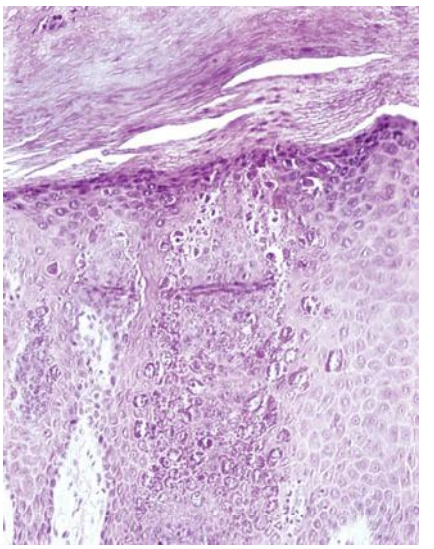
▲ **FIGURE 196-13** Verruca vulgaris. The process is one of extensive hyperplasia, and the hyperplastic cells contain both intranuclear and intracytoplasmic inclusion bodies.

PV-infected cells may have small, eosinophilic granules and dense clumps of basophilic keratohyaline granules. These granules may be composed of or associated with the PV E4 (E1-E4) protein and do not represent conglomerates of virus particles. Flat warts have less acanthosis and hyperkeratosis and do not have parakeratosis or papillomatosis. Koilocytotic cells are usually abundant, indicating the viral origin of the lesion. Anogenital warts may have slight or extensive acanthosis and parakeratosis: they lack a granular layer as they are within or adjacent to a mucosal surface. The rete ridges often form thick bands extending extensively into the underlying, highly vascular dermis.

Plane warts have a similar histologic appearance whether in the general population or in patients with EV (Fig. 196-14). The granular and upper spinous layers contain many cells with perinuclear vacuolization. In EV, lesions containing HPV-5 or -8 have a characteristic basket-weave–like hyperkeratosis with many large clear cells in the granular and spinous layers (Fig. 196-15).

DIAGNOSIS

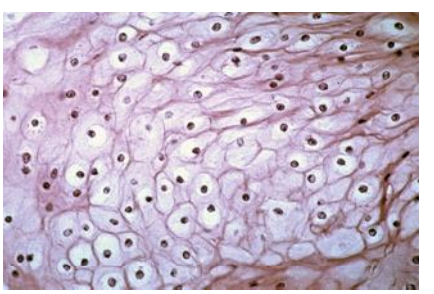
The clinical appearance and history of acquired, slowly enlarging papules usually lead to the diagnosis of viral wart. Histologic examination can be used to confirm the diagnosis. Application of 3 percent to 5 percent acetic acid to genital warts enhances visualization of these lesions, particularly with colposcopic magnification, although the diagnosis should not rest only on the presence of white lesions as the test is non-specific. Antibodies to detergent-disrupted PV particles expose L1 and L2 antigens shared among most PVs. Immunohistochemical detection can be used to detect these capsid proteins in clinical materials, including formalin-fixed tissue, but is insensitive and not routine.



▲ **FIGURE 196-14** Human papillomavirus-3–associated plane wart–like lesion in patient with epidermodysplasia verruciformis. Numerous cells show perinuclear vacuolization in the granular and upper spinous layers.

PCR techniques detect cutaneous or EV-type HPVs but are generally limited to research and diagnostic laboratories. Highly sensitive and specific diagnostic hybridization tests to identify genital-mucosal HPV types are commercially available (Digene Hybrid Capture 2; Roche Amplicor).[62]

Cutaneous warts are commonly found in all age groups. Multiple warts that do not spontaneously resolve, always recur after treatment, persist for years, or have an unusual morphology (especially if familial) suggest EV. HPV typing may be of benefit in confirming the diagnosis of EV and will disclose whether the patient is infected with a type that is associated with cutaneous malignancy. Immunocompromised patients, such as those with acquired immunodeficiency syndrome, lymphoproliferative disorders, or drugs to prevent transplant rejection, often have multiple warts.



▲ **FIGURE 196-15** Characteristic cytopathic effect of epidermodysplasia verruciformis–specific human papillomavirus (HPV) in a patient found to be infected with HPV-5, -8, and -9. Very abundant clear large cells with small pyknotic nuclei replace almost the entire epidermis.

DIFFERENTIAL DIAGNOSIS

Common lesions, such as seborrheic and solar keratoses, nevi, acrochordons, sebaceous hyperplasia, clavi, small pyogenic granuloma, or SCC, may resemble a verruca. The different diagnosis varies considerably with the type of lesions and the site of involvement (Box 196-1).

Papules of lichen planus may resemble flat warts; the former may be differentiated by their color, polygonal shape, Wickham's striae, and buccal involvement (Box 196-2). Acrokeratosis verruciformis and epidermolytic hyperkeratosis are characterized by verrucous papules on the extremities. Warts in epidermodysplasia may resemble pityriasis versicolor but are not transient.

Penile and vulvar warts may resemble nevi, benign keratoses, cysts, or ectopic sebaceous glands (Box 196-3). A history of increasing number of acquired, grouped lesions is suggestive of warts. Syphilitic condylomata must be ruled out.

COMPLICATIONS (See Chap. 111)

Although most PVs are limited to causation of benign lesions, epidemiologic and experimental studies document that specific PV genotypes have oncogenic potential.[63,64] In animals, the benign warts induced in rabbits by the (Shope) cottontail rabbit PV can spontaneously convert to invasive SCC. Small doses of chemical carcinogens induce a high rate of malignant conversion in these lesions. In cattle, esophageal papillomas induced by bovine PV type 4 become malignant if the infected animals graze on bracken fern, which contains a potential carcinogen. The skin cancers that develop in EV are usually in sun-exposed regions. Metastatic tumors in EV contain the viral DNA, implying that its presence is not from skin contamination and that retention of the HPV genome is necessary for maintaining the

malignant phenotype. The benign but locally obstructive verrucae in respiratory papillomatosis, if they are treated by x-rays, often progress to invasive SCC. These observations suggest that oncogenic PVs do not induce malignant tumors directly but predispose the infected cell to tolerate genetic damage that, together with viral oncogenes, contributes to the malignant state.

Robust epidemiologic studies confirm that infection with high-risk HPVs is the cause of virtually all cases of cervical cancer. Even with high-risk HPVs, however, cervical infection usually has a benign outcome.[56,57] Persistent infection with high-risk HPV types is likely necessary but not sufficient to induce development of malignant epithelial tumors. Individuals with impaired cellular immune function, such as renal transplant recipients or HIV infection and acquired immunodeficiency syndrome, are at greater risk of having persistent HPV infection that progresses to severe dysplasia and to cancer.[60]

Epidemiologic and molecular evidence has also linked some penile, vulvar, anal, and oral carcinomas with HPV infection.[65] As with cervical cancer, these tumors are associated primarily with high-risk HPV types. High-risk HPVs, especially HPV-16, have been identified in some periungual cutaneous tumors. The giant condyloma acuminatum, also called the *Buschke-Lowenstein tumor*, is a low-grade, locally invasive SCC. Low-risk HPVs, such as types 6 and 11, are usually found in these tumors. Epithelioma cuniculatum, another rare type of verrucous carcinoma, is found on the sole and is thought to arise from a plantar wart.

There have been many studies that report detection of low levels of HPV DNA, often of EV types, in actinic keratoses, basal cell carcinomas and SCCs, psoriasis, and other skin lesions.[66–70] Because PCR detects HPV DNA in normal skin and hair follicles,[71] the etiologic role of HPV in the pathogenesis of these benign, pre-malignant, and malignant lesions remains controversial.[66,72,73]

TREATMENT

The management of warts depends on the degree of physical and emotional discomfort, the extent and duration of lesions, the patient's immunologic status, and the patient's desire for therapy.[74] With all types of treatments, recurrences are frequent.

Most treatments for verrucae involve physical destruction of the infected cells. The existence of multiple treatment modalities reflects the fact that none is uniformly effective or directly antiviral. The choice of treatment depends on the location, size, number, and type of wart, as well as on the age and cooperation of the patient. Pain, inconvenience, risk of scarring, and the benefit to the patient should be considered. Children with common warts may not require treatment as spontaneous regression is common. However, new warts may appear, and virus can be spread to other areas or susceptible individuals. In patients with anogenital warts (including bowenoid papulosis), sexual partners should be examined, the cervix should be evaluated, and a Pap smear obtained; male contacts of women with cervical disease should also be examined. Anogenital warts in sexual contacts should be treated.

Cryotherapy using liquid nitrogen applied with a cotton tip or a spray canister to achieve a halo of ice in and around the

lesion is a standard and effective treatment for most warts.[75,76] Caution must be used near the nail matrix when treating periungual warts. Aggressive cryotherapy with a spray canister can injure underlying structures such as nerves. Therefore, its use on the lateral surfaces of the digits and genitalia mandates caution. Warts on the elbows and knees of children may be particularly susceptible to scarring with cryotherapy; although effective, this modality should be used in moderation in these patients.

Warts may be curetted or surgically excised, particularly large anogenital warts unresponsive to topical treatments. Electrodesiccation of condyloma acuminata requires local anesthesia but is also effective. Laser treatment in several different energy formats, including photodynamic therapies, can be useful for destroying warts that are treatment-resistant or those that require careful control of width and depth, such as large periungual warts. Use of a surgical mask should be routine because infectious PV has been identified in the vapor plume with laser or with electrocoagulation of warts.[77] Microscopically controlled (Mohs) surgery has been useful in the treatment of verrucous carcinoma. X-irradiation of verrucae is contraindicated because of its association with the development of malignancy in respiratory papillomatosis and EV. Avoidance of and protection from sun exposure is critical in EV.

Chemotherapeutic agents are commonly used to treat warts. Topical podophyllin resin is useful for moist anogenital warts. Podophyllin is contraindicated during pregnancy, and the potency of podophyllin preparations may be variable. Purified podophyllotoxin (Condylox) has activity that is uniform from batch to batch and is approved for treatment of genital and perianal warts.[78] Topical 5-fluorouracil has been used to treat cutaneous and genital warts, and has been reported to be highly effective, with occlusion in the treatment of plantar warts.[79] Intralesional bleomycin may eradicate verrucae but should be used cautiously because of the possibility of extensive tissue necrosis.[80] Anecdotal reports suggest topical application of the nucleotide analog cidofovir may be effective in the treatment of warts, however, pain and ulceration are potential side effects.[81,82]

Caustics and acids, such as salicylic acid, lactic acid, and trichloroacetic acid, destroy and peel off infected skin. Retinoic acid has been used topically for flat warts and probably has a similar mechanism of action. Home use of salicylic acid preparations can be particularly efficacious in young children who cannot tolerate other modalities. Cantharidin is an extract of the green blister beetle that is painlessly applied and causes delayed blistering and focal destruction of epidermis.

Immunotherapies have been attempted in various forms. Induction of allergic contact dermatitis with dinitrochlorobenzene, squaric acid dibutylester, or diphenylcyclopropenone allows localization of inflammation to warts on which the allergen is painted; it has been speculated that this treatment stimulates local immunity.[83,84] Dinitrochlorobenzene is positive in the Ames bacterial test of mutagenicity, and its use remains controversial. Cimetidine has been associated with the resolution of cutaneous warts, particularly in children. Although this regimen has its supporters, a double-blind controlled study showed no beneficial effect.[85] Interferon has been effective in short-term studies, reducing warts in laryngeal papillomatosis and EV, but lesions return when therapy is stopped. Recombinant interferons have been used by intralesional injection of refractory genital warts.[86] It is not clear that interferon acts through stimulation of immune response. Imiquimod, a potent stimulator of the release of several proinflammatory cytokines that acts at least in part by activation of Toll-like receptors 7 and 8,[87] is patient-applied therapy that is approved for treatment of genital warts, although cure rates are significantly lower than treatments with physical modalities.[88] Imiquimod is less effective for cutaneous warts. Recently, anecdotal reports suggest that intralesional injections of candidal extracts induce wart regression.[89–91] Because yeast and viruses share no homologous proteins, the mechanism of action is obscure. Imiquimod and low-dose retinoids may reduce the development of cutaneous malignancies in renal transplant recipients.[92,93]

PREVENTION

For non-genital warts, no approaches have been documented to prevent transmission, although direct exposure to lesions or to fomites that contain virus represent likely sources of infection. For genital HPV infection, the risk is correlated with the number of sexual partners, which implies that reducing that number should reduce the likelihood of infection. The risk of genital infection appears to be lower in circumcised males and in their sexual partners,[94] and there is some evidence that regular use of condoms may partially protect against the acquisition of genital HPV infection.[95] Widespread Pap smear screening in the United States and other developed countries has greatly reduced the incidence of cervical cancer.

A prophylactic HPV vaccine represents the newest approach to preventing genital HPV infection. The vaccine, which is non-infectious, is based on the observations that the L1 protein, when expressed in cells, self-assembles to form virus-like particles (VLPs) that morphologically resemble authentic capsids (see Fig. 196-2). VLPs exhibit the same type-specific epitopes as the authentic virus, and purified VLPs induce high titers of neutralizing antibodies.[96] In human clinical trials, the L1 VLP vaccine, which is given intramuscularly, has been shown to induce seroconversion in more than 99 percent of vaccinees, to induce serum neutralization antibody titers that are 40 times or greater than those that develop after natural infection, and to confer close to 100 percent protection in women against the development of lesions attributable to the genital HPV types in the vaccine.[97–100] A quadrivalent version of the vaccine (Gardasil), composed of L1 VLPs from HPV-6, -11, -16, and -18, was approved by the U.S. Food and Drug Administration in 2006 for girls and women ages 9 to 26 years. Despite its high level of efficacy in preventing HPV infection, the vaccine does not appear to have therapeutic activity against established infection. Another limitation is that its protection appears to be largely type-specific, which means that most infections caused by HPV types other than those in the vaccine will not be prevented. However, HPV-6 and -11 cause approximately 90 percent of genital warts, whereas HPV-16 and -18 cause about 70 percent of cervical cancer. Thus, the quadrivalent vaccine has the potential to drastically reduce the incidence of genital warts in vaccinees and to protect against the majority of HPV infections that lead to cervical cancer. A bivalent HPV-16 and -18 VLP vaccine (Cevarix) is also being developed commercially, primarily as a vaccine to prevent cervical cancer.

CHAPTER 197

Human Retroviral Disease: Human T-Lymphotropic Viruses

Erwin Tschachler

The first known pathogenic human retrovirus was isolated in 1980 from the lymphocytes of a patient with cutaneous T-cell lymphoma (CTCL) by Poiesz and co-workers.[1] Independently, Miyoshi and co-workers later isolated an identical retrovirus from a Japanese leukemia patient.[1] The name *human T-cell leukemia virus type 1* (HTLV-1) is used now for all isolates previously called *adult T-cell leukemia virus* in Japan and *HTLV* in the United States.

EPIDEMIOLOGY

An estimated 10 to 20 million individuals are infected by HTLV-1 worldwide,[1–3] with an endemic pattern in southern Japan, the Caribbean islands, and some countries in equatorial Africa. In some of these locations seroprevalence ranges from 1 percent to 36 percent.[1–3] Small clusters of HTLV-1/HTLV-2 seropositive populations have been reported in restricted areas in South America, among Australian aborigines, and in the Middle East.[1–3] In the United States and Europe the incidence of HTLV-1 infection is below 0.1 percent, and clusters are found predominately among immigrants from endemic areas, especially those from the West Indies and Africa.[1–4]

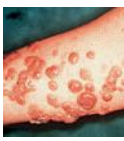
Sexual intercourse is the main mode of horizontal transmission of HTLV-1.[1,2,5] In vertical transmission, breast-feeding plays a more important role than perinatal or intrauterine transmission.[2,5] Parenteral transmission of HTLV-1 is also possible, and approximately one-half of patients who received transfusions from an HTLV-1–infected donor seroconvert.[1,2,5] By contrast, cell-free fresh frozen plasma appears not to be infectious. Transfusion-mediated HTLV-1 infection in Japan has been virtually eliminated by mass screening of donated blood. Parenteral transmission via needle sharing very likely accounts for clusters of HTLV-1/HTLV-2 seropositivity in intravenous drug users in certain areas of the United States and Europe.[6]

ETIOLOGY AND PATHOGENESIS

HTLV-1 together with HTLV-2, a virus that has not yet been clearly associated with any human disease, and bovine leukemia virus form their own genus within the retroviridae.[2] Many strains of HTLV-1 have been isolated in different areas of the world, including the United States, the Caribbean islands, Africa, and Japan.[3] The overall nucleic acid sequence variation among different HTLV-1 strains does not exceed 7 percent. By comparison, the nucleotide sequence conservation between HTLV-1 and HTLV-2 is only approximately 55 percent.[7] In addition to genes coding for viral structural proteins, both the HTLV-1 and HTLV-2 genomes contain an extra sequence of approximately 1.6 kilobases between the *env* and the 3′ LTR, which contains several regulatory genes. These include the transregulatory proteins Tax (transactivator in the region x) and Rex (regulator in the region x), whose functions have been elucidated,[8] but the function of the other proteins of the pX region—p21Rex, $p12^{I}$, $p13^{II}$, and $p30^{II}$—still awaits full clarification.

HUMAN T-LYMPHOTROPIC VIRUS 1–INDUCED SKIN DISEASES AT A GLANCE

- An estimated 10 to 20 million people are infected by human T-cell lymphotropic virus type 1 (HTLV-1) worldwide, with endemic pockets of high prevalence in southern Japan and the Caribbean islands.
- Infective dermatitis is a recalcitrant form of eczema occurring in HTLV-1–infected children in the Caribbean.
- Adult T-cell leukemia (ATL) shows monoclonal HTLV-1 provirus integration in tumor cells and occurs in four clinical variants, all of which tend to show skin involvement:
  - Smoldering ATL—5 percent of all cases
  - Chronic ATL—15 percent of all cases
  - Lymphoma-type ATL—20 percent of all cases
  - Acute ATL—60 percent of all cases
- The prognosis of lymphoma-type and acute ATL is very poor despite chemotherapy, with a projected 4-year survival of 5 percent.



Infection of human, monkey, and rabbit T lymphocytes by HTLV-1 in vitro leads to their continuous growth in tissue culture and the development of cell lines with growth characteristics of transformed cells. In infected patients, HTLV-1 is present mainly in $CD4^+$ T cells.[9] The steps leading from virus infection to the development of the different HTLV-1–associated diseases are still only partly understood. Only a small percentage of patients infected with HTLV-1 ultimately develop adult T-cell leukemia (ATL), and the time from infection to the appearance of leukemia is usually several decades.[2]

Tax, the viral transactivator, is necessary for the transformation of T cells. It interferes with at least two inhibitors of cell cycle progression, including the tumor suppressor protein $p16^{ink}$ and p53.[2,8] In the transformed state, HTLV-1–infected T cells proliferate in the absence of exogenous growth factors. This event correlates with both the constitutive activation of the Janus kinase/signal transducer and activator of transcription (Jak/STAT) signaling pathway[8] and the constitutive activation of the cyclin E/cyclin-dependent kinase 2 complex. The in vitro model of T-cell transformation appears to mirror the event that leads to leukemogenesis. In most cases of ATL, genetic mutation or deletion of p53 or $p16^{ink}$ occurs,[8] and the leukemic cells of 70 percent of patients display constitutive activation of the Jak3 and STAT proteins.[8]

Although HTLV-2 has been less well studied than HTLV-1, most of the properties described for the latter, including the transformation of T cells in vitro and the presence and importance of transregulatory genes, are also true for the former.[2] To date, however, no disease has been associated with HTLV-2 infection.

HUMAN T-LYMPHOTROPIC VIRUS 1 INFECTION AND CLINICAL DISEASES

Adult T-Cell Leukemia/Lymphoma

Uchiyama and co-workers first described ATL in 1977 as a distinct malignancy of mature T cells occurring primarily in patients born in southwestern Japan.[1–3,5] At the beginning of the 1980s, HTLV-1 was linked to ATL by virus isolation from leukemic cells, by the demonstration of oligoclonal or monoclonal integrated HTLV-1 provirus in leukemic cells, and by extensive seroepidemiologic studies.[2,5] Besides Japan, the West Indies are a major region where HTLV-1 infection and ATL are endemic.[2,5]

Although the presence of HTLV-1 is a prerequisite for ATL development, infection with this virus does not necessarily lead to the occurrence of leukemia. More than 90 percent of infected individuals remain asymptomatic carriers.[2,5] The annual incidence rate of ATL among HTLV-1 carriers older than 40 years of age is approximately 0.6 to 1.7 in 1000.[10] The cumulative incidence rate of ATL in HTLV-1 carriers approximates 2 percent to 5 percent. The latent period from infection to outbreak of leukemia is 20 years or longer, as concluded from studies in migrants.[11] Interestingly, the average age of onset of ATL differs in patients in Japan (56 years) and in the Caribbean (43 years).[12]

According to the World Health Organization's lymphoma classification, ATL is a peripheral T-cell lymphoma. Based on the clinical course and laboratory parameters, ATL is classified into four subtypes—(1) smoldering (5 percent of cases), (2) chronic (15 percent), (3) lymphoma type (20 percent), and (4) acute or prototypic ATL (60 percent)—for which diagnostic criteria have been formulated (Table 197-1).[13,14]

Acute, prototypic ATL is a fatal malignancy of adult onset with a clinical presentation that appears to be identical in all endemic areas.[5] It is characterized by the variable combination of multiorgan involvement, including hepatosplenomegaly, systemic lymphadenopathy, central nervous system involvement, and skin lesions, with the massive presence of multi-lobated leukemic cells in the peripheral blood (Fig. 197-1A). The presence of leukemic infiltrates in different organs determines the clinical presentation and the morbidity: central nervous system involvement may alter the mental status of the patient; lymphoma within the liver may lead to abnormalities in liver function test results and jaundice; and lung involvement may lead to tachypnea, cyanosis, and dyspnea.

A striking feature in a high percentage of patients with acute ATL is refractory hypercalcemia, which may be the first sign of the disease and indicates an aggressive course.[5,15,16] Patients may have weakness, lethargy, polyuria, and polydipsia. Lytic bone lesions resembling those of multiple myeloma are often present at the time of diagnosis, and levels of alkaline phosphatase may be elevated.[15,16] Parathyroid hormone levels and 1,25-dihydroxyvitamin D levels are normal in ATL patients with hypercalcemia. Factors produced by leukemic cells themselves have been suggested to account for the hypercalcemia and bone resorption in ATL patients.[16]

TABLE 197-1
Diagnostic Criteria for Adult T-Cell Leukemia (ATL)

Features Common to All ATL Sub-Types
- Positive results on serologic testing for HTLV-1
- Clonal integration of HTLV-1 in tumor cells
- Expression of CD25 and HLA class II antigens by tumor cells

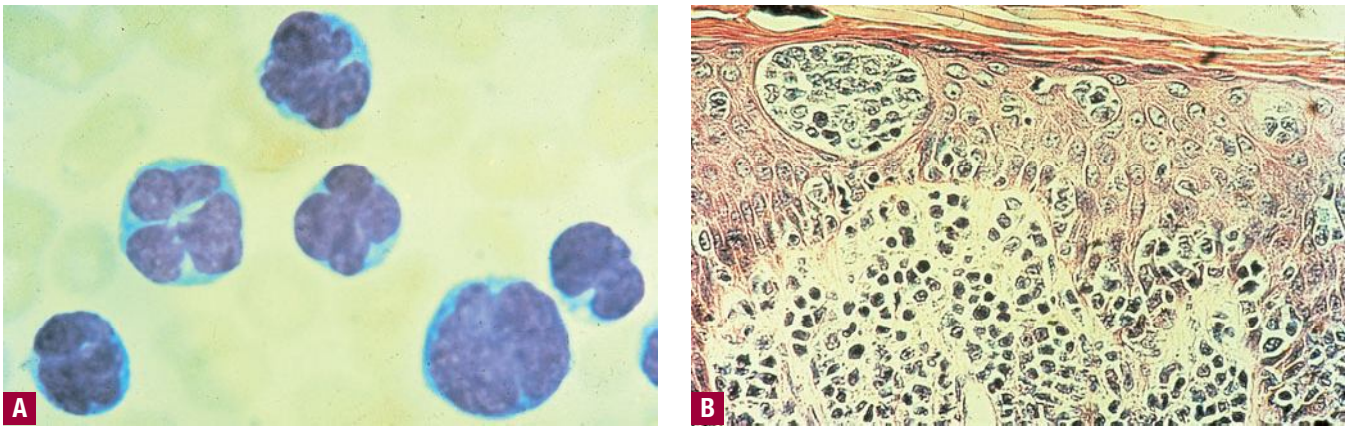
Distinguishing Features of ATL Sub-Types
- Smoldering ATL
  - Normal lymphocyte counts with 1%–5% leukemic cells present
  - Skin lesions and/or lung lesions present but no other visceral involvement
  - No lymphadenopathy, no hypercalcemia
  - Serum LDH level up to 1.5× the normal upper limit
- Chronic ATL
  - Lymphocytosis ($> 4 \times 10^9$/L) with 5% or more leukemic cells present
  - Skin, liver, lung, or lymph node involvement; other viscera not involved
  - No hypercalcemia
  - Serum LDH level above 2× the normal upper limit
- Lymphoma-type ATL
  - Normal lymphocyte counts with < 1% leukemic cells present
  - Possible involvement of multiple visceral organs, lymphadenopathy
  - Possible hypercalcemia
  - Serum LDH level strongly elevated
- Acute ATL
  - Large numbers of leukemic cells present in peripheral blood
  - Involvement of multiple visceral organs with organomegaly
  - Frequently hypercalcemia with osteolytic lesions
  - Serum LDH level strongly elevated

HTLV-1 = human T-cell lymphotropic virus type 1; LDH = lactic acid dehydrogenase.

Lymphoma-type ATL also shows severe organ involvement and high serum levels of lactic acid dehydrogenase and may be associated with hypercalcemia. Unlike in acute ATL fewer than 1 percent leukemic cells are present in the peripheral blood. Both lymphoma-type and acute ATL have a poor prognosis, with a projected 4-year survival of no more than 5 percent.[17]

Smoldering and chronic ATL have more protracted courses; however, they may convert into acute ATL.[5,13]

The skin involvement in ATL varies considerably among patients but is present to a variable degree in all forms



▲ **FIGURE 197-1** **A.** Abnormal lymphocyte with multi-lobated nucleus ("flower cell") from a patient with adult T-cell leukemia (ATL). (Used with permission from K. Takatsuki, MD, Kumamoto University, Japan.) **B.** ATL tumor cells infiltrate the epidermis, creating Pautrier's microabscesses. (Used with permission from B. Hanchard, MD, University of the West Indies, Kingston, Jamaica.)

of ATL.[5,17–19] Skin lesions may appear as uncharacteristic erythematous patches, as papules and nodular tumors (Fig. 197-2), and as erythroderma. Non-specific skin lesions may precede the onset of acute ATL by up to two decades.[20] Specific skin infiltrates may occur as the first manifestations of ATL, and monoclonality of skin-infiltrating cells may be evident by the criteria of both T-cell receptor rearrangement and integration of HTLV-1 DNA. This occurs at a time when circulating T cells of these patients still appear unaffected.[18] To designate this latter situation, the term *cutaneous-type ATL* has been proposed.[18] However, it is questionable whether this form represents an independent type of ATL or should be included in the smoldering form. Alternatively, it may reflect very early detection of prototypic or chronic ATL as a result of improved diagnostic methods.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF ADULT T-CELL LEUKEMIA Not only does prototypic ATL show a characteristic clinical course but examination of the leukemic cells yields a characteristic picture: numerous multi-lobated cells called *ATL cells* or *flower cells* (see Fig. 197-1A) are present in peripheral blood and can usually be readily distinguished from cells of other T-cell leukemias by light microscopy, although sometimes occasional cells indistinguishable from Sézary cells may be present.[5,16] In smoldering-type ATL and chronic-type ATL, multi-lobated cells are less frequent, and in lymphoma-type ATL they may comprise fewer than 1 percent of lymphocytes (see Table 197-1). Monoclonal integration of HTLV-1 DNA[5,8,16,18] in leukemic cells as well as in affected organs is a diagnostic criterion. Immunophenotyping shows that leukemic cells display predominantly a mature $CD2^+/CD3^+/CD4^+/CD8^-/CD25^+$ phenotype.[5,16] Although most of these T-cell markers can be found in other T-cell malignancies, the strong expression of the interleukin 2 receptor α chain (CD25) can be regarded as a distinguishing marker differentiating ATL and Sézary syndrome.[5,21]

The histopathologic features seen in affected organs and lymph nodes are more variable than the signs in peripheral blood, and ATL is associated with lymphomas of several histologic subtypes. Differentiation of ATL from other peripheral T-cell lymphomas, especially HTLV-1–positive and HTLV-1–negative cases, on morphologic grounds is not possible. No specific pathologic finding distinguishes ATL from other forms of non-Hodgkin lymphoma. Difficulties can also be encountered in differentiating the skin manifestations of ATL from mycosis fungoides (MF) and Sézary syndrome, because focal epidermal infiltration by T cells or Pautrier's microabscesses (see Fig. 197-1B) can be present in skin lesions of ATL.[20,22,23] Indeed, the

▲ **FIGURE 197-2** Skin manifestations of adult T-cell leukemia (ATL). **A.** Generalized papular infiltrates in a patient from Jamaica with prototypic ATL. **B,C.** Nodular skin tumors in Japanese ATL patients. (Used with permission from K. Takatsuki, MD, Kumamoto University, Japan.)

diseases of patients from whom the original U.S. HTLV-1 isolates were obtained were classified as Sézary syndrome and CTCL.[1] Four diagnostic criteria have been put forward that must be fulfilled to unequivocally establish the diagnosis of HTLV-1–associated ATL[5,13,14]: (1) a histologically or cytologically proven lymphoid malignancy with T-cell surface antigens must be present; (2) abnormal T lymphocytes must be detected in peripheral blood, except in the lymphoma type; (3) anti–HTLV-1 serum antibodies must be present; and (4) the clonality of HTLV-1 proviral DNA must be demonstrated.

The fact that the first HTLV-1 isolates were obtained from patients misclassified as having MF and Sézary syndrome, together with the earlier reports regarding the presence of retroviral particles in the skin and lymph nodes of patients with these diseases, has prompted an intensive search for HTLV-1 in CTCL. Although several reports claimed that HTLV-1 DNA sequences were detectable in tumor tissue and in cell lines derived from MF patients,[24] an overwhelming majority of investigators, studying patients from the same geographic regions with comparable methods, were unable to find HTLV-1 DNA in CTCL samples.[25–27] It is now well accepted by most that HTLV-1 is not involved in the pathogenesis of CTCL (see Chap. 146).

PROGNOSIS AND TREATMENT OF ADULT T-CELL LEUKEMIA The prognosis of ATL depends largely on the sub-type. In the most extensive study on the course of ATL to date, 818 Japanese patients newly diagnosed with the disease were studied for a median follow-up time of 13.3 months.[5,12] Median survival time was 6.2 months for those with the acute type, 10.2 months for those with the lymphoma type, and 24.3 months for those with the chronic type. Projected 2- and 4-year survival rates were, respectively, 16.7 percent and 5.0 percent for the acute type, 21.3 percent and 5.7 percent for the lymphoma type, 52.4 percent and 26.9 percent for chronic type, and 77.7 and 62.8 percent for the smoldering type. The presence of hypercalcemia, high levels of lactic acid dehydrogenase, and an excessively high white blood cell count are prognostic factors[5,12–14] associated with poor survival.

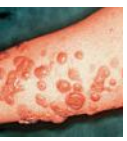
Treatment of ATL remains disappointing. Combination cytotoxic therapy used to treat non-Hodgkin lymphoma has little effect on prototypic ATL and ATL lymphoma.[27] Although complete remission can be achieved in up to 40 percent of patients with different combinations of conventional chemotherapy, most of the patients experience relapse within weeks or months, and the 4-year overall survival rate is below 10 percent.[27,28] Frequent complications of treatment include septicemia and opportunistic infections, which result from chemotherapeutic intensification of the immune suppression already present in ATL patients.[15,16] Besides conventional chemotherapy, the combination of interferon-α and zidovudine, a nucleoside analog used against human immunodeficiency virus type 1, has shown some effect in the treatment of acute and lymphoma-type ATL.[5,28,29] Allogeneic bone marrow transplantation, which has been used in a few cases of ATL,[5,28] as well as the combination of chemotherapy and administration of hemopoietic growth factors,[30] might still hold some promise for the future. Other therapeutic approaches, including the use of monoclonal antibodies against surface molecules of leukemic cells, arsenic trioxide, proteasome inhibitors, and angiogenesis inhibitors, have been under study; however, to date no breakthrough has been reported.

The course of smoldering and chronic ATL is less dramatic, internal organ involvement and hypercalcemia are observed less frequently than in ATL lymphoma and acute ATL,[5,12,16,28] and the prognosis is better.[5,12,16,28] Because chemotherapy-associated immunosuppression increases the immunosuppression caused by the disease itself, early chemotherapy may be more harmful than beneficial for patients with smoldering and chronic ATL. Therefore, these patients should not be treated with chemotherapy unless they enter a more aggressive phase of their disease. The combination of zidovudine and interferon-α has been suggested as a possible treatment for these clinical variants.

Non-Malignant Sequelae of Human T-Lymphotropic Virus 1 Infection

NEUROLOGIC DISEASE HTLV-1 infection is associated with chronic progressive myelopathy, which is referred to as *tropical spastic paraparesis* (TSP) in the Caribbean and *HTLV-1–associated myelopathy* (HAM) in Japan.[31] Patients with TSP/HAM are generally younger than ATL patients, and the latent period from infection to development of clinical neurologic symptoms has been described to be very short in individual cases. The lifetime risk for developing TSP/HAM has been estimated at 1 percent.[32] In contrast to ATL, which is associated with HTLV-1 infection very early in life, TSP/HAM frequently occurs in patients who became infected only in adolescence. In particular, the acquisition of HTLV-1 by blood transfusion has been reported to play an important role in the development of TSP/HAM.

INFECTIVE DERMATITIS Infective dermatitis (Fig. 197-3) is a severe, chronic, relapsing eczema in Jamaican children[33] associated with infection by *Staphylococcus aureus* and β-hemolytic streptococci.[33] An association between infective dermatitis and HTLV-1 infection has been reported. Bacterial infection in infective dermatitis is difficult to control, and although it responds to antibiotic treatment, prolonged therapy is necessary and relapses are common after discontinuation. The characteristic clinical picture, the recalcitrant course, and HTLV-1 seropositivity sets infective dermatitis apart from other forms of recurrent eczema, including atopic eczema.[33] Immunosuppression observed by other investigators in HTLV-1 carriers, as well as in ATL patients,[34] may play a role in the pathogenesis of infective dermatitis. Although HTLV-1–infected individuals are over-represented among patients hospitalized for infectious diseases in Japan, infective dermatitis has rarely



▲ **FIGURE 197-3** Infective dermatitis in a Jamaican girl infected with human T-cell lymphotropic virus type 1. (Used with permission from L. LaGrenade, MD, University of the West Indies, Kingston, Jamaica.)

been reported in regions outside the Caribbean. Regional, cultural, or genetic factors may play an additive role in the occurrence of infective dermatitis. Evidence that infective dermatitis in childhood might be associated with subsequent development of ATL comes from a report of a patient who developed ATL 17 years after having been diagnosed as having infective dermatitis in Jamaica.[35] In addition to infective dermatitis, several other infectious and non-infectious skin disorders are frequently observed in HTLV-1–infected individuals.[36]

OTHER DISORDERS In addition to the diseases described in the previous sections, certain types of uveitis, polymyositis, chronic inflammatory arthropathy, and peripheral neuropathy have been suggested to be associated with HTLV-1 infection.[5] However, future epidemiologic and virologic studies will be necessary to establish the causative role of the virus in the pathogenesis of these diseases.

CHAPTER 198

Cutaneous Manifestations of Human Immunodeficiency Virus Disease

Arturo Saavedra
Richard Allen Johnson

Over 30 million people have died from infection with human immunodeficiency virus (HIV). In the United States, roughly 1.2 million people are currently infected, and there are approximately 300,000 undiagnosed cases. It is estimated that 40,000 new infections occur annually. In 2005, 40.3 million people were estimated to be living with HIV worldwide, twice the number in 1995. Fewer than 15 percent of those who need highly active antiretroviral therapy (HAART) are currently being treated, and the majority of those in regions of higher prevalence, such as sub-Saharan Africa, do not know they are infected. Identification of HIV-associated dermatologic disease may therefore lead to testing and diagnosis, particularly in resource-poor countries.[1]

Cutaneous disorders occur in nearly every patient during the course of HIV disease as a result of the acquired immunodeficiency or the effects of treatment. The spectrum of dermatologic manifestations of HIV disease is very broad and diverse.[2] Individuals who have access to HAART, in most cases those living in North America, Western Europe, and Australia, have a markedly altered course of HIV disease if immune restoration is achieved.[3] In most cases, there is a significant reduction in the incidence of opportunistic infections and neoplasms. Globally, however, more than 95 percent of HIV-infected individuals have no access to any medical interventions, and therefore many of the cutaneous manifestations associated with HIV disease become chronic and progressive.

ETIOLOGY AND EPIDEMIOLOGY

HIV is a lymphotropic human retrovirus. HIV-1 is the cause of nearly all HIV infection in the United States and Europe; HIV-2 infection has been detected mainly in West Africa. HIV is a bloodborne pathogen, transmitted by sexual contact with an infected person, significant exposure to infected blood (such as needle sharing among users of injected drugs, including crack cocaine), and perinatal transfer from an infected mother to her child. Both HIV-1 and HIV-2 cause similar clinical HIV disease. HIV-1 has at least 10 sub-types, designated A through J, each with several recombinant forms. Sub-type B is prevalent in the United States and Western Europe and is found mainly among men who have sex with men and injecting drug users. Sub-type E—unlike sub-type B—is spread very efficiently through heterosexual intercourse. Unlike HIV-1, HIV-2 leads to slower progression of immunosuppression, the duration of heightened infectivity is shorter, and usually the virus is not responsive to nonnucleoside reverse transcriptase inhibitors.[4]

PATHOGENESIS

Four mechanisms are critical for the establishment and propagation of HIV infection over time and for the progression of HIV disease. HIV is not eliminated after primary infection. Persistent viral replication occurs in lymphoid organs throughout the course of HIV infection. Chronic stimulation of the immune system causes inappropriate immune activation and progressive exhaustion of the immune response. Destruction of lymphoid tissue results in severe impairment of the ability to maintain an effective ongoing HIV-specific immune response and to generate immune responses against new pathogens. Experiments in rhesus monkeys demonstrate that Langerhans cells in the cervicovaginal epithelium fuse with $CD4^+$ lymphocytes that transport the virus to deeper tissues.[5] Langerhans cells may become infected by HIV, and decreased Langerhans cells function could account for some of the cutaneous manifestations of HIV disease.[6]

NATURAL HISTORY

HIV disease is a continuum that progresses from primary infection to death, with a sequence of opportunistic

CUTANEOUS MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS DISEASE

AT A GLANCE

- Over 40 million people are living with human immunodeficiency virus (HIV) infection/acquired immunodeficiency syndrome.
- HIV-1 and HIV-2 are blood-borne human lymphotropic retroviruses that replicate in lymphoid organs and infect many cell types.
- Decreased function of infected epidermal Langerhans cells may account for cutaneous manifestations of HIV disease.
- Dermatologic disease in HIV is a spectrum of inflammatory, infectious, and oncogenic disorders that either may be opportunistic or may also be seen in non-infected individuals.
- HIV-associated dermatoses along with systemic symptoms may suggest the diagnosis and lead to testing earlier in the course of disease or during the acute retroviral syndrome.
- Dermatologic disease may help in estimating the level of immunosuppression, particularly in resource-poor countries.

infections and opportunistic neoplasms marking the gradual destruction of the immune system (Table 198-1). The World Health Organization has published revised criteria for clinical staging in children, adolescents, and adults with confirmed HIV infection.[7] Medically, acquired immunodeficiency syndrome (AIDS) is defined by precise clinical and laboratory parameters. In an individual whose HIV status is unknown or inconclusive and who has no other cause for immunodeficiency, the following mucocutaneous findings are AIDS defining: candidiasis of the esophagus, trachea, bronchi, or lungs (however, not oropharyngeal candidiasis alone); cryptococcosis with hematogenous dissemination to the skin; a herpes simplex virus (HSV) mucocutaneous ulcer that persists longer than 1 month; and Kaposi sarcoma in a patient younger than 60 years of age. In an individual who is HIV seropositive, the following are AIDS defining: coccidioidomycosis or histoplasmosis with hematogenous dissemination to the skin, invasive cervical carcinoma, and Kaposi sarcoma at any age.

TABLE 198-1
Stages of Human Immunodeficiency Virus Disease

Stage and Clinical Features	Typical Duration	$CD4^+$ Cell Range (Cells/μL)
Acute retroviral syndrome (brief mononucleosis-like illness)	1–2 wk	1000–500
Asymptomatic (no symptoms or signs other than lymphadenopathy)	> 10 yr	750–500
Early symptomatic (non–life-threatening infections, chronic or intermittent illness)	0–5 yr	500–100
Late symptomatic (acquired immunodeficiency syndrome; increasingly severe symptoms, life-threatening infections and cancers)	0–3 yr	200–50
Advanced (increasing risk of death, fewer transferable opportunistic infections)	1–2 yr	50–0

Acute Retroviral Syndrome or Primary Human Immunodeficiency Virus Infection

The incubation period of HIV infection (from presumed exposure to development of acute febrile illness) ranges from 3 to 6 weeks, varying with the route of infection and the size of the viral inoculum. Commonly reported clinical manifestations include fever (more than 80 percent to 90 percent of cases), fatigue (more than 70 percent to 90 percent), rash (morbilliform, papulosquamous, vesicular on the upper trunk, palms, and soles; 50 percent to 60 percent) (Fig. 198-1), myalgia/arthralgia (50 percent to 70 percent), pharyngitis (50 percent to 70 percent), night sweats (50 percent), and/or nausea, vomiting, and diarrhea (30 percent to 60 percent). Less commonly reported manifestations include decreased white blood cell count and platelet count (40 percent to 45 percent of cases), weight loss (25 percent), aseptic meningitis (24 percent), anorexia (21 percent), abnormal liver function test results (20 percent), oral ulcers (10 percent to 20 percent), and/or genital ulcers (5 percent to 15 percent).[8] The health care professional must maintain a high index of suspicion in those with sexually transmitted diseases (STDs) or with a suggestive constellation of symptoms. Studies have documented that up to 25 percent of those with HIV disease are not tested, despite having suggestive symptoms.[5] In fact, retrospective HIV testing of samples from patients thought to have Epstein-Barr virus infection were positive for HIV infection 2 percent of the time, and roughly half of those had acute primary HIV infection.[9]

The laboratory diagnosis of HIV-1 infection is made by four methods: detec-

▲ **FIGURE 198-1** Acute retroviral syndrome: Exanthem. Discrete, erythematous macules and papules on the trunk and arm; associated findings were fever, scrotal ulcers, erythematous macules on the palate, and lymphadenopathy.

TABLE 198-2
Laboratory Diagnosis of Human Immunodeficiency Virus (HIV) Infection[5]

Test	Component Tested	Window Period	Role in Diagnosis
Enzyme-linked immunosorbent assay[a]	Antibodies (IgM and IgG)	3–6 wk	Screening
Antigen capture[b]	HIV p24 antigen	2–3 wk	Screening
Western blotting	Antibody (IgG)	3 wk	Confirmatory
Immunofluorescence	Antibody (IgG)	3 wk	Confirmatory
Nucleic acid testing	HIV RNA or DNA	2 wk	Confirmatory
Viral culture	Virus, usually from peripheral blood mononuclear cells, not serum or plasma	—	Confirmatory, research

Ig = immunoglobulin.
[a]Rapid tests as well as particle agglutination tests are also available.
[b]Detection can be increased with the use of immune complex dissociation techniques.
Modified from Maldarelli F: Diagnosis of human immunodeficiency virus infection, in *Principles and Practice of Infectious Diseases*, edited by Mandell GL et al. Philadelphia, Elsevier, 2005, p 1506, with permission.

tion of viral antigens, detection of viral nucleic acids, identification of antibodies to viral proteins, and isolation of HIV by viral culture (Table 198-2). A delay of 3 to 4 weeks exists between new acquisition of HIV-1 infection and development of antibodies, the "window period." The core structural protein p24 antigen can be detected a week before antibodies can be measured. The viral RNA assay detects infection up to 5 days earlier than the p24 assay and appears to be more sensitive.[5]

Course after Acute Retroviral Syndrome

After the initial burst of viral replication and the peak of viremia, the plasma RNA level decreases and then stabilizes to a level called the *viral set point*. Cytotoxic T lymphocytes, particularly those specific for envelope antigens, help control viral replication and are associated with slower declines in $CD4^+$ cell counts. Approximately 6 months after transmission of HIV, the plasma HIV RNA level reaches a relatively stable set point that dictates the subsequent course. In patients with high viral concentrations (viral load), such as 100,000 or more copies per microliter, the disease will have a relatively rapid course, and in those with relatively low concentrations, such as 10,000 copies/μL, it will have relatively slow progression. Undetectable viral load levels may correspond with nonprogression of HIV disease. The average annual decrease in $CD4^+$ cell count is 50 cells/μL (Fig. 198-2). Early treatment with antiretroviral drugs may reduce the viral set point and alter the prognosis of HIV infection.

Multiple variables are known to influence the rate of progression of HIV disease, contributing to induction of HIV expression and potentially modifying and accelerating the course of HIV disease: the size of the HIV inoculum, the site of infection, the immune status of the host, the virulence of the given HIV strain, and re-activation of latent herpesvirus infection.

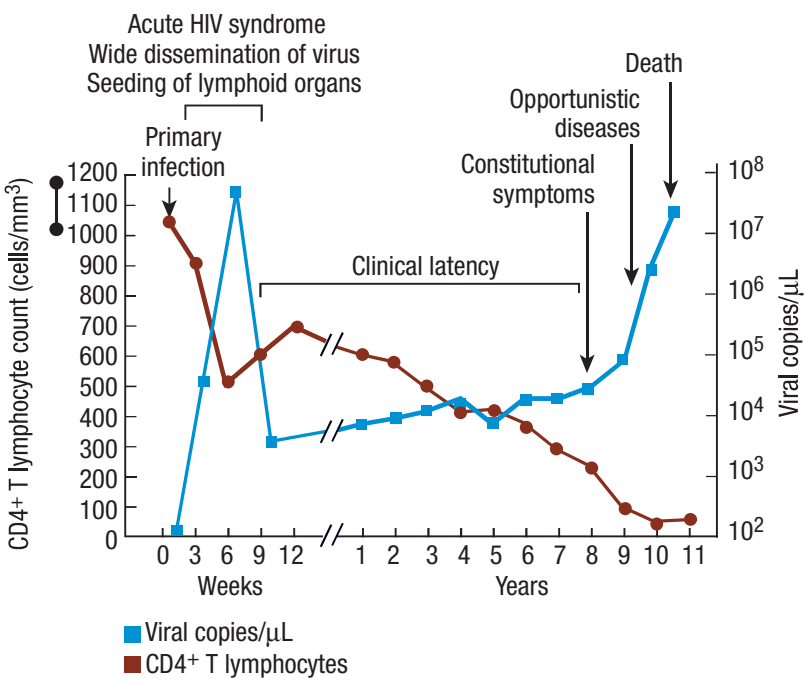
Antiretroviral Drug Therapy and Highly Active Antiretroviral Therapy

The four main groups of antiretroviral drugs are nucleoside analog reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors, protease inhibitors (PIs), and fusion inhibitors. (See Table 198-3 for mechanisms and side-effects.[10])

MUCOCUTANEOUS FINDINGS

More than 90 percent of HIV-infected individuals will experience opportunistic infections, opportunistic neoplasms, dermatoses, adverse cutaneous drug reactions, and pruritus involving the skin and/or mucosa, which occur more commonly as immune function deteriorates. In association with low CD4 cell counts, cutaneous lesions may become quite atypical. Certain cutaneous disorders correlate with low CD4 cell counts (200 to 300 cells/μL), including Kaposi sarcoma, oral hairy leukoplakia (OHL), multiple-lesion facial molluscum contagiosum, xerosis, and oropharyngeal candidiasis. Genital ulcerations can represent infection by treponemes, HSV, and other sexually transmitted agents, but studies have reported that 30 percent to 60 percent of such cases have no proven etiologic agent and may be related to HIV infection itself.[11] Mucocutaneous disorders are commonly the indication for initial HIV testing (Table 198-4).

Immune restoration syndrome is defined by manifestations of HIV disease, which may worsen despite an adequate response to HAART, as measured by an



▲ **FIGURE 198-2** Typical disease course in an individual with human immunodeficiency virus (HIV) infection. (From Fauci A et al: Immunopathogenic mechanisms of HIV infection. *Ann Intern Med* **124**:654, 1996.)

TABLE 198-3
Treatment of Human Immunodeficiency Virus (HIV)/Acquired Immunodeficiency Syndrome: Antiretroviral Medications

Drug Class	Mechanism	Drug Names	Relevant Properties and Side Effects
Nucleoside analog reverse transcriptase (RT) inhibitors (NRTIs)	NRTIs are inserted into the growing viral DNA chain and halt reactions catalyzed by RT, preventing formation of DNA copies in HIV.	Zidovudine (ZVD, AZT) Didanosine (ddI) Zalcitabine (ddC) Stavudine (d4T) Lamivudine (3TC) Emtricitabine Tenofovir disoproxil fumarate Abacavir	ZVD may cause longitudinal melanonychia in 40% of patients, noted 4–8 wk after initiation of therapy; pigmented macules and diffuse hyperpigmentation can also occur. Hypertrichosis, leukocytoclastic vasculitis, and paronychia are reported. DdI may cause vasculitis, SJS, pancreatitis, and peripheral neuropathy. DdC causes aphthous-like ulceration of the oropharynx and esophagus. Rechallenge with abacavir has been associated with several deaths.
Nonnucleoside RT inhibitors (NNRTIs)	NNRTIs bind directly to RT and prevent conversion of RNA to DNA in HIV-infected cells.	Nevirapine Delavirdine Efavirenz	Twenty percent of patients develop rash to nevirapine (1% with SJS) in the first 4–6 wk of therapy. Delavirdine causes rash in 18%–50% of patients.
Protease inhibitors (PIs)	PIs prevent cleavage of protein precursors (HIV-1 protease) essential for HIV maturation, infection of new cells, and replication.	Saquinavir Ritonavir Indinavir Nelfinavir Amprenavir Atazanavir Fosamprenavir Lopinavir	PIs may lead to lipodystrophy, hypersensitivity reaction, and acute generalized exanthematous pustulosis. Indinavir may cause xerosis with or without eczematous or nummular dermatitis, retinoid-like effects, cheilitis, defluvium of the scalp, paronychia, pyogenic granuloma, acute porphyria, hypersensitivity, SJS, "frozen shoulder," and venous thrombosis. Nelfinavir causes morbilliform eruptions in 3%–28% of patients and, less commonly, urticaria.
Fusion inhibitors (FIs)	FIs inhibit the action of gp41 (which is required for membrane fusion) and the binding of virus to host $CD4^+$ cells.	Enfuvirtide/T-20	In up to 98% of patients, an injection-site reaction may occur within the first week of treatment, but discontinuation of therapy is required in only 3% of patients.

gp41 = glycosylated protein spanning viral envelope; SJS = Stevens-Johnson syndrome.

TABLE 198-4
Mucocutaneous Disorders That Are Indications for Human Immunodeficiency Virus (HIV) Serotesting

Highly indicative of HIV infection (correlated with risk factors for HIV infection)
- Exanthem of acute retroviral syndrome
- Proximal subungual onychomycosis
- Chronic herpetic ulcers
- Oral hairy leukoplakia
- Kaposi sarcoma
- Eosinophilic folliculitis
- Molluscum contagiosum, multiple facial lesions in adults

Strongly associated with HIV infection (correlated with risk factors for HIV infection)
- Any sexually transmitted disease (indicative of unsafe sexual practices)
- Herpes zoster
- Signs of injecting drug use
- Candidiasis: Oropharyngeal or recurrent vulvovaginal

May be associated with HIV infection (correlated with risk factors for HIV infection)
- Generalized lymphadenopathy
- Seborrheic dermatitis (extensive, refractory to therapy)
- Aphthous ulcers (recurrent, refractory to therapy)

increase in CD4 cell counts and a decrease in or disappearance of serum HIV RNA. With progressive HIV disease, T helper 2 immune responses dominate, which facilitates development of many dermatologic disorders. With HAART, T helper 1 responses are restored, and some skin disorders regress; however, some conditions, such as varicella-zoster virus (VZV) infections, HSV infections, eosinophilic folliculitis (EF), human papillomavirus (HPV) infections, leishmaniasis, and mycobacterial infections, may worsen.[12] These seemingly paradoxical responses may occur as the host's immune responses recognize silent or latent infections.[13]

CUTANEOUS DISORDERS OCCURRING IN HUMAN IMMUNODEFICIENCY VIRUS DISEASE

Pruritus and Pruritic Eruptions of Human Immunodeficiency Virus Disease

Pruritus, a common complaint in patients with late symptomatic and advanced HIV disease, is a surrogate cutaneous marker for disease progression, occurring more commonly in patients with CD4 counts of less than 50 cells/μL than in those with counts higher than 250 cells/μL. In most cases, primary or secondary dermatoses rather than metabolic disorders are the cause of pruritus.[14] The differential diagnosis of primary pruritic skin disorders includes EF, papular pruritic eruption of HIV (PPE), adverse cutaneous drug eruptions, atopic dermatitis, xerosis, dermatographism, allergic contact dermatitis, scabies, and insect bites.[15] Much less commonly, systemic and metabolic disorders such as lymphoma, renal failure, viral hepatitis (hepatitis B or C), and obstructive liver disease are associated with pruritus in the absence of cutaneous findings (i.e., "metabolic" pruritus; Box 198-1).

An atopic diathesis may become manifest in individuals with advanced HIV disease and pruritus. Changes secondary to chronic rubbing and scratching include excoriations, atopic dermatitis, lichen simplex chronicus, and prurigo nodularis. Secondary *Staphylococcus aureus* infection (impetiginization, furunculosis, or cellulitis) is very common in any of these traumatized lesions. In fact, one cross-sectional study has documented that, in

Box 198-1

Differential Diagnosis of Pruritus in Human Immunodeficiency Virus (HIV)–Infected Individuals

INFLAMMATORY DISORDERS
- Papular pruritic eruption of HIV
- Eosinophilic folliculitis
- Prurigo nodularis
- Atopic dermatitis
- Psoriasis
- Seborrheic dermatitis

INFECTIONS OR INFESTATIONS
- Scabies
- Arthropod assault
- Viral hepatitis

SYSTEMIC AND METABOLIC DISORDERS
- Renal failure
- Liver disease (viral, obstructive)
- Lymphoma

MISCELLANEOUS DISORDERS
- Xerosis
- Ichthyosis vulgaris
- Photodermatitis
- Dermographism
- Allergic contact dermatitis
- Adverse cutaneous drug eruptions

addition to folliculitis, prurigo is the most common cutaneous disorder encountered in patients with CD4+ counts of less than 200 cells/μL. Furthermore, the findings were the same when only those who had never received HAART were examined. On the other hand, idiopathic pruritus and candidiasis were the most common disorders observed in the population with viral loads higher than 55,000 copies/μL.[16] These initial findings may begin to elucidate which dermatoses are related to low CD4+ counts and which are secondary to direct viral effects.

Ichthyosis vulgaris and xerosis are common in advanced HIV disease and may be associated with mild pruritus. PIs (especially indinavir) frequently cause xerosis with or without eczematous dermatitis or nummular eczema, which may be associated with mild or moderate pruritus (see Adverse Cutaneous Drug Eruptions later). These changes occur relatively soon after initiation of therapy.

Eosinophilic Folliculitis and Papular Pruritic Eruption of Human Immunodeficiency Virus

EF is a chronic pruritic dermatosis occurring in persons with advanced HIV disease. In one study, low CD4 count (under 125 cells/μL) and low nadir (average of 66 cells/μL) were associated with EF, regardless of antiretroviral therapy status.[17] EF may occur in immune restoration syndrome. The etiology and pathogenesis are unknown, but EF may be associated with a T helper 2 immune response to an unknown antigen.[18] Clinically, small pink to red edematous, follicular or centric papules (and, much less commonly, pustules) occur symmetrically above the nipple line on the chest (Fig. 198-3), proximal arms, head, and neck. Secondary changes include excoriations, excoriated papules, lichen simplex chronicus, and prurigo nodularis, as well as secondary *S. aureus* infections. In individuals with darker skin, post-inflammatory hyperpigmentation often produces significant cosmetic disfigurement. Once significant immune restoration has been achieved, EF resolves. Histologic findings are specific for EF; peripheral eosinophilia is common, with up to 35 percent eosinophils in some cases.

The most effective therapy for EF is prednisone. The initial prednisone dose is 70 mg by mouth, and the dose is then tapered by 10 or 5 mg over 7 or 14 days. Established lesions resolve, new lesions do not occur, and pruritus subsides. In the majority of persons with successfully treated EF, lesions and pruritus recur within a few weeks after prednisone has been discontinued. In those with severe symptoms, prednisone can be given on alternate days or weekly. Oral isotretinoin is effective and safe for the treatment of EF. It is usually give at a dosage of 40 mg twice a day until lesions and symptoms resolve, then tapered to 40 mg daily for several weeks, and then reduced to 20 mg daily or 40 mg every other day.[19] Isotretinoin can raise serum triglyceride levels, which are often high in HIV-infected persons; serum lipid levels should be monitored regularly. Phototherapy with ultraviolet radiation (UVR) using ultraviolet A or ultraviolet B light, with or without topical or systemic psoralen, is considered to be a safe topical treatment modality in HIV-infected persons.[20] UVR does not appear to have a significant deleterious effect on HIV viral load.[21] High-potency topical corticosteroid preparations may reduce the formation of new EF lesions as well as treat eczematous dermatitis, thus providing symptomatic relief. Cutaneous atrophy is of concern with long-term application. Topical tacrolimus or pimecrolimus may be effective. Sedating antihistamines, such as doxepin, are most effective for symptomatic control of nocturnal pruritus; nonsedating antihistamines are ineffective in relieving pruritus.

PPE has been classified with other pruritic disorders in HIV disease in the continuum between EF and non-specific pruritus. The prevalence is estimated to be between 12 percent and 46 percent in Africans and Haitians; the disease is rarely observed in Europe and North America. The positive predictive value of PPE for HIV infection is approximately 85 percent, and, thus, it is often diagnostic of HIV in countries where serotesting is limited.[22] In addition, it ap-

◀ **FIGURE 198-3** Eosinophilic folliculitis. **A.** Multiple erythematous pruritic papules on the trunk in an individual with a CD4 cell count of 50/μL. **B.** Close-up showing urticarial papules, pustules, and erosions secondary to rubbing and crusts.

▲ **FIGURE 198-4** Papulopruritic eruption of human immunodeficiency virus infection. There are multiple, disseminated excoriated papules, post-inflammatory pigmentation, and small scars. The eruption is very pruritic. (Used with permission from Anisa Mosam, MD.)

pears to be a marker of severe immunosuppression, because over 80 percent of patients with this disorder have CD4 counts of fewer than 100 cells/μL.[23]

The primary lesion is a firm urticarial papule (although sterile pustules have been described as well). Variable erythema may be distributed symmetrically on the trunk and extremities and less commonly on the face (Fig. 198-4). It is occasionally but not always folliculocentric and may be associated with excoriations, post-inflammatory hyperpigmentation, and scarring, which result from the intense pruritus caused by the disease. One report of studies in Uganda has suggested that PPE may be a hypersensitivity reaction to arthropod bites based on histopathologic evaluation of affected skin. The authors proposed changing the name of this disorder to *arthropod-induced prurigo of HIV*.[22] PPE is particularly difficult to treat and is only moderately responsive to antihistamines and topical steroids. Ultraviolet B irradiation appears to be the most effective therapy, although its usefulness is limited by the lack of treatment centers in the resource-poor settings in which the prevalence is highest. Studies of other alternatives are lacking.

Psoriasis Vulgaris

The prevalence of psoriasis vulgaris and psoriatic arthritis (see Chaps. 18 and 19) is increased in HIV disease. The onset of psoriatic lesions may be before or after HIV infection. The appearance of psoriasis in an individual at risk for HIV disease may be an indication for HIV serotesting. Psoriasis with onset after HIV infection has been observed to improve more with HAART than psoriasis that was present before HIV infection. For management of psoriasis vulgaris, see Chap. 18. Short-term administration of retinoids, such as isotretinoin or acitretin, is usually safe. Hyperlipidemia is more likely in HAART-treated individuals. Etanercept and infliximab have been effective for the treatment of psoriasis and psoriatic arthritis in HIV disease but are associated with infections.[24,25]

Erythroderma (See Chap. 23)

Erythroderma in HIV disease may be related to drug hypersensitivity, atopic dermatitis, psoriasis vulgaris, photosensitivity dermatitis, hypereosinophilic syndrome, co-existing human T-cell lymphotrophic virus 1 (HTLV-I) infection, histoplasmosis, or cutaneous T-cell lymphoma.[26]

Pigmentary Disorders

Post-inflammatory hyperpigmentation and hypopigmentation are the most common disorders affecting HIV-infected individuals. Except in light-skinned individuals of northern European heritage, significant lightening or darkening of the skin occurs after any type of inflammatory dermatosis or infection. In addition to pigmentary alterations, significant atrophic or hypertrophic scarring can follow herpes zoster. This alteration in normal skin color results in significant cosmetic disfigurement, especially when it occurs on highly visible sites such as the face, neck, and upper extremities. If the dermatosis is chronic, the pigmentary change can become persistent and progressive. If the dermatosis resolves, the pigmentary disorder can take months to years to fade gradually to uniform pigmentation. The primary goal in management of these pigmentary disorders is to treat the primary skin disorder. Topical preparations containing 4 percent hydroquinone may be helpful in treating post-inflammatory hyperpigmentation.

Photosensitivity (See Chaps. 90 and 91)

Idiopathic photosensitivity is an uncommon phenomenon in HIV disease but may be the presenting complaint of advanced disease.[27] The most common types of photosensitivity in HIV disease are related to drug therapy, and African American ethnicity and the use of HAART increase the likelihood of development of photosensitivity.

Porphyria, Pseudoporphyria, and Vasculitis

Porphyria cutanea tarda in HIV disease is most often associated with an underlying hepatopathy such as hepatitis C, alcoholism, or hepatitis B. Pseudoporphyria occurs in the absence of abnormalities of porphyrin metabolism and usually is drug induced (see Chap. 91).

Cutaneous and systemic vasculitis has been reported to occur in HIV disease from many causes, including adverse cutaneous drug reaction, cytomegalovirus infection, erythema elevatum diutinum, polyarteritis nodosa, lymphomatoid granulomatosis, Kawasaki syndrome, and, possibly, HIV infection itself.[28,29] Causative drugs should be discontinued if possible. Most other causes are not specifically treatable. Systemic immunosuppressive therapy may be indicated in some cases.

Disorders of the Oropharynx

Nearly all HIV-infected, untreated individuals experience disorders of the oropharynx during the course of the disease.[30] Oropharyngeal disorders have been reported to be the first sign of HIV disease in 10 percent of cases, and their detection may be an indication for HIV serotesting (see Table 198-4). In a study of oropharyngeal disorders (in 103 consecutively treated patients with late symptomatic and advanced HIV disease), candidiasis was the most common finding, diagnosed in more than 90 percent.[31] Other disorders of the lips and oropharynx included herpetic ulcers (10 percent), xerostomia (10 percent), exfoliative cheilitis (9 percent), OHL (7 percent), Kaposi sarcoma (4 percent), patchy depapillation of the tongue (6 percent), and ulcers of uncertain cause (3 percent).

OROPHARYNGEAL CANDIDIASIS See Mucocutaneous Candidiasis later in the chapter.

ORAL HAIRY LEUKOPLAKIA OHL, a lesion specific to HIV disease caused by Epstein-Barr virus, has been reported in up to 28 percent of HIV-infected patients and is a marker for disease progression.[32] OHL presents as one or more hyperplastic, whitish epithelial plaques on the lateral tongue with corrugations accentuat-

▲ **FIGURE 198-5** Oral hairy leukoplakia. White plaques with vertical corrugations on the inferolateral aspect of the tongue. The lesions are fixed, unlike those of thrush, which can be brushed off with a gauze pad.

ing the normal tongue ridges (Fig. 198-5). OHL is usually bilateral but not symmetric. The differential diagnosis includes hyperplastic oral candidiasis, condyloma acuminatum, HPV-induced neoplasia [squamous intraepithelial lesion (SIL), squamous cell carcinoma in situ (SCCIS), and invasive squamous cell carcinoma (SCC)], geographic tongue, lichen planus, tobacco-associated leukoplakia, mucous patch of secondary syphilis, and occlusive trauma. The diagnosis of OHL is usually made on clinical findings; however, if the diagnosis is uncertain, confirmatory lesional biopsy is advised. For the most part, OHL is asymptomatic, but its presence may be associated with some degree of anxiety. In patients receiving HAART, OHL usually either does not occur or resolves without additional interventions. Acyclovir, valacyclovir, famciclovir, ganciclovir, and foscarnet, given for other indications, are often effective therapies for OHL. In addition, podophyllin, topical tretinoin, and imiquimod cream may be helpful.

APHTHOUS ULCERS (See Chap. 74)

NEOPLASMS Kaposi sarcoma (see Chap. 128) commonly occurs on the palate, gingiva, and tongue. Untreated, Kaposi sarcoma can evolve into large nodular lesions and ulcerate. Oral presentations of non-Hodgkin lymphoma usually occur on the palate, gingiva, or tonsillar area. HPV-induced SCC, both in situ and invasive, arises on the buccal mucosa, tongue, and palate.

Opportunistic Neoplasms

The prevalence of the opportunistic neoplasms, including Kaposi sarcoma, HPV-induced neoplasia (SIL, SCCIS, and invasive SCC of the cervix, external anogenitalia, and perineum), undifferentiated non-Hodgkin B-cell lymphoma, and primary central nervous system lymphoma, is increased in HIV disease.[33,34] The incidence of non-melanoma skin cancer, Hodgkin lymphoma, T-cell lymphomas, lung cancer, seminoma, and pediatric leiomyosarcoma is also increased.[35] Many of these opportunistic neoplasms (non-Hodgkin lymphoma, Kaposi sarcoma, and anogenital in situ and invasive SCC) are associated with oncogenic human viruses [Epstein-Barr virus, human herpesvirus 8 (HHV-8), HPV] and diminished immune-mediated tumor surveillance.

Non-Melanoma and Melanoma Skin Cancer

The prevalence of UVR-induced SCC appears to be increased threefold to fivefold in HIV disease, as it is in immunosuppressed solid organ transplant recipients. As with transplant recipients, UVR-induced SCC may be more aggressive in individuals with HIV disease than in immunocompetent hosts.[36,37] The ratio of SCC to basal cell carcinoma (BCC) in HIV-infected patients is 1:7, unlike in renal transplantation patients, in whom the ratio is roughly 2:1.[38] Risk factors for the development of SCC and BCC are fair skin, blonde hair, blue eyes, and excessive sun exposure. HPV is not an oncogenic factor in the development of these cutaneous tumors, unlike with neoplasia of the anus, cervical canal dysplasia, oral cancer, and lesions of the nail unit; however, p53 overexpression is hypothesized to play an etiologic role. Nonetheless, SCCs appear at a younger age and display more aggressive behavior and higher metastatic rate in this population. Interestingly, both an increase in the frequency of BCC and more aggressive subtypes of BCC have also been reported in HIV-positive patients. As in immunosuppressed transplant recipients, the incidence of Merkel cell carcinoma is increased in HIV-infected individuals, and although treatment of this tumor in HIV-positive patients has not been studied prospectively, a case report has documented sustained remission of metastatic disease after initiation of HAART.[39,40]

Data on the incidence of melanoma in HIV-disease are limited and in the form of case reports, although several agree that incidence may be increased in this population.[38]

Human Immunodeficiency Virus–Associated Kaposi Sarcoma (See Chap. 128)[40]

Human Papillomavirus–Induced Dysplasias and Cancers

See Human Papillomavirus Infections later in the chapter.

Adverse Cutaneous Drug Eruptions (See Chap. 40)

NON-ANTIRETROVIRAL DRUGS The incidence of adverse cutaneous drug eruptions (ACDEs) to a variety of drugs is high in individuals with untreated HIV disease (100 times more common than in the general population) and increases with advancing immunodeficiency.[41] Drug hypersensitivity complicated 3 percent to 20 percent of all prescriptions in one large series. ACDEs were noted more commonly in white than in black individuals. The onset of the majority of ACDEs was within 6 to 14 days of initiation of therapy. Trimethoprim-sulfamethoxazole (TMP-SMX), other sulfonamide drugs, and penicillins were the causative agents in 75 percent of cases of ACDE. Exanthematous/morbilliform eruptions were by far the most common ACDEs, occurring in 95 percent of cases; other ACDEs observed were urticaria, erythema multiforme, lichenoid eruption, and fixed drug eruption. Systemic symptoms, including fever, headache, myalgia, and arthralgia, were reported in 20 percent of cases. In most cases, the implicated or suspected drug should be discontinued. In some instances, such as with morbilliform eruptions, the offending drug can be contin-

▲ **FIGURE 198-6** Adverse cutaneous drug reaction to trimethoprim-sulfamethoxazole. A typical exanthematous eruption occurred on the trunk on the tenth day after initiation of therapy with the drug.

ued, and the eruption may resolve. In cases of urticaria/angioedema or early Stevens-Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN; see Chap. 39), the acute drug reaction can be life threatening, and the drug should be discontinued.

Between 50 percent and 60 percent of untreated HIV-infected individuals given intravenous TMP-SMX develop an exanthematous eruption (often associated with fever; Fig. 198-6) 1 to 2 weeks after starting therapy, an incidence 10 times higher than that in the general population. Successful desensitization has been accomplished in patients with prior exanthematous/morbilliform or urticarial reactions to TMP-SMX, sulfadiazine, and dapsone.[42] Desensitization in patients with prior SJS also has been reported.[43] Co-administration of corticosteroids with TMP-SMX reduced the incidence of adverse cutaneous reactions from 47 percent to 13 percent.[44] The occurrence of acute cutaneous drug reactions to TMP-SMX also has been noted to be associated with more rapid decline in CD4 cell counts. Severe bullous eruptions appear to be more common in HIV disease. In a report of six cases of erythema multiforme major and six of TEN, all adverse reactions were to sulfonamides: sulfadiazine, TMP-SMX, and sulfadoxine-pyrimethamine.[45] In 14 cases of TEN occurring over a 6-year period (1984 to 1989), sulfa drugs were the most common causative agents.[45] The number of cases of TEN was 375 times that expected. TEN occurred in patients with advanced HIV disease and was associated with a 21 percent mortality rate.

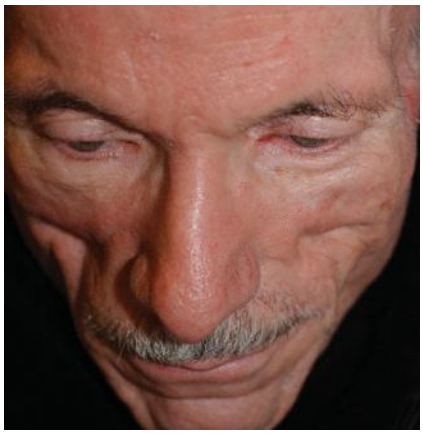
Oral corticosteroid therapy in HIV-infected individuals raises concerns regarding increased immunosuppression with exacerbation of opportunistic infections and neoplasms such as HSV infections and Kaposi sarcoma. A cohort of 44 asymptomatic HIV-infected individuals (200 to 799 CD4 cells/μL) was treated with oral prednisolone (0.5 mg/kg for 6 months; 0.3 mg/kg thereafter). After 1 year of prednisolone therapy, no major side effects or HIV disease–related events had occurred. Serum p24 antigen and HIV RNA levels remained stable; CD4 cell counts increased significantly at all time points (median increase at 1 year, 119 cells/μL). A more recent study concluded that short-term prednisone was well tolerated and reasonably safe.[46] Short-term oral corticosteroid therapy, although complicated by hyperglycemia and oral candidiasis, appears to be safe in most HIV-infected individuals. Follow-up studies and case reports of treatment using a maximum dosage of 30 mg/day of prednisone have confirmed these findings and shown no effect on CD4 count.[47]

ANTIRETROVIRAL ***Hypersensitivity Reactions.*** Antiretroviral therapy is associated with a significant incidence of acute cutaneous drug reactions, including hypersensitivity reactions, lipodystrophy syndrome (LDS), and drug interactions.[48] Drug hypersensitivity commonly occurs with the nonnucleoside reverse-transcriptase inhibitors nevirapine, delavirdine, and efavirenz; the NRTI abacavir; and the PI amprenavir.[31] Approximately half the cases of antiretroviral hypersensitivity resolve despite continuation of therapy. Drug therapy should be discontinued if the following occur: mucosal involvement, blistering, exfoliation, clinically significant hepatic dysfunction, fever higher than 39°C (102.2°F), or intolerable fever or pruritus (see Table 198-3).

Nearly 20 percent of nevirapine-treated patients experience severe rash, most commonly an exanthematous eruption and rarely SJS. Nevirapine causes rash in nearly 8 percent of treated individuals in the first 4 to 6 weeks of therapy; SJS occurs in 1 percent of treated individuals.[49] Drug hypersensitivity syndrome also has been reported.[50] Interestingly, prospective trials involving fewer than 200 patients have failed to show a beneficial effect of a 2-week course of prednisone (40 mg) or cetirizine (10 mg for 10 days) in preventing nevirapine-associated rash.[51,52]

▲ **FIGURE 198-7** Lipohypertrophy. The subcutaneous fatty tissue of the cervico-thoracic region as well as the preauricular cheeks and neck are strikingly enlarged.

Lipodystrophy Syndrome and Metabolic Syndrome. (See Chap. 69) LDS has been associated with PI therapy, although treatment with NRTIs can also lead to LDS.[48,53–55] HIV-related LDS is characterized by abnormal fat distribution: lipohypertrophy with central obesity, cushingoid habitus ("buffalo hump"), increased neck girth (Fig. 198-7), increased abdominal girth associated with increase intra-abdominal fat ("protease paunch," "crix belly"), and breast enlargement. Lipoatrophy of subcutaneous fat produces a pseudoathletic appearance, manifested on the face (Fig. 198-8) and extremities as a prominent venous pattern and musculature. Additional findings that indicate general metabolic abnormalities include insulin resistance, hyperglycemia, and hypertriglyceridemia, hypercholesterolemia, increased free fatty acid levels, and decreased levels of high-density lipoprotein cholesterol.[56] Of note, not all elements of the syndrome are present in all patients, so there is significant variability and heterogeneity in presentation. In a study of 581 patients (61 percent of whom were treated with PIs), the overall prevalence of lipodystrophy was 38 percent; of fat wasting, 16 percent; of peripheral fat accumulation, 12 percent; and of mixed syndromes, 10 percent.[57] The



▲ **FIGURE 198-8** Lipoatrophy. The cheeks are hollowed secondary to loss of subcutaneous fat, causing a significant cosmetic concern in this patient with human immunodeficiency virus infection who was taking highly active antiretroviral drugs. Lipohypertrophy was also present on the neck and upper central back.

prevalence of metabolic abnormalities was 49 percent for lipid disorders and 20 percent for glucose disorders. The pathogenesis of LDS is not known. It is hypothesized that the phenomenon occurs as a result of immune restoration or a metabolic adverse effect of medication that may or may not include mitochondrial oxidative dysfunction or deficient mitochondrial DNA replication.[58] Discontinuation or replacement of PI/NRTI therapy does not result in reversal of dysmorphic changes in most persons.[59]

Liposuction (see Chap. 254) has been used to treat buffalo hump, but the result is most often unsatisfactory. It is estimated that between 15 percent and 80 percent of patients taking HAART will develop lipoatrophy within 10 months of starting therapy. Facial lipoatrophy has been treated with fat transfer from the abdominal panniculus and injection or insertion of various inert agents, again with limited cosmetic success (see Chap. 255). Poly-L-lactic acid has been used with longer-lasting effects, with noticeable results 2 years after application.[60] In addition, 1000-cSt silicone oil has also been studied and shows a favorable side-effect profile. Long-term safety, however, remains unknown.[61]

COMPLICATIONS OF HUMAN IMMUNODEFICIENCY VIRUS DISEASE

Opportunistic Infections

Opportunistic infections of the skin and mucosa occurring in HIV disease for the most part represent overgrowth of resident flora (*Candida albicans*), extension beyond sites of colonization (dermatophytosis), re-activation of latent infection (human herpesviruses), or transformation of sub-clinical to clinical infection [HPV, molluscum contagiosum virus (MCV)]. The natural history of opportunistic infections has continued to evolve because of the availability of HAART and more effective treatments for infections. In individuals responding to HAART, the incidence of all opportunistic infections, with the exception of HPV infections, is markedly reduced.[62] Opportunistic infections continue to be frequent, however, occurring in more advanced and/or untreated HIV disease.

BACTERIAL INFECTIONS *S. aureus* is the most common bacterial pathogen causing cutaneous and systemic infections in HIV disease. An increased prevalence of *S. aureus* carriage in the nares and perineum has been noted in asymptomatic and symptomatic HIV-infected individuals (up to 50 percent). The relative increase in *S. aureus* in skin and soft-tissue infection in HIV-positive patients has not been noted in HIV-negative individuals.[63] In addition, an increase in methicillin resistance in *S. aureus* has been documented, particularly in strains acquired from the community. Risk factors associated with these skin infections appear to be related to high-risk sex and drug-using behaviors rather than absolute level of immunosuppression.[64]

Prophylaxis with agents such as TMP-SMX and clarithromycin is associated with a decreased nasal carriage rate as well as a reduced rate of infections. Primary cutaneous infections and secondary infection of dermatoses or breaks in the epidermal integrity usually occur in chronic *S. aureus* carriers. No unique staphylococcal infections occur in HIV disease. Rather, a wide range of *S. aureus* pyodermas and soft-tissue infections is seen, and the incidence increases with the degree of immune deficiency. Primary staphylococcal infections include impetigo, bullous impetigo, and ecthyma; folliculitis; furuncles and carbuncles; cellulitis; botryomycosis; and pyomyositis. Secondary infection of underlying dermatoses and superinfections occur commonly in persons with chronic atopic (eczematous) dermatitis, which may be associated with elevated immunoglobulin E levels; excoriations; herpetic ulcers; Kaposi sarcoma; molluscum contagiosum; scabies; injection sites in injecting drug users; and intertrigo. Staphylococcal bacteremia may complicate either primary or secondary cutaneous infections (psoriasis or scabies); however, the most common site for hematogenous dissemination is an intravenous catheter, which is the source in 73 percent of cases of bacteremia. As with the majority of infections in HIV disease, staphylococcal infections tend to be recurrent. Management (see Chap. 177) should be directed at the acute infection, treatment of any underlying dermatoses, eradication of nasal carriage of *S. aureus* with mupirocin (pseudomonic acid) ointment, and long-term oral prophylaxis for recurrent infections.

Pseudomonas aeruginosa (see Chap. 180) causes primary infections such as cellulitis (i.e., ecthyma gangrenosum), infection at catheter sites, and secondary infection of underlying disorders such as Kaposi sarcoma in advanced HIV disease. Cutaneous *P. aeruginosa* infection occurs by local invasion, with the organism gaining entry through breaks in the skin; by primary infection of skin appendages in the anogenital or axillary regions; or by hematogenous dissemination to the skin. Cutaneous pseudomonal infection may extend into the bloodstream, with resulting bacteremia and seeding of many organ systems.

Tuberculosis is the most common opportunistic infection in HIV disease in developing countries. Cutaneous tuberculosis (see Chap. 184), however, is relatively uncommon. In non-HIV–infected individuals with tuberculosis, the incidence of extrapulmonary tuberculosis is 15 percent; in those with HIV disease, it is 20 percent to 40 percent. In individuals with advanced HIV disease, the incidence of extrapulmonary disease increases to 70 percent. *Mycobacterium* species other than *M. tuberculosis* (see Chap. 184) (also known as *environmental mycobacteria*: *M. chelonae*, *M. fortuitum*, *M. kansasii*, *M. malmoense*, *M. gordonae*, *M. marinum*, and *M. haemophilum*) have been reported to cause cutaneous lesions in HIV disease. The most common mycobacterial agent other than *M. tuberculosis* causing illness in advanced HIV disease is *M. avium-intracellulare* complex (MAC); however, this infection rarely presents with cutaneous manifestations. The incidence of MAC infections has fallen with primary prophylaxis with azithromycin and, more recently, with HAART.

Bacillary angiomatosis (BA) and bacillary peliosis (see Chap. 182), caused by *Bartonella henselae* and *B. quintana*, occur most commonly in the setting of advanced HIV-induced immunodeficiency.

▲ **FIGURE 198-9** Bacillary angiomatosis. Cherry hemangioma–like papules and a larger pyogenic granuloma–like nodule on the skin of a man with advanced human immunodeficiency virus disease. Subcutaneous nodular lesions were also present.

They are characterized by angioproliferative lesions resembling cherry hemangiomas, pyogenic granulomas, or Kaposi sarcoma.[65] Currently, the prevalence of BA in North America and Western Europe is very low due to improved immune function in HIV-infected patients taking HAART and due to prophylactic therapy for infection by organisms such as MAC. Clinically, the cutaneous lesions of BA are red to violaceous, dome-shaped papules, nodules, or plaques resembling Kaposi sarcoma or pyogenic granuloma and ranging in size from a few millimeters to 2 to 3 cm in diameter (dermal vascular lesions with thinned or eroded epidermis; Fig. 198-9). Less commonly, domed subcutaneous masses occur without the characteristic red color of more superficial vascular lesions.[66] Lesions are soft to firm and may be tender to palpation. The number of lesions ranges from a single lesion to more than a 100 and, in rare cases, more than 1000. Nearly any cutaneous site may be involved, but the palms, soles, and oral cavity are usually spared. After hematogenous or lymphatic dissemination, the spectrum of internal disease caused by *B. henselae* and *B. quintana* includes soft-tissue masses, bone marrow involvement, lymphadenopathy, splenomegaly, and hepatomegaly; internal involvement can occur with or without cutaneous lesions. The course of BA is variable. In some patients, lesions regress spontaneously. As with other opportunistic infections in HIV disease, BA can recur. The antibiotic of choice is erythromycin (250 to 500 mg by mouth four times daily) or doxycycline (100 mg twice daily), continued until the lesions resolve, usually 3 to 4 weeks. Rifampin, ciprofloxacin, and TMP-SMX are also effective in those who cannot tolerate first-line agents.[67] Secondary prophylaxis is indicated in patients with recurrent BA.

FUNGAL INFECTIONS Cutaneous fungal infections in HIV disease occur as superficial infections (dermatomycoses), invasive cutaneous infections, or systemic fungal infections with hematogenous dissemination to the skin. Superficial pathogens such as *Trichosporon beigelii* may disseminate with progressive deterioration in immune status.[67] Often, dissemination of superficial pathogens may present atypically. For instance, *Trichophyton rubrum* has been reported to disseminate and mimic Kaposi sarcoma.[68] HAART has markedly diminished the incidence of these infections, and adverse drug interactions between HAART and antifungal medication appear to be less clinically significant than previously thought.[69–71]

Dermatophytoses. (See Chap. 188) *T. rubrum* causes proximal subungual onychomycosis, an infection of the undersurface of the proximal nail plate.[72] Proximal subungual onychomycosis occurs most often in HIV-infected individuals; the diagnosis is an indication for HIV testing (see Table 198-4). Epidermal dermatophytosis can be extensive in HIV disease. Unless immunocompetency is restored, dermatophytic infections are chronic and recurrent.

Mucocutaneous Candidiasis. (See Chap. 189) Cutaneous *Candida* infections such as intertrigo are relatively uncommon in adults with HIV disease, but concomitant diabetes mellitus associated with HAART may increase the prevalence. Candidiasis of moist, keratinized cutaneous sites, such as the anogenital region, occurs with some frequency. Candidal angular cheilitis occurs at the corners of the mouth as an intertrigo, unilaterally or bilaterally; it may appear in conjunction with oropharyngeal or esophageal disease or as the only manifestation of candidal infection. Children with HIV infection commonly experience candidiasis in the diaper area and intertrigo in the axillae and neck fold. Chronic fingernail *Candida* paronychia with secondary nail dystrophy (onychia) also is common in HIV-infected children.[73]

Candida colonization of the oropharynx is common in HIV-infected individuals, frequently in the absence of any clinical findings and may be an indication for HIV testing (see Table 198-4). *C. albicans* is the most prevalent colonizing species, but multiple species may be present. Isolation of non-*albicans* species alone correlates with advanced HIV disease and very low CD4 cell counts. Oropharyngeal candidiasis is a marker of HIV disease progression. Oropharyngeal candidiasis and esophageal candidiasis have been reported to occur as a manifestation of primary HIV infection. Esophageal candidiasis, an AIDS-defining condition, occurs only with advanced CD4 count reduction (fewer than 100 cells/μL). Oropharyngeal candidiasis presents in four different patterns: pseudomembranous (thrush), atrophic (erythematous), hyperplastic, and as an angular cheilitis. Despite a high prevalence of candidiasis in HIV-infected individuals, disseminated candidiasis is distinctly uncommon, probably because of B-cell activation and the presence of anti-candidal protective antibody.

HIV-infected women with CD4 counts of 200 to 500 cells/μL had a 33 percent incidence of vaginal candidiasis; incidence was 44 percent if the CD4 count was fewer than 200 cells/μL. In a study of 117 HIV-infected women, recurrent candidal vaginitis was the most common initial clinical manifestation of HIV disease (43 of 117 women).[74] Other studies have failed to confirm an increased incidence of candidal vaginitis in HIV-infected women.

Invasive Fungal Infections. Invasive fungal infections arise by local invasion of the skin or mucosa, often followed by lymphatic or hematogenous dissemination to viscera or skin or, more commonly, activation of a latent pulmonary focus of infection. Latent pulmonary fungal infections such as cryptococcosis, histoplasmosis, coccidioidomycosis, sporotrichosis, and penicilliosis can re-activate and disseminate to various organs, including meninges and skin, in persons with advanced HIV disease. The cutaneous manifestations most commonly are multiple molluscum contagiosum–like lesions that occur most often on the face and upper trunk. Disseminated deep mycoses are much less common with HAART (see Cryptococcosis, Coccidioidomycosis, and Histoplasmosis).

CRYPTOCOCCOSIS. (See Chap. 190) Disseminated cryptococcosis is by far the most common life-threatening fungal infection occurring in advanced HIV disease; cutaneous cryptococcosis occurs in 5 percent to 10 percent of cases.[75] Sero-

type D shows greater tropism for skin than other serotypes.[76] Skin lesions may be present for weeks or many months before presentation. They occur most commonly on the head and neck (78 percent) but may be widespread. The most common morphology of cutaneous cryptococcosis is molluscum contagiosum–like lesions (i.e., umbilicated skin-colored or pink papules or nodules), which occur in 54 percent of cases. Other types of cutaneous lesions include pustules, cellulitis, ulceration, panniculitis, palpable purpura, subcutaneous abscesses, vegetating plaques, and pyoderma gangrenosum–like lesions.[77,78]

COCCIDIOIDOMYCOSIS. (See Chap. 190) Cutaneous lesions of disseminated coccidioidomycosis are usually asymptomatic, beginning as papules and evolving to pustules, plaques, or nodules with minimal surrounding erythema. Lesions often resemble molluscum contagiosum. In time, lesions may enlarge and become confluent, with the formation of abscesses, multiple draining sinus tracts, ulcers, subcutaneous cellulitis, verrucous plaques, granulomatous nodules, and healing scars. Erythema multiforme–like lesions and erythema nodosum may be observed, perhaps more commonly in women.[76]

HISTOPLASMOSIS. (See Chap. 190) Disseminated cutaneous histoplasmosis presents with erythematous macules; necrotic or keratin-plugged, molluscum contagiosum–like papules and nodules; pustules, folliculitis, acneform lesions, a rosacea-like eruption, or a guttate psoriasis–like eruption; ulcers; vegetative plaques; panniculitis; or erythroderma.[79] Several different types of lesions may be seen in the same patient. Lesions occur most commonly on the face, followed by the extremities and trunk. Oral mucosal lesions include nodules and vegetations; ulceration occurs on the soft palate, oropharynx, epiglottis, and nasal vestibule. A subtle, widespread exanthematous or psoriasiform eruption occasionally may develop in HIV-infected patients who are already taking systemic antifungal therapy and in whom systemic symptoms are completely lacking. Hepatosplenomegaly and/or lymphadenopathy occur commonly in patients with disseminated histoplasmosis.

SPOROTRICHOSIS. (See Chap. 190) In HIV disease, dissemination of local sporotrichositic infection to other organs occurs from lung or skin foci. Hematogenously disseminated cutaneous lesions present as papules to nodules that may become eroded, ulcerated, crusted, or hyperkeratotic, usually sparing the palms, soles, and oral mucosa. Ocular involvement results in hypopyon, scleral perforation, and prolapse of the uvea. Other organs involved in disseminated sporotrichosis in HIV disease include joints, lung, liver, spleen, intestine, and meninges.[80]

ASPERGILLOSIS. (See Chap. 190) Invasive aspergillosis is rare in HIV disease. It presents as a primary cutaneous infection, appearing under adhesive tape near central venous catheters, or occurs as disseminated infection.[81] Risk factors for invasive aspergillosis in HIV disease include leukopenia and therapy with glucocorticoids, broad-spectrum antibiotics, and antineoplastic agents. Skin lesions appear as skin-colored to pink umbilicated papules resembling molluscum contagiosum. The majority of patients with invasive disseminated aspergillosis die despite treatment with amphotericin B. Because of the high mortality rates as well as the toxicities related to amphotericin therapy, treatment with newer azole derivatives (voriconazole, posaconazole, and ravuconazole) or the echinocandins (caspofungin, micafungin) has become more common, in some cases, with better outcomes and side-effect profiles.[82]

PENICILLINOSIS. (See Chap. 190) The dimorphic fungus *Penicillium marneffei* is the third most common cause of opportunistic infection in HIV-infected residents of countries of Southeast Asia and the southern part of China. A report of 92 patients described clinical presentations that included fever, weight loss, cough, anemia, and disseminated papular skin lesions (71 percent).[83] The most common skin lesions were umbilicated papules, which occurred most frequently on the face, pinnae, upper trunk, and arms. Genital ulcers also were reported, ranging in size from less than 1 to 3 cm in diameter. Oral lesions included papules and ulcers.

VIRAL INFECTIONS Viruses are major pathogens causing opportunistic infections in HIV disease, many of which are manifested at mucocutaneous sites, ranging from cosmetically disfiguring facial molluscum contagiosum to extensive genital warts and life-threatening and invasive HPV-induced SCC. In the majority of cases, viral opportunistic infections represent activation of sub-clinical infection (HPV, MCV) or re-activation of latent infection [human herpesviruses: HSV-1, HSV-2, VZV, cytomegalovirus, Epstein-Barr virus, and human herpesvirus 8 (Kaposi sarcoma–associated virus)]. In HIV-infected individuals treated with HAART, the incidence of opportunistic viral infections has diminished markedly, with the exception of those caused by HPV; the incidence of benign and dysplastic HPV-induced lesions is stable or has increased despite restoration of immune function with HAART.

Herpes Simplex Virus 1 and 2 Infections. (See Chap. 193) With more advanced immunocompromise, HSV lesions tend to be subacute or chronic, indolent, and atypical, responding less promptly to oral antiviral therapy. The presence of chronic herpetic ulcers of longer than 1 month's duration are an AIDS-defining condition (see Table 198-4). With increasing immunocompromise, recurrent HSV infection may become persistent and progressive. Erosions occurring at the typical sites (perioral, anogenital, and digital) enlarge and deepen into painful ulcers (Fig. 198-10). In addition to ulceration, chronic HSV infections also can present as proliferative lesions of the epidermis with or without scale. Foscarnet and cidofovir are administered intravenously for infections caused by acyclovir-resistant HSV.[84] Cidofovir gel has been effective as a topical therapy for acyclovir-resistant HSV infections.[85] Imiquimod 5 percent cream is also an effective topical treatment for cutaneous herpetic infections, including those caused by acyclovir-resistant HSV strains. Imiquimod 5 percent cream is

▲ **FIGURE 198-10** Chronic herpetic lesions. Chronic ulcers and ulcerated tumor on the penis, scrotum, and pubic area in a patient with human immunodeficiency virus disease. The herpes simplex virus was acyclovir resistant, and lesions resolved after treatment with topical cidofovir.

applied to the lesion(s) daily, or every other day if irritation occurs.[86]

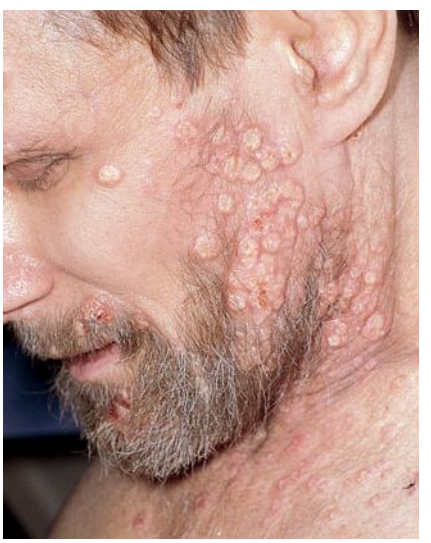
The incidence of re-activation of HSV infection appears to be unchanged with HAART; however, patients treated with HAART report fewer days with active lesions.[87] In addition, because infection with HSV-2 is associated with a twofold to fourfold increase in transmission of HIV-1, treatment may be important, particularly for HIV-discordant couples. In one study, HIV-1 mucosal shedding was more frequent during HSV-2 replication. In addition, HSV-2–infected individuals had a fivefold higher risk of acquiring HIV infection, compared with HSV-2–negative individuals.[88] Other studies have verified this observation, finding that up to 52 percent of transmission risk was attributable to HSV-2 positivity.[89]

Varicella-Zoster Virus Infections. (See Chap. 194) Primary VZV infection manifests as varicella (chickenpox). Re-activation of VZV from a dorsal root ganglion or cranial nerve ganglion manifests as herpes zoster (HZ). In the immunocompromised host, VZV infection can present as severe varicella, persistent varicella, dermatomal HZ, disseminated HZ (sometimes without dermatomal HZ), and chronic or recurrent HZ.[90] Disseminated HZ is defined as cutaneous involvement by more than three contiguous dermatomes, more than 20 lesions scattered outside the initial dermatome, or systemic infection (hepatitis, pneumonitis, encephalitis). Disseminated VZV infection in an individual harboring latent VZV can present with a clinical pattern of scattered vesicles in the absence of dermatomal HZ. Chronic HZ in patients with HIV disease may manifest as multiple dermatomal lesions or single or few nondermatomal lesions that are ulcerated (Fig. 198-11) or hyperkeratotic. Acyclovir-resistant VZV is rare.[91]

Molluscum Contagiosum. (See Chap. 195) MCV commonly infects keratinized skin sub-clinically and can cause lesions at sites of minor trauma and in the infundibular portion of the hair follicle.[92] The clinical course of MCV infection in HIV disease differs significantly from that in the normal host and is an excellent clinical marker of the degree of immunodeficiency. Large and confluent lesions cause significant morbidity and disfigurement (Fig. 198-12). Before the advent of HAART, MCV infections were detected in 10 percent of individuals with HIV disease and in 30 percent of those with CD4 counts of fewer than 100 cells/μL, with the number of lesions being inversely related to the CD4 cell count.[93] In HIV-infected individuals, MCV infection tends to be progressive and recurrent after the usual therapies. With response to HAART, MCV infections regress, resolve completely, or do not occur, due to increased CD4 cell counts and reduced viral load.[94] For cases resistant to standard therapies, imiquimod 5 percent cream may be effective in both children and adults.[95] Cidofovir, a nucleotide analog with activity against several DNA viruses, given either intravenously or topically as a cream, may be an effective therapy.[96,97] In addition, treatment with photodynamic therapy and 5-aminolevulinic acid may decrease lesion count and severity.[98]

▲ **FIGURE 198-11** Varicella-zoster infection: Ulcerated, ecthymatous lesions. Two ulcerated, crusted, painful lesions in the trochanteric region and the lateral thigh had been present for 9 months and resolved with oral acyclovir therapy.

Human T-Cell Lymphotrophic Virus Infections. (See Chap. 197) HTLV-1 infection presents most commonly as chronic "eczema" in children. Initially termed *infective dermatitis*, it manifests in the scalp, neck, and groin as erythematous, scaly patches with crusts. The exudative nature of these lesions may help in differentiating this disease from atopic dermatitis. Periorbital papules with seborrheic-like scale may be observed with increasing frequency near the eyebrows. Retroauricular fissuring and generalized ichthyosis may be observed in a minority of cases.[99] Breastfeeding appears to be the main route of transmission from an infected mother. In regions of high seropositivity, such as Brazil and the Caribbean, "infective" dermatitis may be an indication for HTVL-1 serotesting. In HIV-infected adults, an increased incidence of inflammatory dermatosis, including seborrheic dermatitis, psoriasis, and prurigo, has been reported after infection with HTLV-1.[100]



▲ **FIGURE 198-12** Molluscum contagiosum virus infection. Before highly active antiretroviral therapy, multiple facial mollusca would enlarge to cause significant cosmetic disfigurement.

Human Papillomavirus Infections. (See Chap. 196) HPV infections occur commonly during the course of HIV disease. Of interest, the incidence of HPV infections does not decrease with HAART and restoration of immune function but actually may be increased.[101]

COMMON WARTS. With advancing HIV disease, verrucae can enlarge, become confluent, and become unresponsive to therapy.[102] HPV-5 can cause an unusual pattern of extensive verruca plana and pityriasis (tinea) versicolor–like warts, similar to the pattern seen in epidermodysplasia verruciformis[103] (see Chap. 196). With moderate or advanced immunodeficiency, warts may become much more numerous, confluent, and refractory to usual treatment modalities. Pre-cancerous lesions identical to mucosal lesions (SCCIS)

▲ **FIGURE 198-13** Human papillomavirus–induced invasive squamous cell carcinoma in a 32-year-old man with human immunodeficiency virus infection. The para-anal tumor had been present for several months, and histologic analysis showed invasive squamous cell carcinoma.

can occur periungually and on the nail bed epidermis (usually of the fingers). In some cases, invasive SCC can arise at one or multiple sites on the fingers and/or nail bed. These tumors are aggressive and invade to the underlying periosteum and bone relatively early because of the proximity of the underlying bony structures. Despite immune restoration with HAART, HPV infections often persist and progress, unlike other opportunistic viral infections.

ANOGENITAL WARTS. HPV-6 and HPV-11 infect nonkeratinized or minimally keratinized epithelium such as anogenital sites and the oropharynx and cause genital warts; HPV-16 and HPV-18 cause pre-cancerous lesions, low-grade SIL, high-grade SIL, and invasive SCC (Fig. 198-13).[104,105]

ORAL WARTS. Oropharyngeal HPV-induced lesions resemble anogenital condylomata and are pink or white. Extensive intra-oral condylomata acuminata (oral florid papillomatosis) presents as multiple large plaques that can transform to verrucous carcinoma. Interestingly, in one study, advanced markers of HIV disease, such as high viral loads or low $CD4^+$ count, were not predictive of oral HPV infection; rather, HAART therapy was associated with detection of oral HPV infection.[106] Reports have documented successful treatment of oral HPV with 1 percent to 3 percent cidofovir solution.[107]

HUMAN PAPILLOMA VIRUS–INDUCED DYSPLASIA: LOW-GRADE SQUAMOUS INTRAEPITHELIAL LESION, HIGH-GRADE SQUAMOUS INTRAEPITHELIAL LESION, AND INVASIVE SQUAMOUS CELL CARCINOMA. The natural history of external anogenital HPV-induced dysplasia is not known. Prolonged, severe immunodeficiency provides the necessary milieu for the emergence of HPV-induced anogenital neoplasia.[108] Specifically, HIV and anal co-infection with HPV are independent risk factors for high-grade dysplasia and cancer.[109] There is a stronger association with a decline in $CD4^+$ counts than with rising viral HIV RNA titers, which suggests that immune dysfunction may be more important that direct viral effects in the pathogenesis.[110] One study of 357 HIV-positive men who have sex with men and who had no history of previous anal cancer showed that up to 81 percent had anal intraepithelial neoplasia of any grade and that 95 percent had evidence of anal HPV infection.[111] A separate study documented that 86 percent of men who have sex with men had evidence of HPV infection on their first visit to a screening clinic.[112] HPV-16 was the most commonly isolated sub-type in this group of patients.

The incidence of transformation of SCCIS to invasive SCC appears to be low. The relative risk for HPV-related, anal, invasive SCC is much higher in HIV-infected than in non–HIV-infected homosexual men and is more likely in advanced HIV disease. The most common sites for HPV-induced SIL, SCCIS, and invasive SCC are the cervix, anus, perineum, vulva, penis, oropharynx and tongue, conjunctivae, and nail apparatus.[113] Anogenital dysplasias are likely to become more common manifestations of HIV disease, because patients with profound immunodeficiency who previously would have succumbed to opportunistic infections are now surviving for extended periods because of HAART.[114] HAART and restoration of immune function may not cause regression of these dysplasias.[115,116] Cervical, anal, and external anogenital low-grade SIL, high-grade SIL, and invasive SCC have become more common in long-term survivors of HIV disease. Invasive SCC arising on external anogenital sites is usually detected earlier and is less aggressive than that arising on the cervix or anal canal.

Management of external anogenital HPV infection in HIV-infected individuals is directed at identifying high-grade SIL before progression to invasive SCC has occurred. All HIV-infected individuals should be examined annually for evidence of HPV infection, especially those with prior HPV infections. Because HPV-induced neoplasia may extend to the cervix and/or anus, direct examination by speculum and anoscope also should be performed; samples for cytologic analysis should be obtained using a cervical brush and fixed with Cytofix solution during the examination. High-resolution anoscopy and biopsy are performed on individuals with high-grade SIL.[117] Individuals with documented external anogenital SIL should undergo periodic follow-up examinations (every 4 to 6 months), and an appearance of new lesions at these sites or an enlarging nodule or ulcerated site should be noted. Biopsy of these sites is recommended. Anal intraepithelial neoplasia may be treated with topical therapy, including imiquimod, podophyllotoxin, 80 percent trichloroacetic acid, or liquid nitrogen. Lesions may also be excised or treated using destructive modalities such as fulguration.[110] For minimally invasive SCC arising on the anal verge (nonkeratinized to keratinized epithelium) or on external anogenital sites (penis, vulva, perineum), surgical excision is recommended, with adequate borders around the lesion. Invasive SCC of the anus (transformation zone) is treated by radiation therapy and chemotherapy. Prognosis for invasive anal SCC is better in those with higher CD4 cell counts at the time of diagnosis.

The development of anti-HPV vaccination may decrease infection and disease burden, particularly if the vaccine is directed against various serotypes. Vaccination against HPV-16 has been tested in women and shown to be 100 percent effective in preventing cervical disease.[110]

Sexually Transmitted Diseases (See Chaps. 200 to 205)

The great majority of HIV infections are transmitted during sexual intercourse. Individuals presenting with any STD should be screened for HIV infection, syphilis, chlamydiosis, gonorrhea, and trichomoniasis. Possible interrelationships between STDs and HIV disease include the potential for STDs to increase the rate of both primary HIV acquisition and transmission, the potential

for STDs to accelerate the natural progression of HIV infection, and the potential for HIV co-infection to alter critical clinical and/or serologic parameters used to diagnose and treat STDs. Genital ulcerative diseases such as syphilis, herpes genitalis, and chancroid increase the risk of acquisition of HIV. Gonorrhea and trichomoniasis also increase the risk of HIV transmission.

Parasitic Diseases

LEISHMANIASIS (See Chap. 206) *Leishmania* can cause various forms of disease, depending on the immune status and geographic location of the host, as well as on the infecting species. Cutaneous, mucocutaneous, and visceral disease usually follows the bite of a vector sandfly, but transmission from contaminated syringes in intravenous drug users and congenital disease have also been reported.[118] *L. donovani*, in particular, has been shown to upregulate viral replication in vitro and in co-infected individuals. Like HSV-2, *L. donovani* may modulate pathogenesis and increase HIV-1 infectivity.[119] In addition, patients co-infected with *L. guyanensis* show a higher rate of recurrent leishmaniasis and re-infection that is more difficult to treat.[120] *Leishmania* infection may worsen with reconstitution of immune function.[121] Treatment for mucocutaneous, disseminated, and visceral leishmaniasis is with pentavalent antimonials, pentamidine, or amphotericin. Successful oral treatment with miltefosine in recalcitrant cases has been reported.[122] Localized cutaneous disease has been treated with 5 percent imiquimod.

SCABIES (See Chap. 208) Scabies is included in the differential diagnosis of pruritus in HIV disease. In individuals with advanced immunocompromise, scabies can occur with minimal or no pruritus but with an extensive papulosquamous eruption (i.e., hyperkeratotic, crusted scabies). Secondary *S. aureus* infection can occur, complicated in rare cases by bacteremia. Oral ivermectin (200 µg/kg weekly) is the most effective therapy.

CHAPTER 199

The Rickettsioses, Ehrlichioses, and Anaplasmoses

Analisa V. Halpern
Justin J. Green
Warren R. Heymann

Rickettsial disease should be considered in any patient who presents with fever, headache, myalgia, and a characteristic rash. Before the early 1990s, the taxonomic classification of rickettsial organisms was based on heterogeneous characteristics such as obligate intracellularity, geographic origin, and common vectors. The advent of modern molecular technologies, including genetic analysis, has allowed for significant taxonomic reclassification of the rickettsiae in recent years. The ability to characterize microorganisms on a molecular level has facilitated a more accurate organization scheme, including moving the family *Bartonella* (see Chap. 182) and the genus *Coxiella* out of the order Rickettsiales to the orders Rhizobiales and Legionellales, respectively. Several non-rickettsial agents that were historically included in the group of infections loosely termed the *rickettsioses* remain incorporated in the discussion of rickettsial disease herein to reflect that precedent.[1]

"Rickettsiae" now includes a polyphyletic group of microorganisms in the class Proteobacteria, comprising species belonging to the genera *Rickettsia*, *Orientia*, *Ehrlichia*, *Anaplasma*, and *Neorickettsia* (see eFig. 199-0.1 in on-line edition). The ehrlichioses and anaplasmoses often present with clinical findings indistinguishable from the rickettsioses, and the Centers for Disease Control and Prevention (CDC) has outlined case definitions for the three major diseases attributed to these organisms in the United States. (http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5504a1.htm).

In many areas of the world, rickettsiae and *Rickettsia*-like organisms are endemic pathogens, yet the rise of international travel has allowed for the spread of rickettsial infections to nonendemic areas as well. In addition, there has been increasing global concern for rickettsial pathogens as potential agents of bioterrorism.[2,3] Indeed, *R. rickettsiae* [Rocky Mountain spotted fever (RMSF)], *R. prowazekii* (epidemic typhus), and *C. burnetii* (Q fever; note that *Coxiella* is no longer included in the order Rickettsiales) are listed as Category B on the CDC list of potential weapons of biowarfare (see Chap. 213).

HISTORICAL ASPECTS

RICKETTSIAE

Etiology and Pathogenesis of Spotted Fever Group and Typhus Group

Rickettsiae are obligate, intracellular, Gram-negative bacteria. They are pleomorphic 0.3 µm to 1 µm coccobacilli composed of DNA and RNA and repro-

RICKETTSIAL, EHRLICHIAL, AND *ANAPLASMA* INFECTIONS

AT A GLANCE

- Rickettsiae primarily target endothelial cells, causing febrile illness and rash in the mammalian host.
- Fever, headache, myalgia, and malaise are common to rickettsial, ehrlichial, and *Anaplasma* infections; rash is common in rickettsial disease, occasional in ehrlichial infection, and rare in anaplasmosis.
- Transmission is predominantly via tick bites, with certain pathogens transmitted by human body lice and mites.
- Effective therapy with tetracycline antibiotics, when initiated early in the disease process, is curative in most cases.
- The early signs and symptoms of infection are often non-specific and can mimic self-limited viral illnesses, with potentially catastrophic delays in diagnosis and treatment.
- Empiric treatment should be considered in highly suspicious cases until rickettsial infection is definitively ruled out, as delayed treatment can lead to severe sequelae and high mortality rates.

duce through binary fission. Rickettsiae are propagated by arthropod vectors that use mammals (and sometimes the arthropods themselves) as reservoirs of infection. Rickettsiae are separated into the spotted fever group and the typhus group on the basis of common genetics, immunologic patterns, and intracellular growth characteristics. The typhus group lives entirely within the cell cytoplasm, while the spotted fever group can reside within the cytoplasm or nucleus. Rickettsiae are differentiated by unique antigenic structures on cell surface proteins. Certain rickettsial cell wall lipopolysaccharides that are highly immunogenic are shared by the Gram-negative bacteria *Proteus* and *Legionella*.[5] Before 1984, only five species of rickettsiae were identified as definitively causing human disease. That number rose to 16 species between 1984 and 2004, and up to 21 species if one includes those with only a presumptive association with human disease.[1]

Infection occurs through arthropod-induced breaks in the skin allowing access of the pathogen to the blood and lymph. Further manipulation of the bite site and a longer duration of exposure to the arthropod are factors that aid in the transmission of pathogenic organisms. For example, scratching a flea bite enables inoculation of *R. typhi* which is carried in the flea's feces. *R. rickettsii* requires at least a 6-hour feeding period to be transmitted by the infected tick. Infection can also be acquired in persons exposed to arthropod hemolymph during tick removal.

Rickettsial organisms spread via the hematogenous and lymphatic systems, attach to endothelial cell membranes, and are phagocytosed. The severe clinical manifestations of rickettsial infection (e.g., hypovolemia, purpura, and edema of the skin, lungs, and brain) are caused by proliferation of bacteria within the endothelial cells of capillaries, arterioles, and venules, resulting in a multifocal, systemic vasculitis and microvascular leakage.[5]

Spotted Fever Group

ROCKY MOUNTAIN SPOTTED FEVER RMSF was first recognized in 1896 in the Snake River Valley of Idaho and was originally called *black measles* because of the characteristic appearance of the rash. RMSF has been a reportable disease in the United States since the 1920s and is the most frequently reported rickettsial infection in the United States. It is caused by the tick-borne *R. rickettsii*, and if left untreated, carries a fatality rate of approximately 23 percent among previously healthy persons. Even with proper treatment, hospitalization rates of 72 percent and mortality rates of 5 percent to 10 percent have been reported.[8,9]

Epidemiology. The principal epidemiologic characteristics of RMSF are outlined in Table 199-1. In 2004, a total of 1,514 cases of RMSF were reported in the United States, the highest number ever in a single year.[10] The vector largely responsible for RMSF in the eastern two-thirds of the United States is the American dog tick, *Dermacentor variabilis*, while the Rocky Mountain wood tick, *D. andersoni*, is prevalent in the western United States (Fig. 199-1).

Historically, children younger than 10 years of age had the highest incidence of RMSF; however, surveillance data in the United States during 2003 demonstrate a higher age-specific incidence in persons aged 40 to 64 years.[10] Cases have been reported from each of the 48 contiguous states except Vermont and Maine. Between 1997 and 2002, 56 percent of reported cases of RMSF in the United States were from five states: North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas. The incidence of RMSF is also high in Georgia, and the disease has been increasing in frequency in Arizona.[11]

Clinical and Laboratory Findings. Table 199-2 outlines the cutaneous and systemic manifestations of RMSF, as well as common laboratory abnormalities. A history of a tick bite is reported in approximately 60 percent of patients. One or two classic symptoms may be seen at presentation, but only about 60 percent of patients will have the complete clinical triad of fever, headache, and rash. The characteristic rash usually begins on the wrists and ankles, and spreads centripetally over the next 6 to 18 hours. Cutaneous lesions are initially blanchable red macules that within days become papular and display evidence of petechiae or purpura (Fig. 199-2). Atypical "spotless" fever (seen in approximately 20 percent of cases) does not imply milder disease, and is more common in the elderly and darker-complected individuals.[5] Periorbital edema, abdominal pain mimicking appendicitis, conjunctival injection, palatal petechiae, edema of dorsal hands, and calf pain are sometimes appreciated. Necrosis from overwhelming vasculitis is rare (4 percent), and preferentially occurs in peripheral locations such as the digits, penis, and scrotum (Fig. 199-3).

Thrombocytopenia (30 percent to 50 percent of patients), anemia (5 percent to 24 percent), and mild hyponatremia (50 percent) may be present. Multisystem involvement in RMSF is secondary to infiltration of endothelial cells with resultant systemic vascular leakage. Severe and life-threatening cardiac, gastrointestinal, hepatic, neurologic, ophthalmologic, renal, and pulmonary manifestations can occur with delayed or inadequate treatment. In patients with severe RMSF who survive the acute illness, long-term sequelae are usually the result of neurologic deficits or acral necrosis.

Pathology. Histopathologic examination shows a septic vasculitis (Fig. 199-4). Early lesions show a predominantly perivascular lymphohistiocytic infiltrate accompanied by extravasated erythrocytes and dermal edema. Lymphohistiocytic vasculitis can progress to leukocytoclastic vasculitis. Less often, basal cell vacuolization, lymphocytic exocytosis, fibrin thrombi, and capillary wall necrosis is appreciated. Immunohistology reveals positive staining for *R. rickettsii* in infected endothelial cells and tick hemolymph. (Fig 199-5).

Diagnosis and Differential Diagnosis. Serologic examination with immunofluorescence assay (IFA) is the gold standard for diagnosis of RMSF. The IFA for RMSF detects convalescent antibodies [at a diagnostic titer of ≥ 64 immunoglobulin G (IgG) and ≥ 32 IgM], but is seldom diagnostic before the seventh day of disease, and often not until far into the second week. As effective treatment for RMSF must begin at least by the fifth day of illness to avoid fatal outcomes, it is vital to begin empiric therapy when relying on serologies alone. Due to inferior sensitivity and specificity, the Weil-Felix test (agglutination of certain *Proteus* sp.) and complement fixation tests have been largely supplanted by newer diagnostic methods. Direct immunofluorescence (DIF), immunoperoxidase staining, polymerase chain reaction (PCR) of blood or tissue specimens, and isolation from blood and skin cultures using centrifugation-shell vial inoculation are available alternatives. PCR is generally the most accurate method and offers more rapid diagnosis during the acute phase of the illness, although it is not widely available, and false positives may occur. Advances in genome sequencing, proteomics, and microarray technology may optimize diagnostic testing in the future.[12]

When a patient presents without a rash, the differential diagnosis for RMSF is broad (Boxes 199-1 and 199-2). Macules and papules, petechiae, or purpuric lesions may sometimes develop in these diseases as well, further precluding the ability to distinguish them from RMSF on clinical grounds alone.

Treatment and Prognosis. Treatment and management strategies for RMSF are listed in Boxes 199-3 and 199-4. Fulminant RMSF leading to more rapid decompensation has characteristically been reported in black males with glucose-6-phosphate dehydrogenase deficiency; these patients also have a higher risk of cutaneous necrosis. Prompt empiric administration of appropriate antibiotic therapy is recommended, as it is the most important factor affecting prognosis.

Tetracyclines are first-line therapy for all rickettsial disease, including RMSF, with doxycycline preferable to tetracycline, especially in patients with renal failure. Sulfa-based medications are contraindicated, as they have been associated with a more complicated disease course.[13] Aggressive supportive care is necessary, with particular attention toward electrolyte and fluid replacement. Chloramphenicol is the preferred treatment in pregnancy; however, doxycycline should be considered in severe cases and in near-term gravidas to prevent gray baby syndrome.[14]

The use of tetracyclines to treat children with RMSF is no longer a subject of controversy. Although repeated exposure to tetracycline increases the risk of tooth staining, studies suggest that limited use of this antibiotic in children during the first 6 to 7 years of life has a negligible effect on the color of permanent incisors. A prospective study of children treated with doxycycline for RMSF demonstrated that these children did not have substantial discoloration of permanent teeth compared with those who had never received the drug.[15] Because RMSF can be life-threatening, and limited courses of therapy with tetracycline-class antibiotics do not pose a substantial risk for tooth staining, the American Academy of Pediatrics Committee on Infectious Diseases revised its recommendations in 1997 and has identified doxycycline as the drug of choice for treating presumed or confirmed RMSF in children of any age.[16]

Prevention. Avoiding tick exposure, wearing protective clothing, performing tick checks regularly while in tick-infested areas, and proper tick extractions are important for lowering the risk of infection. Chemical repellants, such as diethyltoluamide (DEET) in concentrations up to 35 percent, are safe for use in adults and children.

OTHER SPOTTED FEVERS ***Tick-Bite Associated.*** **MEDITERRANEAN SPOTTED FEVER AND AFRICAN TICK BITE FEVER.** Several other tick-borne rickettsial species are pathogenic to humans. Mediterranean spotted fever (MSF), also known as *Boutonneuse fever* or *Marseilles fever*, caused by *R. conorii*, was first documented as a cause of human rickettsial disease is 1932. MSF is the prototypical illness of the non-RMSF spotted fever group. African tick bite fever (ATBF), caused by *R. africae*, is now recognized as a distinct clinical entity. The presence of multiple tick bites, multiple eschars (seen in 50 percent of patients with ATBF), lymphadenopathy, and lymphangitis, distinguish ATBF from MSF.[1]

Epidemiology. *R. conorii* is transmitted by an infected *Rhipicephalus sanguineus* tick (see Fig. 199-1) and is endemic throughout Africa, the Middle East, and southern Europe. Contact with dogs is reported in up to 90 percent of cases of MSF. Other epidemiologic characteristics of MSF are described in Table 199-1. *R. africae* is transmitted by an infected *Amblyomma* tick and is endemic in sub-Saharan Africa.

Clinical and Laboratory Findings. The constitutional symptoms, systemic complications, and laboratory abnormalities of the tick-bite–associated spotted fevers are similar to those of RMSF. The classic cutaneous hallmark of this group is the tache noir, occurring in up to 72 percent of cases with *R. conorii* infection (Fig.199-6A).[17] The tache noir presents as an erythematous, indurated papule with a central necrotic eschar that represents locally aggressive endothelial invasion by rickettsiae. The temporal and morphologic pattern of the rash in this group of spotted fevers is similar to RMSF; however, the eruption may be more diffuse and is less frequently petechial or purpuric (see Fig. 199-6B).

Diagnosis and Differential Diagnosis. Diagnosing MSF or ATBF uses the same techniques as those used for RMSF. For MSF, a diagnostic IFA titer ≥ 40 occurs in 46 percent between days 5 and 9 of the illness, in 90 percent between days 20 and 29, and in 100 percent thereafter. Biopsy from an eschar for immunohistochemistry is particularly sensitive in MSF. PCR or Western blot analysis can be used to differentiate between *R conorii* and *R. africae.* Newer serologic assays and PCR have been useful in identifying several emerging agents of spotted fever such as of *R. japonica* and *R. slovaca*.[1]

The rash of MSF generates a similar differential diagnosis as that of RMSF. If a tache noir is seen, also consider brown recluse spider bite, cutaneous anthrax, scrub typhus, rickettsialpox, aspergillosis, or mucormycosis.

TABLE 199-1
Epidemiologic Features of *Rickettsia*, *Ehrlichia*, and *Anaplasma* Infection

Disease (Agent)	Primary Vector(s)	Approximate Distribution	Seasonal Variation	Incubation Period	Average Annual Incidence (United States)	Risk Factors[a]	Prognosis	Case-Fatality Rate
Rocky Mountain spotted fever (*Rickettsia rickettsii*)	*Dermacentor variabilis* (American dog tick), *D. andersoni* (Rocky Mountain wood tick), *Amblyomma americanum* (lone star tick), *Rhipicephalus sanguineus* (brown dog tick), *A. cajennense* (Central and South America), *Haemaphysalis leporispalustris* ticks	Widespread in the United States, concentration in south Atlantic and south-central states; Argentina, Brazil, Columbia, Costa Rica, Mexico, Panama, Canada	April–September	2–14 days	~ 400–600 cases/yr (1996–2000); ~ 1500 cases/yr (2000–2004)	Males; adults 40–64 yr, children < 10 yr; rural dwelling	Severe disease: G6PD deficiency (rapid decompensation, fulminant disease with higher incidence of necrosis), males, elderly, neurologic disease, hepatitis, jaundice, thrombocytopenia, acute renal failure, sulfa medications, delayed diagnosis and treatment.	5%–10% (treated), ~ 30% (untreated).
Mediterranean spotted fever (*R. conorii*)	*R. sanguineus* (brown dog tick)	Endemic to southern Europe, Middle East, southwest Asia, India, and Africa	Peaks during summer months (June–September) in temperate regions	5–7 days	~ 50 cases reported in United States	Exposure to dogs	Mild disease (mainly in children) has good prognosis. Severe disease "malignant Mediterranean spotted fever": Alcoholics, elderly, G6PD deficiency, diabetes mellitus, heart disease, delayed diagnosis and treatment.	~ 2%–5% in hospitalized patients (treated), ~ 30% (untreated cases).
Rickettsialpox (*R. akari*)	*Liponyssoides sanguineus* (*Allodermanyssus sanguineus*) (house mouse, *Mus musculus*, mite)	United States (mainly eastern seaboard), South Africa, Korea, Ukraine, Croatia	Sporadic	~ 7 days (eschar), ~ 7–24 days (systemic symptoms and rash)	Unknown (34 cases in New York City from 2001–2002)	Males; urban dwellers (likely from mice exposure); intravenous drug users	Excellent.	Self-limited. Typically resolves in 2 wk.
Endemic typhus (*R. typhi*; *R. felis*)	*Xenopsylla cheopis* (rat flea), *Ctenocephalides felis* (cat flea)	Southeast United States, Gulf region, Southern California; worldwide most cases in Africa (reported on all continents except Antarctica)	Warm weather months in temperate and subtropical locales	1–2 wk (~ 12 days)	< 40–60 cases/yr (mainly in California and Texas)	Exposure to fleas, poverty, poor hygiene	Excellent prognosis with treatment. Complicated disease occurs with alcoholism, elderly, hematologic disorders, and exposure to sulfa-containing drugs.	1%–4% (treated).
Epidemic typhus (*R. prowazekii*)	*Pediculus humanus* var. *corporis* (human body louse), *Neohaematopinus sciuropteri* lice, *Orchopeas howardii* fleas	United States, Eastern Europe, Africa, Central and South America, China, Himalayan region	Sporadic (more common in winter months)	~ 1–2 wk (8 days, average)	~ 15 documented cases in the United States	Wartime, poor hygiene, natural disasters, cold weather	Good prognosis with treatment. Fever abates in 2 wk (without treatment) and 48 h (with treatment). Recovery of strength in 2–3 mo.	3%–4% (treated), ~ 20% (untreated), ~ 60%–70% (untreated, elderly or debilitated).

(continued)

TABLE 199-1
Epidemiologic Features of *Rickettsia*, *Ehrlichia*, and *Anaplasma* Infection (Continued)

Disease (Agent)	Primary Vector(s)	Approximate Distribution	Seasonal Variation	Incubation Period	Average Annual Incidence (United States)	Risk Factors[a]	Prognosis	Case-Fatality Rate
Human monocytic ehrlichiosis (*Ehrlichia chaffeensis*)	*A. americanum* (lone star tick), *D. variabilis* (American dog tick), *Ixodes pacificus* ticks	South and mid-Atlantic, north/south central United States, isolated areas of New England[b]	Spring and summer (peak in May–July)	5–14 days	189 cases/yr (1999–2003)[a]	Males; adults > 70 yr	Poor prognosis: Immunosuppression (HIV, transplantation, glucocorticoids); cough, lymphadenopathy, diarrhea; use of trimethoprim-sulfamethoxazole.	2%–3%.
Human granulocytic anaplasmosis (*Anaplasma phagocytophilum*)	*I. scapularis* (eastern United States) and *I. pacificus* (western United States), *I. ricinus* (Europe) (black-legged ticks)	New England, upper Midwest United States, mid-Atlantic, northern California,[c] and Europe	Spring and summer (peaks in July and November)	5–21 days	314 cases/yr (1999–2003)[d]	Males; adults 60–69 yr	Poor prognosis: Elderly, high lymphopenia, anemia, immunosuppression (HIV, transplantation, glucocorticoids); development of opportunistic infections (e.g., *Aspergillosis*, disseminated candidiasis, etc.).	< 1%.

G6PD = glucose-6-phosphate dehydrogenase; HIV = human immunodeficiency virus.
[a]Males appear to be at higher risk of all tick-borne rickettsial diseases, presumably because of greater recreational and occupational exposure. Disease occurs in all age groups; numbers reflect highest age-specific incidence.
[b]In 2003, 70% of cases of human monocytic ehrlichiosis were reported from seven states: Arkansas, Georgia, Missouri, Maryland, North Carolina, Oklahoma, and Tennessee.
[c]In 2003, 71% of cases of human granulocytic anaplasmosis were reported from four states: Massachusetts, Minnesota, New York, and Rhode Island.

Treatment and Prognosis. Guidelines for the treatment of MSF are outlined in Box 199-4. Overall, non-RMSF spotted fevers run a less aggressive course than RMSF. However, the death rate in patients hospitalized with MSF ranges from 1.4 percent to 5.6 percent. Higher death rates (33 percent) have been reported when delays in diagnosis and therapy occur. In general, all non-RMSF spotted fevers are treated similarly to MSF. Macrolide antibiotics may offer a better risk/benefit ratio than tetracyclines in the pediatric age group.[18]

TABLE 199-2
Clinical and Diagnostic Findings in Rocky Mountain Spotted Fever (RMSF), Human Monocytic Ehrlichiosis (HME), and Human Granulocytic Anaplasmosis (HGA)

	RMSF	HME	HGA
Tropism	• Endothelial cells.	• Monocytes.	• Granulocytes.
Common initial signs and symptoms	• Fever to 38.9°C (102°F), chills, malaise, myalgia, nausea, vomiting, anorexia, headache. • Periorbital edema, abdominal pain mimicking appendicitis (children > adults), conjunctival injection, palatal petechiae, edema of dorsal hands, calf pain.	• Fever, chills, headache, malaise, myalgia, nausea, vomiting, anorexia, photophobia. • Abdominal pain mimicking appendicitis (children > adults), conjunctival injection, palatal petechiae, edema of dorsal hands, calf pain.	• Malaise (94%), fever (92%), myalgia (77%), headache (75%). • Less common: Arthralgia, nausea, vomiting, diarrhea, cough.
Common laboratory abnormalities	• Common: Thrombocytopenia (30%–50% of patients), anemia (5%–24%), mild hyponatremia (50%). • Variably elevated: Serum transaminase levels, lactate dehydrogenase, creatine kinase, serum bilirubin, alkaline phosphatase, blood urea nitrogen, creatinine. • Cerebrospinal fluid with increased leukocytes, moderately elevated protein (100–200 mg/dL), and a normal glucose level.	• Leukopenia (< 4000/mm^3), lymphopenia (< 1500/mm^3), thrombocytopenia (50,000–150,000/mm^3), transaminitis (aspartate aminotransferase > 55 units/L), hyponatremia (< 135 mEq/L), and anemia (hematocrit < 30%).	• (Similar to HME). • Thrombocytopenia (71%–94%), transaminitis (71%), leukopenia (49%–53%), anemia (37%), elevated creatinine. • Neutropenia is more common than lymphopenia.
Systemic sequelae	• Cardiovascular: Hypotension, hypovolemia, and peripheral edema. Inappropriate tachycardia. Myocarditis, cardiac arrhythmias. • Gastrointestinal: Bleeding and perforation, hepatomegaly (25% of cases), jaundice (8% of cases). • Neurologic: Confusion, delirium, stupor, meningismus, coma, motor deficits, cranial nerve palsy, deafness, photophobia, hallucinations, seizures, Guillain-Barré syndrome. • Other: Conjunctivitis (30%), acute renal failure, adult respiratory distress syndrome.	• (Severe or fatal sequelae less common than RMSF). • 50% of patients require hospitalization, and 5%–7% of patients require intensive care unit level care. • Respiratory: Cough, dyspnea, respiratory insufficiency/ adult respiratory distress syndrome. • Neurologic: Meningoencephalitis, altered mental status, cranial or peripheral motor nerve paralysis, sudden transient deafness. • Other: Acute renal failure, disseminated intravascular coagulation, and pericarditis.	• (Severe or fatal sequelae less common than RMSF). • 50% of patients require hospitalization, and 5%–7% of patients require intensive care unit level care. • General: Septic or toxic-shock like syndrome (see Chap. 178), coagulopathy/ disseminated intravascular coagulation (see Chap. 145), rhabdomyolysis, pancreatitis. • Respiratory: Adult respiratory distress syndrome. • Neurologic: Brachial plexopathy, demyelinating polyneuropathy, cranial nerve paralysis. • Other: Acute abdominal syndrome, myocarditis, acute renal failure, hemorrhage, opportunistic infections.
Rash	• Maculopapular rash ~ 2–4 days after fever onset in 50%–80% of adults, > 90% of children; starts at wrists/ankles and spreads centripetally; may involve palms, soles. Individual lesions are blanchable, red macules evolving over few days to petechial and purpuric lesions.	• Macular, maculopapular, petechial (or a combination) ~ 5 days after onset systemic symptoms in ~ 33% of adults, ~ 60% of children.	• Rare (~ 6%).

Mite-Bite Associated. **RICKETTSIALPOX.** Rickettsialpox is an acute, self-limited, febrile disease so named because of its clinical resemblance to varicella (chickenpox). Its etiologic agent is *R. akari*, the house mouse (*Mus musculus*) is the reservoir, and the vector is the rodent mite, *Liponyssoides sanguineus* (*Allodermanyssus sanguineus*).[19] The rodent mite inflicts a painless bite and is too small to be readily recognized by the victim.

Epidemiology. Most cases of rickettsialpox in the United States have occurred in large metropolitan areas of the northeastern United States, with approximately one-half of the cases reported from New York City alone. Table 199-1 describes the salient epidemiologic features of rickettsialpox.

Clinical and Laboratory Findings. A primary lesion occurs at the site of the mite bite as early as 1 to 2 days after transmission. It consists of a painless, erythematous, indurated papule ranging in size from 0.5 to 3.0 cm. Vesicle formation is followed by desiccation and a subsequent eschar to form the characteristic tache noir (Fig. 199-7). Regional lymphadenopathy is common. Resolution of the primary lesion occurs within 1 month.

Approximately 7 days after the primary lesion appears, fever, chills, drenching sweats, myalgia (often manifesting as backache), malaise, and headache begin. The fever persists with remissions for about 1 week before abating. Two to 3 days after the onset of systemic symptoms, a generalized papulovesicular eruption occurs (see Fig. 199-7B). Small vesicles or pustules appear with subsequent

▲ **FIGURE 199-2** **A.** Early macular blanchable macules and papules on the ankle and sole. No truncal lesions were present at this time. **B.** Truncal and facial hemorrhagic macules and papules 7 days after the onset of the rash. **C.** Erythematous macular lesions on the palm may develop into a petechial rash that spreads centrally. (Reprinted from Collins SP: Cutaneous conditions, in *Atlas of Emergency Medicine*, 2nd ed, edited by Knoop KJ, Stack LB, Storrow AB. New York, McGraw-Hill, 2002, p 382.). **D.** Petechial lesions on the arm of a child with fulminant Rocky Mountain spotted fever. [Used with permission from MMWR, *Diagnosis and Management of Tickborne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichiosis, and Anaplasmosis—United States*. March 13, 2006/55(RR04);1–27, http://www.cdc.gov/mmwr.]

◀ **FIGURE 199-3** Gangrene of the toes in Rocky Mountain spotted fever. [Used with permission from Gary Marshall, MD and MMWR, *Diagnosis and Management of Tickborne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichiosis, and Anaplasmosis—United States*. March 13, 2006/55(RR04);1–27. http://www.cdc.gov/mmwr.]

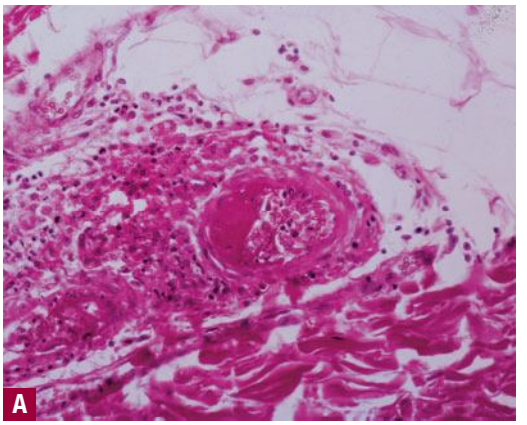
crust formation at the center of the papules. Roughly 5 to 40 lesions may be found, typically resolving in 1 week. Less frequently, an enanthem, photophobia, generalized lymphadenopathy, and gastrointestinal symptoms may be noted. Thrombocytopenia is common during the acute febrile illness, and a mild leukopenia with a relative lymphocytosis may be seen.

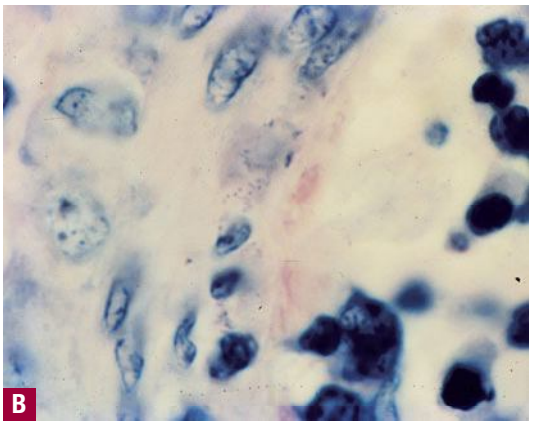
Pathology. In contrast to RMSF, MSF, ATBF, and the typhus group Rickettsioses, the perivascular macrophage, not the endothelial cell, appears to be the target of *R. akari*. Primary lesions are characterized by extensive necrosis and an acute inflammatory infiltrate. Secondary papulovesicular lesions display a sub-epidermal split with superficial edema, and a perivascular lymphohistiocytic infiltrate that can eventuate in vasculitis.

Diagnosis and Differential Diagnosis. Antibody titers peak after 3 to 4 weeks and could be delayed for up to 8 weeks with antibiotic use. Biopsy for DIF with anti-*R. rickettsii* globulin is highly sensitive; however, due to cross-reactivity among the spotted fever group rickettsiae, confirmatory cross-adsorption testing may be considered with *R. akari* and *R. rickettsii* antigens. Tissue for DIF should be taken from a primary eschar, as lesions from the generalized eruption do not contain enough inoculum to become positive by DIF.

The differential diagnosis includes varicella, smallpox, gonococcemia, infectious mononucleosis, echovirus (types 9 and 16), and coxsackievirus infection (A9, A16, and B5), in addition to those diseases discussed under the differential diagnosis of MSF (see Diagnosis and Differential Diagnosis under Mediterranean Spotted Fever and African Tick Bite Fever). In varicella, one observes a "dewdrop on a rose petal" cutaneous lesion, referring to a primarily vesicular lesion surrounded by macular erythema. This is distinct from the erythematous papule surmounted by a vesicle seen with rickettsialpox.[19] Fever occurs with the rash of varicella but precedes the eruption of rickettsialpox.

Treatment and Prognosis. The disease is self-limited, and even without antimicrobial therapy, the illness will resolve within 2 weeks. In the rare severe case, tetracycline antibiotics continued for up to 5 days are the most effective therapy, although defervescence is typical within 48 hours.[19]





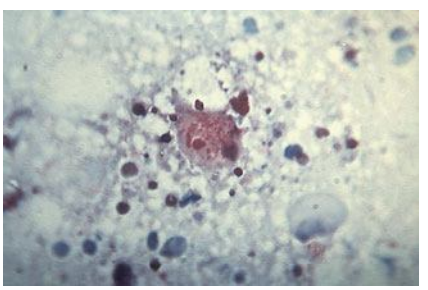
▲ **FIGURE 199-4** **A.** Vascular lesion of Rocky Mountain spotted fever as seen in an arteriole in the skin. An early thrombus is present. **B.** Rickettsiae are seen in endothelial cells from a biopsy of a cutaneous lesion.

Typhus Group

ENDEMIC TYPHUS (MURINE OR FLEA-BORNE TYPHUS) Endemic typhus is caused mainly by *R. typhi*, and is classically transmitted to humans by the rat flea (*Xenopsylla cheopis*), with rats serving as the reservoir. *R. felis* has recently emerged as an important agent of endemic typhus with characteristics of both the typhus and spotted fever group rickettsiae. *R. felis* has been identified in peridomestic cats, dogs, opossums, and their fleas (e.g., cat flea, *Ctenocephalides felis*) in parts of southern Texas, southern California, and Mexico.[20,21]

Epidemiology. Murine typhus has been reported from all continents except Antarctica, although most cases today occur in Africa. Epidemiologic characteristics are outlined in Table 199-1.

Clinical and Laboratory Findings. Most infected persons experience a fever, headache, backache, and joint pain 6 to 14 days after contact with an infected flea. Extremely high fever, 41.1°C (106°F), may last up to 2 weeks. Commonly, a rash begins on the chest and spreads to the sides and back. The palms and soles are rarely involved. The rash may last only a few hours and consists of erythematous macules or macules and papules. Petechiae are found infrequently. Rash is seen in fewer than 20 percent of patients at presentation, but 50 percent to 60 percent of patients will develop a rash over the course of the illness, with a median onset of 6 days after the fever begins.[20] More severe complications are uncommon but may include seizures, meningoencephalitis, retinitis, acute hepatitis, endocarditis, renal insufficiency, pneumonia, and respiratory failure.



▲ **FIGURE 199-5** Gimenez stain of Rocky Mountain spotted fever in tick lymph cells. [From the Centers for Disease Control and Prevention (http://www.cdc.gov/ncidod/dvrd/rmsf/organism.htm.)]

Diagnosis and Differential Diagnosis. Diagnostic IFA titers are present in 50 percent of patients by day 7, and in virtually 100 percent of patients by day 15, but may not distinguish between endemic and epidemic typhus (caused by *R. prowazekii*).

The differential diagnosis is broad as a result of the non-specific nature of the cutaneous eruption (see Box 199-2).

Treatment and Prognosis. Treatment for endemic typhus is similar to that of RMSF (see Box 199-4). With institution of appropriate antibiotics, fever typically resolves in 2 to 3 days. Prior infection with *R. typhi* provides lifelong immunity to subsequent infection.

EPIDEMIC (LOUSE-BORNE) TYPHUS Epidemic typhus (also called *prison fever, famine fever,* or *ship fever*) is caused by *R. prowazekii*, and is transmitted to humans primarily via the body louse (*Pediculus humanus* var. *corporis*). Epidemic typhus may result in long-term latent asymptomatic infection. A recrudescent infection known as Brill-Zinsser disease (BZD) can occur in survivors who may suffer recrudescent infection even decades after the initial infection.

Epidemiology. Louse infestation occurs when cold weather, poor hygiene,

Box 199-1

Differential Diagnosis of Rickettsial and Ehrlichial Diseases

Most Likely

- Enteroviral infection (e.g., coxsackievirus, echovirus)
- Roseola infantum (human herpesvirus 6)
- Drug reaction
- Group A streptococcal pharyngitis
- Vasculitis
- Kawasaki disease
- Measles (coryza, Koplik's spots, cough)
- Epstein-Barr virus/infectious mononucleosis

Consider

- Viral meningoencephalitis
- *Mycoplasma pneumoniae* infection
- Parvovirus B19
- Tularemia
- Leptospirosis
- Immune complex mediated illness
- Atypical erythema multiforme
- Typhoid fever

Always Rule Out

- Meningococcemia (more rapid-onset rash and leukocytosis, but both may show gangrenous lesions)
- Disseminated gonococcal infection
- Lyme disease
- Tick-borne viral fevers (e.g., Colorado tick fever)
- Thrombotic thrombocytopenic purpura and immune thrombocytopenic purpura
- Toxic shock syndrome
- Stevens-Johnson syndrome
- Secondary syphilis

Box 199-2

Selected Differential Diagnosis of Fever and Maculopapular or Petechial Rash

DISEASE	AGENT	SEASON	ONSET	CLINICAL FEATURES
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Spring to summer	Fever, headache, malaise, occasional gastrointestinal symptoms, rash after 2–4 days in ~ 50% of patients; rapid progression to severe systemic illness	Rash may involve palms/soles, moves peripherally to centrally; progresses from MP to petechial
Endemic (murine) typhus	*R. typhi*	Sporadic	Fever, malaise, headache, rash after 4–5 days in ~ 50% of patients	MP rash involving trunk > extremities
Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*	Spring to summer	Fever malaise, headache, rash in ~ 30% of patients	Erythematous, MP, or petechial rash; more common in children > adults
Meningococcal disease	*Neisseria meningitidis*	Year-round, but more common late winter to early spring	Fever and rash within 24 h, rapid progression to severe systemic illness	MP and petechial rash usually begins on lower extremities and moves centrally (early rash may be macular, not petechial)
Group A streptococcal pharyngitis	Group A streptococcus	Fall to winter	Abrupt onset of fever and sore throat, malaise; rash follows acute illness	Cause of petechial rash in children who appear well
Fifth disease (erythema infectiosum)	Human parvovirus B19	Late winter to early summer	Low fever and mild constitutional signs before rash onset	"Slapped cheek" appearance of rash on face, lacy rash on trunk
Roseola infantum	Human herpesvirus 6	Year-round	Fever 3–5 days, then rash, commonly in children < 2 yr of age	MP rash begins on trunk, spreads and fades rapidly
Enteroviral infection	Echovirus, coxsackieviruses, other nonpolio enteroviruses	Summer to early fall most commonly, but occurs year-round	Non-specific febrile illness, with or without rash	Fine MP rash at fever onset; begins on face and spreads to chest and extremities; occasionally petechial

MP = maculopapular.
Adapted from MMWR, Centers for Disease Control and Prevention: *Diagnosis and Management of Tickborne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichioses, and Anaplasmosis—United States*. March 31, 2006/55(RR04), p 1-27, http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5504a1.htm.

crowding, and poverty are prevalent. These conditions are most commonly found today in refugee camps, and among the homeless and the imprisoned. The most recent outbreak of epidemic typhus occurred in refugee camps in Burundi during the mid-1990s.[23] Table 199-1 details the epidemiologic characteristics of epidemic typhus.

Box 199-3

Management of Rickettsial, Ehrlichial, and *Anaplasma* Infections

- Delays in treatment can lead to severe sequelae and fatal outcome.
- Clinical history, symptoms, physical exam, and laboratory findings should guide approach to management and treatment.
- Clinicians may consider a "watch-and-wait" approach for 24–48 h for patients early in the course of illness who have nonsupporting history, non-specific clinical signs, and normal lab findings.
- Doxycycline is the drug of choice for the treatment of presumptive or confirmed rickettsial disease in both adults and children.
- Limited courses of tetracycline-class antibiotics (e.g., doxycycline) do not pose a substantial threat of tooth staining in children.
- Tetracyclines are typically contraindicated in pregnancy but may be warranted in life-threatening cases of Rocky Mountain spotted fever when clinical suspicion.
- When early invasive meningococcal infection cannot be ruled out, provide treatment for both conditions by adding an antimicrobial that has activity against *Neisseria meningitidis*.
- Prophylactic use of antibiotics after a tick bite is not recommended, as atypical presentations may result, delaying adequate diagnosis and treatment. If prophylaxis is given, a full 10-day course should be administered.
- In patients for whom tetracyclines are absolutely contraindicated, chloramphenicol can be used for rickettsial disease; rifampin or rifabutin may be considered for the ehrlichioses/anaplasmosis.
- When treating ehrlichial infections, consider continuation for 14–21 days to allow for adequate treatment of concomitant Lyme disease in areas endemic for *Borrelia burgdorferi*.

Adapted from MMWR, Centers for Disease Control and Prevention: *Diagnosis and Management of Tickborne Rickettsial Diseases: Rocky Mountain Spotted Fever, Ehrlichioses, and Anaplasmosis—United States*. March 31, 2006/55(RR04), p 1-27, http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5504a1.htm.

The major reservoir for disease seems to be humans, with lice acquiring the infection by feeding on persons with primary illness or BZD. The lice are spread through close personal contact or infested clothing. The infected louse will defecate while taking a blood meal, and the organisms in the feces are then scratched into the skin, enabling transmission. Lice die of infection within 3 weeks.

Contact with southern flying squirrels (*Glaucomys volans*) is associated with outbreaks of epidemic typhus in the eastern United States, where the fleas or lice from these rodents may be important vectors.[24]

Clinical and Laboratory Findings. After an incubation period of 1 to 2 weeks, abrupt onset of intractable headache, fever [to 40°C (104°F)], chills, and myalgia occurs. If left untreated, prostration due to overwhelming hypotension and vascular collapse may ensue. Typically, a rash begins in the axillary folds and upper trunk on the fifth day of illness. Initial lesions consist of erythematous ma-

Treatment of Rickettsial, Ehrlichial, and *Anaplasma* Infections

	RMSF	MEDITERRANEAN SPOTTED FEVER	EPIDEMIC TYPHUS	ENDEMIC TYPHUS	HUMAN MONOCYTIC EHRLICHIOSIS	HUMAN GRANULOCYTIC ANAPLASMOSIS
Adults						
First line	Doxycycline, 100 mg q12h for 5–10 days[a] *or* Tetracycline, 500 mg q6h (maximum daily dose, 2 g)	Doxycycline, 200-mg single dose *or* 100 mg bid for 2–5 days *or* Two oral 200-mg doses 12 h apart	Doxycycline, 200 mg single dose (or until patient is afebrile for 24 h)[e]	Doxycycline, 100 mg q12h for 7–14 days	Doxycycline, 100 mg q12h for 5–10 days[a] *or* Tetracycline, 500 mg q6h (maximum daily dose, 2 g)	Doxycycline, 100 mg q12h for 10–14 days
Second line	Chloramphenicol, 50–75 mg/kg/day q6h (maximum daily dose, 4 g)	Ciprofloxacin, 750 mg q12h for 7 days *or* Levofloxacin, 500 mg qd	Chloramphenicol, 80–100 mg/kg/day divided q6h	Chloramphenicol, 80–100 mg/kg/day divided q6h		
Children						
First line	Doxycycline,[b] 2.2 mg/kg q12h (< 99 lb/45 kg) *or* Adult dose if > 100 lb for 5–10 days	(same recommendations as RMSF)	Doxycycline[b] *or* Chloramphenicol	Doxycycline[b] *or* Chloramphenicol	Doxycycline, 4 mg/kg/day in two divided doses; maximum, 100 mg/dose	(same recommendations as RMSF)
Second line	Chloramphenicol, 12.5 to 25.0 mg/kg q6h for 5–10 days	Clarithromycin, 15 mg/kg/day in two divided doses for 7 days or 500 mg bid *or* Azithromycin, 10 mg/kg/day once a day for 3 days or 500 mg qd			Tetracycline, 25 mg/kg/day in four divided doses; maximum, 500 mg/day *or* Rifampin, 20 mg/kg/day in two divided doses; maximum, 600 mg *or* Chloramphenicol,[d] 12.5–25 mg/kg q6h for 5–10 days	Chloramphenicol,[f] 12.5 to 25 mg/kg q6h for 5–10 days
Pregnancy						
First line	Doxycycline,[c] 100 mg q12h for 5–10 days	Azithromycin *or* Clarithromycin	Chloramphenicol[d] *or* Doxycycline[b,c]	Chloramphenicol[d] *or* Doxycycline[b,c]	Doxycycline[b,c]	Doxycycline[b,c]
Second line	Chloramphenicol[d]	Chloramphenicol[d]	Azithromycin	Azithromycin	Rifampin	Rifampin

RMSF = Rocky Mountain spotted fever.
[a]Treat for 3 days after fever subsides and until clinical improvement is noted, typically for a minimum of 5–7 days. More severe illness may require longer duration of therapy.
[b]In severe, life-threatening cases, or when RMSF cannot be ruled out, doxycycline should be considered first line in any age.
[c]Tetracyclines are generally contraindicated for use in pregnant women because of risks associated with malformation of teeth and bones in the fetus and hepatotoxicity and pancreatitis in the mother. However, as the mortality rate is unacceptably high in RMSF, the use of tetracyclines may be warranted during pregnancy in life-threatening situations where clinical suspicion of infection is high.
[d]Use with caution in the third trimester of pregnancy as chloramphenicol may cause gray baby syndrome in neonates (abdominal distention, pallor, cyanosis, vasomotor collapse). Doxycycline should be considered in near-term gravidas. In vitro studies suggest that chloramphenicol may not be effective in human monocytic ehrlichiosis and human granulocytic anaplasmosis. The oral form of chloramphenicol is not available in the United States.
[e]For recrudescent disease (Brill-Zinsser), a second course of antibiotics is usually curative.
[f]Treatment is extended to treat potential co-infection with Lyme disease.

cules that become papular and petechial over several days. In contrast with most rickettsial diseases, the eruption spreads centrifugally but spares the face, palms, and soles. Complications include acral gangrene, cerebral thrombosis, and other neurologic sequelae, multiorgan system failure, and death.

BZD occurs as a recrudescence of previous infection with *R. prowazekii*. Provocation by immunologic stress induced by poor living conditions may play a

◀ **FIGURE 199-6** Inoculation eschar, the "tache noir" (**A**), and maculopapular rash in a patient with Mediterranean spotted fever (**B**). role. The illness is usually milder than the primary disease.

Laboratory abnormalities include thrombocytopenia, elevated transaminases, and elevated lactate dehydrogenase. Leukocytosis is seen in a minority of patients.

Diagnosis and Differential Diagnosis. Techniques for diagnosis are identical to those used for other rickettsial diseases, with the IFA test the most widely used method. The differential diagnosis is similar to that of endemic typhus [see Diagnosis and Differential Diagnosis under Endemic Typhus (Murine or Flea-Borne Typhus)]. The diagnosis of epidemic typhus should be considered when the appropriate clinical characteristics are seen in the setting of known or suspected louse infestation, or, in the United States, when a history of an exposure to flying squirrels is elicited. The centrifugal spread, lack of eschar, and predilection for colder months helps differentiate epidemic typhus from other *Rickettsia*. Endemic (murine typhus) is typically less severe than epidemic typhus. When lice and rats are both prevalent (poor hygienic conditions, prison, etc.), a risk exists for both diseases. In such situations, it is critical to discriminate between *R. typhi* and *R. prowazekii* infections, as the latter has markedly greater epidemic potential.

Treatment and Prognosis. Fatal illness is rare if proper therapy is initiated early (see Box 199-4). Although a single dose of doxycycline may be curative, optimal therapy should be continued for 2 to 3 days after defervescence. BZD is treated identically to primary epidemic typhus. Therapy failures have been documented with azithromycin for BZD.[25]

Prevention. Prevention begins with regular bathing and clothes washing. Delousing with appropriate agents, such as lindane or DDT, is effective. A vaccine is available, but recommended only for high-risk groups.

SCRUB TYPHUS Scrub typhus, also known as *Tsutsugamushi fever* or *chigger fever,* is a mite-transmitted zoonosis caused by *Orientia tsutsugamushi*. The vector is the larval stage (chigger) of the trombiculid mite (*Leptotrombidium deliense* and several other *Leptotrombidium* sp.). The mites and the rodents that carry them serve as the major reservoirs.

Epidemiology. Named for the type of vegetation that harbors the mite vector,

▲ **FIGURE 199-7** **A.** Rickettsialpox: Tache noir. A crusted, ulcerated papule (eschar) with a red halo resembling a cigarette burn at the site of a mite bite. **B.** Rickettsialpox: Exanthem. Multiple, erythematous papules and pustules, some with central hemorrhage and crusting, on the back after hematogenous dissemination of *Rickettsia akari* from the mite-bite site.

scrub typhus is endemic to a region spanning the Indian subcontinent to eastern Asia and the western Pacific rim (Japan, Korea, India, Pakistan, Taiwan, Southeast Asia, and Australia). Scrub vegetation is a transitional terrain between tall forests and cleared land, composed of plantations, fields, groves, and tall grass. Accordingly, the illness is more common in rural settings and is a common occupational disease. An estimated 1 billion people are at risk and about 1 million cases occur annually.[26]

Clinical and Laboratory Findings. An erythematous papule appears within 2 days of the chigger bite and undergoes ulceration and eschar formation in one-half to two-thirds of patients. The eschar may be absent in intertriginous areas. Regional lymphadenopathy is followed by generalized lymphadenopathy. One to 2 weeks after the bite, there is a sudden onset of high fever [40°–40.6°C, (104°–105°F)]. Chills, headache, cough, myalgia, anorexia, nausea, diarrhea, dyspnea, ocular pain, and conjunctival injection are variably present. A centrifugal macular and then papular eruption occurs in approximately 35 percent of cases about 4 to 5 days after the fever begins. The eruption starts on the trunk, then spreads to the extremities, and fades within a few days. Hepatosplenomegaly and a relative bradycardia may be appreciated. Severe complications include adult respiratory distress syndrome, myocarditis, pericarditis, disseminated intravascular coagulation, hemophagocytic syndrome, retinal vein occlusion, renal failure, and hepatitis. Nuchal rigidity and meningoencephalitis, tremors, slurred speech, deafness, and tinnitus are seen rarely. Examination of the cerebrospinal fluid in these cases reveals only a slight monocytosis.

Diagnosis and Differential Diagnosis. Enzyme-linked immunosorbent assay, dot blot urine immunoassay, rapid immunochromatographic flow assay, and PCR have the greatest sensitivity and specificity but are limited by their availability in endemic areas. IFA and the indirect immunoperoxidase assay are very specific (if not as sensitive) and more accessible, and therefore the most commonly used diagnostic techniques worldwide. An IFA titer of ≥ 400 is 96 percent specific and 48 percent sensitive; lowering the cutoff to ≥ 100 raises sensitivity to 78 percent but lowers the specificity to 84 percent.[28] The differential diagnosis is similar to that for endemic (murine) typhus [see Diagnosis and Differential Diagnosis under Endemic Typhus (Murine or Flea-Borne Typhus)].

Treatment and Prognosis. Although single dose or short courses (3 days) of doxycycline may prove to be efficacious, treatment is recommended for 14 days. Naturally occurring doxycycline- and chloramphenicol-resistant strains of *O. tsutsugamushi* have been found in northern Thailand. Azithromycin, rifampin, and ciprofloxacin are alternatives in this setting.[29]

With the institution of proper antibiotics, defervescence occurs abruptly, usually within 24 hours. In untreated patients, fever lasts for about 2 weeks.

Prevention. DEET applied to the skin or impregnated into clothing is effective at preventing transmission. Chemoprophylaxis with weekly doxycycline (200 mg) may be efficacious when traveling to endemic areas.

Q FEVER

THE EHRLICHIOSES

The ehrlichial pathogens were reclassified following the identification in 1994 of the so-called *HGE* agent responsible for causing human granulocytic ehrlichiosis. Based on distinct phylogenetic and pathogenic characteristics, this organism was assigned its own genus, *Anaplasma*, and the disease associated with it was renamed human granulocytic anaplasmosis (HGA).[10]

Epidemiology

Human disease attributed to ehrlichial agents has been reported in the United States since 1986. The causative agent of human monocytic ehrlichiosis (HME) is *Ehrlichia chaffeensis*, and the main reservoirs are deer, dogs, and coyote. The white-footed mouse (*Peromyscus leucopus*) and white-tailed deer (*Odocoileus virginianus*) are the principal reservoirs for *A. phagocytophilum*, the causative agent of HGA. Table 199-1 describes the principal epidemiologic characteristics of HME and HGA.

HGA infection occurs in a geographic pattern identical to that of Lyme disease (*Borrelia burgdorferi*) (see Chap. 187), namely in the northeastern United States, parts of the Pacific Northwest, and the upper Midwest United States. The vector for both HGA and Lyme is the *Ixodes* tick (see Fig. 199-1D and E). In addition to *A. phagocytophilia* and *B. burgdorferi*, *Ixodes* ticks can transmit *Babesia microti*, *Borrelia afzelii*, and *Borrelia garinii*. Not surprisingly, then, most cases of HGA are found in areas that also report high incidences of Lyme and babesiosis.

The lone star tick (*Amblyomma americanum*) and the American dog tick (*D. variabilis*), the vectors of *E. chaffeensis*, also transmit *R. rickettsii* and *Francisella tularensis*, the causative agents of RMSF and tularemia (see Chap. 183), respectively (see Fig. 199-1). It is essential to consider possible co-infection with these potentially life-threatening organisms in patients with known or suspected ehrlichial disease.

Etiology and Pathogenesis

Ehrlichiae and Anaplasmodiae are small, obligate intracellular bacteria. *E. chaffeensis* is trophic for monocytic cells, while *A. phagocytophilum* prefer myeloid or granulocytic cells. The organisms grow within membrane-bound vacuoles, in which they form intracytoplasmic microcolonies called morulae, which may be seen in peripheral blood smears.[10,33]

Clinical and Laboratory Findings

There is substantial overlap in the clinical presentation and laboratory evaluation of patients with HME, HGA, and RMSF (see Table 199-2). Patients give a history of a tick bite in only about 68 percent of cases of ehrlichiosis. The rash of HME is often indistinguishable from that of RMSF, and can present as macules and papules, petechiae, or as a diffuse erythema. It is observed in approximately 33 percent of adult patients and 66 percent of children with HME. Rash is rare in HGA, and indeed, the absence of a rash in a patient with systemic findings suggestive of RMSF should prompt consideration of anaplasmosis.

Pathology

In contrast to the rickettsioses, vasculitis is not a typical feature. A single retrospective case study suggests HME may rarely be associated with cutaneous vasculitis such as polyarteritis nodosa.[35]

Diagnosis and Differential Diagnosis

Clinical illness nearly always precedes laboratory diagnosis by any method. Morulae stained with Wright or Giemsa stains are occasionally observed in the leukocytes in smears of peripheral blood,

buffy coat preparations, or cerebrospinal fluid, usually during the first week of infection (Fig. 199-8). Smear sensitivities are variable and low (1 percent to 20 percent in HME and 20 percent to 80 percent of HGA), and dependent upon the experience of the microscopist.[33] Therefore, a negative smear should not delay treatment. False positives occur with toxic granulation, superimposed platelets, and Döhle's bodies.

Confirmatory testing should be performed with serologic assays available through commercial and state public health laboratories. The sensitivity of the IFA is dependent on the timing of collection and is estimated to be 94 percent to 100 percent sensitive after 14 days. Paired serum samples (acute and convalescent) taken 2 to 3 weeks apart should demonstrate a fourfold or greater rise in titers. PCR of whole blood may be more useful than tissue biopsy in HME and HGA, as these pathogens are trophic for circulating leukocytes. Immunohistochemical staining of formalin-fixed, paraffin-embedded tissue may be useful for documenting infection in the first 48 hours of disease.[10]

The differential diagnosis is extensive and includes diseases considered in the differential diagnosis of RMSF (see Boxes 199-1 and 199-2). The presence of a rash, normal white blood cell count, lack of morulae, and pathologic evidence of vasculitis is more consistent with RMSF.

Treatment and Prognosis

The clinical course ranges from asymptomatic seroconversion to multisystem organ failure and death (see Table 199-1). The median duration of disease is 1 to 2 weeks with treatment, with defervescence usually occurring within 1 to 2 days. Boxes 199-3 and 199-4 detail appropriate therapy. Treatment for 5 to 7 days is generally effective, but continued therapy for 14 to 21 days is indicated if co-infection with *B. burgdorferi* is suspected.[10,33] In vitro studies indicate that chloramphenicol may not be effective for ehrlichial diseases.

Prevention

Preventive measures include avoidance of tick exposure, use of chemical repellants such as DEET, light-colored clothing (to visualize ticks), and careful removal of attached ticks. Concentrations of DEET up to 35 percent have been deemed safe for use in children and adults.

SECTION 32

SEXUALLY TRANSMITTED DISEASES

CHAPTER 200

Syphilis

Miguel R. Sanchez

Syphilis is a systemic infection caused by *Treponema pallidum* (ssp. *pallidum*), a microaerophilic spirochete that infects only humans and a few other primates. The organism is too delicate to be grown in vitro, yet so aggressive that it invades almost any organ in the body, and so evasive that it can elude even a healthy immune system and occasionally even massive doses of antibiotics.[1] The infection is usually acquired through sexual contact with infected lesions or body fluids; less commonly, transplacentally from mother to unborn child; and, rarely, through blood transfusion, accidental inoculation, or puncture with contaminated instruments such as those used for tattooing. Transmission occurs through oral sex in at least 13 percent of cases and in one-fifth to one-third of men who have sex with men.[2]

Dermatologists have a decisive advantage in diagnosing syphilis because of their skill in evaluating cutaneous eruptions. However, the infection is systemic, even in the absence of symptoms, despite the fact that mucocutaneous lesions are the most common sign. The variable clinical course and diverse manifestations were recognized long before Sir William Osler dubbed syphilis "the great imitator," but much remains to be learned about its pathogenesis, which continues to baffle even experienced clinicians, investigators, and epidemiologists.

HISTORY

EPIDEMIOLOGY

In the early part of the twentieth century, 10 percent of the population of the United States and Europe was infected with syphilis.[1] During World War I, the U.S. Congress launched several public health measures, including quarantines and compulsory premarital screening, after syphilis was detected in 13 percent of military draftees. The incidence of syphilis peaked between 1935 and 1947 as efforts to combat the disease were restrained by a conspiracy of silence. Surgeon General Thomas Parran, in his ambitious campaign to wipe out the "shadow on the land," called for a serologic dragnet to screen the population and to institute partner notification through "shoe leather" epidemiology. These aggressive public health policies were largely ineffective.

During World War II, the armed forces instituted successful preventive interventions that included public education, prostitution control, distribution of condoms, and availability of immediate treatment without punitive repercussions. As treatment with penicillin became widely available, syphilis decreased dramatically. The resurgence of sexually transmitted diseases seen in the 1960s was blamed on looser sexual attitudes (permissiveness, promiscuity, and the pill), but in the 1970s, enhanced control efforts again lowered the number of syphilis cases. Since then, the pattern has been sudden bursts in the rate of infected cases followed approximately every 5 to 10 years by periods of low prevalence.[3] The most effective public health strategies have been the selection and confidential screening of high-risk populations, partner notification, free treatment of infected persons and partners, behavior counseling, and rapid response to outbreaks. Still, kindled by the exchange of sex for money to buy crack cocaine, the rate of infectious syphilis catapulted in 1991 to a 50-year high of 102.3/100,000 population, only to decline in 1999 to an all-time low rate of 2.5/

SYPHILIS AT A GLANCE

- A predominantly sexually transmitted infection caused by the spirochete *Treponema pallidum*.
- The most common and recognizable manifestations are cutaneous.
- Syphilis passes through four distinct clinical phases:
  - Primary stage (chancre).
  - Secondary stage (skin eruption with or without lymphadenopathy and organ disease).
  - A latent period of indeterminate duration (no signs or symptoms, only reactive serologic tests).
  - Tertiary stage (gumma, neurosyphilis, or cardiovascular syphilis).
- Latent syphilis is diagnosed by the presence of reactive serologic tests in the absence of syphilitic signs or symptoms. History, physical examination, and further testing when indicated must exclude underlying organ involvement.
- The recommended treatment is long acting benzathine penicillin, with dose and administration schedule determined by disease stage.
- Persons with human immunodeficiency virus infection or other immunodeficiencies are at high risk of therapeutic failure and progression to neurosyphilis.

100,000 population.[4] Encouraged by this success, the Centers for Disease Control and Prevention launched a National Plan for Elimination of Syphilis from the United States in 1998. However, outbreaks of syphilis among homosexual and bisexual men, including those who are human immunodeficiency virus (HIV) seropositive, continue to occur.[5] Also, the rate of syphilis among African Americans is 30 times higher than in Caucasians.[6] The facilitation of casual sex promoted by Internet sites may prove to be an important cause for future outbreaks in industrialized countries.[5]

In many parts of the world, syphilis continues to be a major public health problem. Despite therapeutic "magic bullets," the disease remains a formidable opponent.

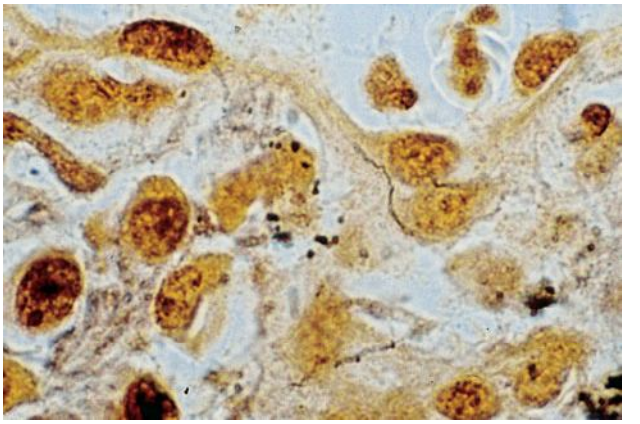
ETIOLOGY

The cause of syphilis is *T. pallidum*, a motile, corkscrew-shaped, prokaryotic bacterium with a flexible, helically coiled cell wall (Fig. 200-1). The organism is microscopically indistinguishable from treponemes that cause pinta, yaws, or endemic syphilis and closely resembles the bacteria that cause Lyme disease, borreliosis, and leptospirosis.

T. pallidum measures between 6 and 15 μm in length and 0.10 and 0.18 μm in width. It has tapered ends between which are 6 to 14 regularly spaced tight spiral coils. When fixed, the spirals impart a wave-like configuration. Its narrow width renders the organism undetectable by light microscopy without silver staining. Under dark-field microscopic examination, the treponemes resemble strings of beads with a characteristic rotatory motion and a flexion and back-and-forth squiggle. This motion is said to be characteristic of virulent treponemes and to facilitate penetration through tissue. However, in fluid medium, the bacteria lack locomotion, which distinguishes them from most saprophytic treponemes. Replication occurs through fission, with an interval of 30 to 33 hours between divisions. The outer envelope, where growth requires approximately 30 steps and several enzymes, is susceptible to damage by antibiotics.

The spirochete has three main components. The protoplast is the central part of the treponeme and contains the genome and the organelles responsible for metabolism.[7] The axial filament (flagellum) consists of six to eight elastic fibrils twisted around the protoplast. It imparts a helicoid shape and contributes to the spirochete's mobility. The outer envelope contains a heteropolymer peptidoglycan macromolecule that preserves the organism's shape, protects the fragile cytoplasm against injury, and filters large molecules. An extracellular, amorphous slime layer may protect the organism against phagocytosis. It has been postulated that the organism evades formidable immune surveillance through a paucity of integral transmembrane proteins in the outer membrane to stimulate specific antibodies and by antigenic variation through gene conversion.

T. pallidum has a relatively small genome, suggesting that it uses host biosynthesis to fulfill some of its metabolic needs.[8]



▲ **FIGURE 200-1** Silver stain of syphilis lesion showing the corkscrew-shaped treponemes.

IMMUNOLOGY

Understanding the disease has been hampered by the difficulty of growing the organism in culture and the laboriousness involved in growing treponemes in rabbits, the only animal model. In addition, the immune responses in patients with syphilis may differ during the various stages of infection. For this reason, contradictory conclusions have been reported.

T. pallidum penetrates mucosal surfaces and abraded skin of humans. Chemotactic factors attract neutrophils to the inoculation site. Skin breakdown results in a chancre, initiating the primary stage. In more mature chancres, neutrophils are replaced by lymphocytes that, through secretion of lymphokines, attract and activate macrophages. In the presence of exogenous antibody, macrophages ingest and destroy the organisms. Consistent with a T helper 1–predominant local cellular response, the lesions contain interleukin 1 (IL-2), interferon-γ, IL-10, and IL-12.[8] Plasma cells are also present in the infiltrate, and a humoral response is elicited. Antibodies to *T. pallidum* are detectable at the time or shortly after the chancre appears. Production of immunoglobulin M (IgM) precedes that of IgG. The combined humoral and cell-mediated immune responses appear to eliminate the spirochetes locally, resulting in the end of the primary stage. Polymerase chain reaction studies indicate that *T. pallidum* spirochetemia occurs during the primary stage (as well as the secondary and relapsing stages).[8]

After a few weeks, proliferation of spirochetes markedly increases, and the disease becomes generalized. During this secondary stage, antibody levels skyrocket in response to the huge numbers of organisms. The antibody response modifies the appearance of the secondary syphilis lesions, which would otherwise resemble primary chancres. At this time, resistance to new infection develops, although delayed-type hypersensitivity to *T. pallidum* becomes unexpectedly deficient. This suppression of cell-mediated immunity allows proliferation of the organisms despite rising antibody levels.

The secondary stage is followed by an asymptomatic stage called *latency*. During this period, delayed-type hypersensitivity reappears. In the tertiary stage, the immune response results in the formation of granulomas, although treponemes are rarely detected, even by immunofluorescence.

Immunity to re-infection develops only in untreated patients. After treatment, most re-infected patients develop typical chancres. The majority of patients with congenital syphilis are refractory to reinoculation and do not develop lesions or elevated antibody levels. A few develop dark-field–negative lesions associated with high antibody titers or gummas at the inoculation site.

The means by which some treponemes resist the immune attack, which

effectively clears practically every organism from early lesions, is unknown. Possible explanations include inhibition of cell-mediated responses, refuge of treponemes in anatomic sites [central nervous system (CNS), eye, aorta, bone, lymph nodes, or perilymph of middle ear] that shield the organisms from detection by the immune system, and protection by the slimy mucopolysaccharide coat surrounding the spirochetal cell wall. Some answers are provided by experimental infection in rabbits. Early on, immunity is normal, resulting in annihilation of most treponemes. However, treponemal antigens are able to induce the host macrophages to secrete twice as much prostaglandin E_2. As a result, IL-2 synthesis by these cells is halved and, consequently, T-cell proliferation is inhibited, leading to suppressed immunity that enables the remaining intact organisms to proliferate, even in the presence of antibody. The suppression persists for at least 1 month and can be reversed by indomethacin or a combination of IL-1 and IL-2.[9]

NATURAL HISTORY OF DISEASE

Syphilis has been described as an on- and off- and on-again disease. Early syphilis includes the primary stage (chancre), secondary disease (mucocutaneous lesions and/or lymphadenopathy, with or without organ involvement), and subsequent clinical relapses. Latent disease is subdivided into early (less than 1 year) and late (1 year or longer) stages. Tertiary (late) disease can present with cutaneous, cardiovascular, or neurologic involvement (Table 200-1).

TABLE 200-1
Stages of Syphilis

Contact (1/3 become infected)
↓ (10–90 days)
Primary (chancre)
↓ (3–12 wk)
Secondary (mucocutaneous lesions, organ involvement)
↓ (4–12 wk)
Early latent → Relapsing (in 25%)
(1 yr from contact)
↓
Late latent
(more than 1 yr)
↙ ↘
Remission (2/3) Tertiary (1/3)
Late benign (16%)
Cardiovascular (9.6%)
Neurosyphilis (6.5%)

Although the danger of direct transmission is exceedingly low after 5 years of infection, inoculation from gummas has been reported. Latent syphilis follows the secondary stage and may persist for life in an asymptomatic form in about two-thirds of untreated patients. The rest develop tertiary syphilis, which usually manifests as cutaneous (16 percent), cardiovascular (9.6 percent), or CNS (6.5 percent) disease (see Table 200-1). Syphilis was the cause of death in 11 percent of the patients in the Oslo study. In African American men with untreated syphilis, the mortality appears to be even higher, as cardiovascular disease was found in approximately one-half of autopsies from persons participating in the Tuskegee experiment.[10]

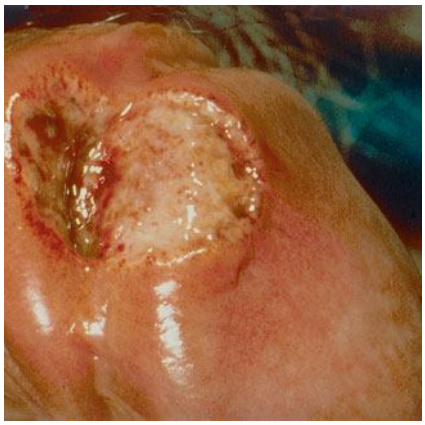
More recent analyses suggest that 1 in 25 persons with untreated syphilis become crippled, 1 in 44 insane, and 1 in 200 blind (see on-line version).

CLINICAL FINDINGS

Primary Syphilis

CUTANEOUS FINDINGS Studies from the pre-antibiotic era typically found that 50 percent to 75 percent of persons who come in contact with a lesion of primary or secondary syphilis become infected. Even in the absence of clinical or serologic evidence of syphilis at the time of evaluation, 30 percent of exposed partners will develop the infection. At the site of treponemal penetration, after an incubation period that ranges from 10 to 90 days (average, 3 weeks), a dusky red macule appears that grows into a papule and becomes a chancre by ulcerating in the center (Fig. 200-2). The length of the incubation period varies inversely with the number of inoculated treponemes. The chancre is round or oval, measures approximately 1 cm in diameter, has sharply demarcated, regular, raised, firm, rubbery borders (Fig. 200-3), and, in the absence of trauma or impetiginization, is nontender. The smooth, ham-colored ulcer base may be covered with yellowish crust or grayish slough.[12] Untreated, the chancre persists from 1 to 6 weeks; it resolves within 1 to 2 weeks after treatment and heals without scarring. However, deviation from the above description is common, and the classic "Hunterian" chancre is seen in approximately 60 percent of cases.[13] In a significant number of cases, the lesions go unnoticed. Multiple chancres (Fig. 200-4) may be present in up to 47 percent of cases, and edema, phimosis, erosive balanitis, lymphangitis, and thrombophlebitis of the dorsal vein may

▲ **FIGURE 200-2** Early chancre presenting as a flat, eroded papule with raised, indurated borders and a smooth, clean base.



▲ **FIGURE 200-3** Classic "Hunterian" chancre with raised, indurated borders and a slightly hemorrhagic necrotic base.

▲ **FIGURE 200-4** Multiple chancres at the base of the penis and adjacent pubis. Chancres in this location are associated with use of condoms.

be found. In industrialized countries, co-infection with herpes genitalis is the most plausible explanation for the presence of multiple chancres. In men, the commonly involved locations are the glans, the coronal sulcus, and the foreskin. Chancres in the urethral orifice have been reported to cause an inflammatory phimosis that may eventuate in penile gangrene. Retraction of the foreskin with a chancre in its mucosal surface causes the foreskin to flip briskly, a sign known as the *Dory flop*.

In women, the labia, fourchette, urethra (Fig. 200-5), and perineum are affected, in descending order of frequency. Chancres in women tend to have an edematous rather than a cartilaginous induration. Edema indurativum is a unilateral labial swelling with rubbery consistency and intact surface, characteristic of a deep-seated chancre in this site. Chancres develop in the cervix in as many as 44 percent of infected women but are rarely detected. Kissing chancres are common in areas of skin-to-skin contact such as the vulva.

Approximately two-thirds of extragenital chancres occur above the neck, and approximately one-half of these are seen on the lips, the perioral region, or in the oral cavity (Fig. 200-6). Orolabial chancres invariably result from oral sex. The rest appear on the fingers, breasts, trunk, abdomen, and extremities. Chancres on the fingers may be painful. The precise prevalence of anorectal chancres is difficult to establish, but anyone who has anal sex is at risk. Anorectal primary syphilis is often asymptomatic and underdiagnosed and should be considered in any at-risk person with rectal pain, bloody stools, anal fissures, or a precipitously appearing mass or ulcer in the anorectal area.

▲ **FIGURE 200-5** Chancre in a female. An ulcer covered with fibrin and necrotic slough at the orifice of the urethra.

▲ **FIGURE 200-6** Extragenital chancre. A deep ulcer with an indurated border and base. Most extragenital chancres are located on the lips or the perioral region.

In 70 percent to 80 percent of all primary syphilis cases, enlarged, rubbery, movable, non-tender, non-suppurative, discrete lymph nodes (buboes, also scleradenitis) appear during the first week of infection.[13] The nodes are usually unilateral at first and most commonly palpated in the inguinal area, although, in women, the femoral nodes are often enlarged. In one study, the nodes were tender in 14 percent of patients. Relapses of primary syphilis, called *monorecidive syphilis* or *chancre redux*, are rare.

DIFFERENTIAL DIAGNOSIS Primary stage lesions of syphilis should be considered in the evaluation of any perianal, anal, or genital ulcer, and should be excluded in any ulceration of the lips, oral mucosa (Box 200-1).

Box 200-1

Differential Diagnosis of Primary Syphilis

Most Likely

- Chancroid
- Herpes simplex
- Granuloma inguinale
- Traumatic erosion or ulcer

Consider

- Herpes simplex
- Early lymphogranuloma venereum
- Chancriform pyoderma
- Aphthous ulcer
- Behçet disease
- Squamous cell carcinoma
- Basal cell carcinoma
- Fixed-drug eruption
- Erosive candidal vulvitis or balanitis

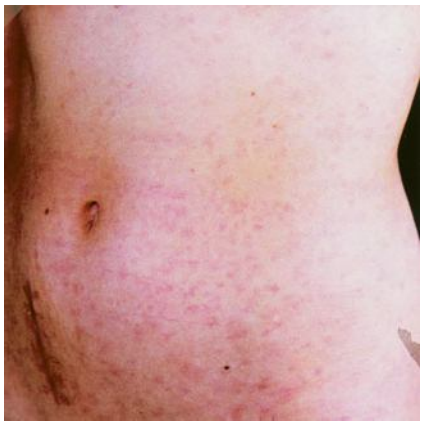
Secondary Syphilis

CUTANEOUS FINDINGS Lesions of secondary syphilis erupt 3 to 12 weeks after the appearance of the chancre but may develop months later or, in up to 15 percent of cases, before the chancre disappears. The secondary stage usually recedes in 2 to 12 weeks.[12] Not all patients present with classic symptoms and clinical findings. These may be subtle, transient, and easily overlooked or so severe that hospitalization is required. Almost 60 percent of patients with latent or late syphilis deny ever experiencing signs or symptoms of secondary disease. One-fourth of these patients cannot recall the appearance of a chancre. Patients with secondary syphilis may experience symptoms such as malaise, appetite loss, fever, headache, stiff neck, lacrimation, myalgias, arthralgias, nasal discharge, and depression. However, between 80 percent and 95 percent of cases present with a skin eruption, which invariably is the salient diagnostic feature of the infection. The precise frequency of organ involvement differs among studies. In a series of 2269 cases of secondary syphilis, the skin was involved in 81.1 percent, the oral cavity and pharynx in 36.3 percent, the genitalia in 19.9 percent, the CNS in 9.9 percent, the eyes in 4 percent, and visceral organs in 0.2 percent. Wise clinicians learn to consider the "great imitator" when confronting a combination of signs and symptoms that cannot be readily explained.[13]

Most eruptions are macular and/or papular.[12] Nodular and pustular eruptions occur infrequently, but vesiculo-bullous lesions are seen only in congenital syphilis. Early on, the lesions of secondary syphilis often have a symmetric pattern and become polymorphic later. Pruritus may be more common among African Americans. With or without treatment, non-ulcerated secondary lesions heal without scarring after 2 to 12 weeks.

Macular eruptions (roseola syphilitica) consist of .05- to 2.0-cm, pink, discrete, non-scaling, oval macules and patches, which predominantly involve the trunk and flexor aspects of the upper extremities (Fig. 200-7). The face is usually spared, but any area, including the palms and soles, may be involved.

Macular and papular eruptions represent an evolution of the macular lesions toward papules and plaques, as some



▲ **FIGURE 200-7** Macular syphilis (roseola syphilitica) with non-scaling, oval pink, ill-defined macules and patches on the chest and abdomen.

macules become palpable and develop a dark coppery hue (Figs. 200-8 and 200-9). Lesions are often present on the genitalia, face, palms, and soles. Lesions around the hairline form a crown-like pattern known as the *corona veneris*.

Papular eruptions include papulosquamous, follicular, lenticular, corymbose (bombshell), nodular, annular, and follicular varieties. They may be generalized (see Fig. 200-9) or grouped, aggregated, and localized to defined sites (Figs. 200-10 and 200-11).

Papulosquamous eruptions have discoid, copper-colored or erythematous, oval or circular, indurated papules or plaques with a flat, shiny, scaly surface (see Fig. 200-10). When the lesions are pruritic and lichenoid, the eruption may be difficult to distinguish from lichen planus (see Fig. 200-11) and, when hyperkeratosis is pronounced, the eruption may resemble psoriasis. The occasional presence of the Koebner phenomenon further contributes to this confusion. A thin white ring of scales on the surface of a lesion (Biette's collarette) is a valuable but not pathognomonic diagnostic sign. The palms and soles are often involved (Fig. 200-12). On the soles, the lesions may become hyperkeratotic and be mistaken for calluses (clavi syphilitici) or tinea pedis.

▲ **FIGURE 200-9** Generalized papulopustular syphilitic eruption. Note coppery tone of the papules and central crusting of some of the pustular lesions.

▲ **FIGURE 200-11** Lichenoid syphilitic eruption with pink to violaceous, planar, polygonal papules resembling lichen planus.

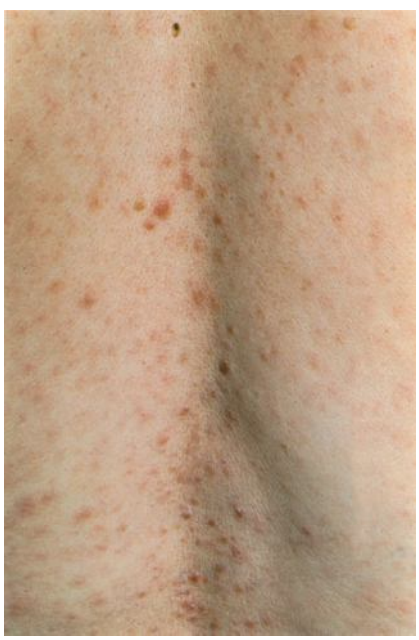
Lenticular eruptions consist of pinhead to lentil-size, brown to red papules with smooth surfaces or fine scaling. The face, especially the forehead, oral commissures, nasolabial folds, and the genitalia, are favored sites.

Corymbose eruptions are rare and seldom occur before 6 to 8 months of infection. Typically, a large central papule or plaque is surrounded by smaller satellite papules (Fig. 200-13).

Nodular eruptions consist of dermal nodules, frequently misdiagnosed as lymphoma or a granulomatous disease (Fig. 200-14).

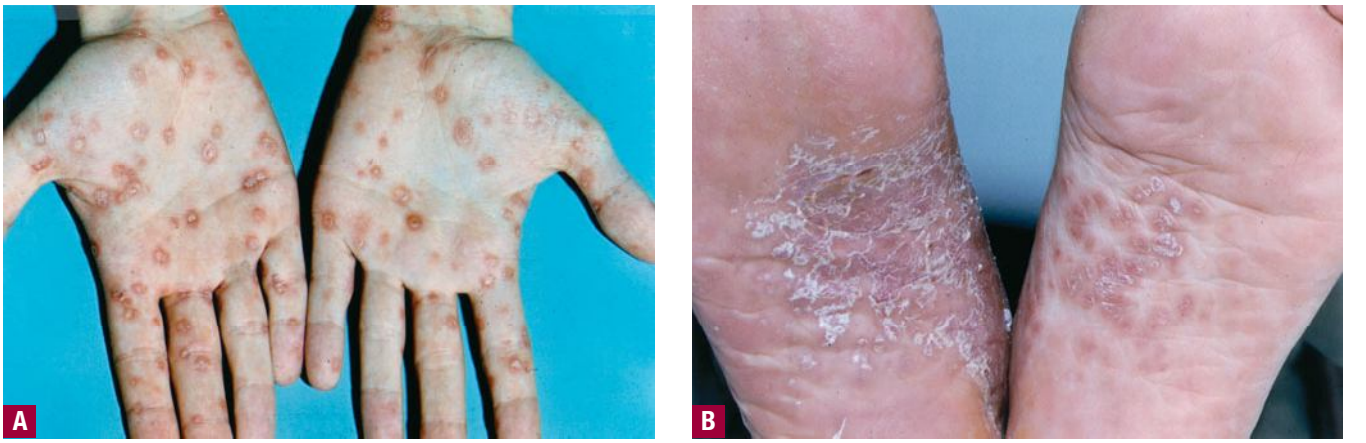
Annular eruptions consist of oval or round ring-like papules and plaques with a predilection for the face, anogenital area, body folds, palms, and soles. The eruption is often misdiagnosed as sarcoid, granuloma annulare, or tinea corporis. Serpiginous, concentric, or arcuate configurations may be seen.[13]

Follicular eruptions consist of pinpoint, acuminate, or rounded erythematous papules that arise in crops on the torso and extremities. This eruption is uncommon and has been reported predominantly in debilitated persons such as alcoholics.



▲ **FIGURE 200-8** Syphilis showing a combination of erythematous macules and coppery papules.

◀ **FIGURE 200-10** Papulosquamous syphilitic eruption with erythematous, well-demarcated, flattened plaques covered with scales (Biette's collarette).



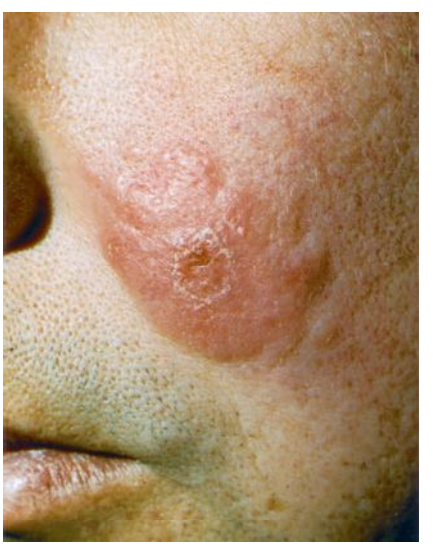
▲ **FIGURE 200-12** Characteristic secondary syphilis lesions on the palms (**A**) and soles (**B**). Palmo-plantar lesions may be macular or papular, discrete or diffuse, and non-scaling, slightly scaly, or hyperkeratotic ("syphilitic corn").

Pustular eruptions include several morphologic variants. In miliary pustular eruptions, small acuminate pustules and papules resolve with depressed pigmented scars. In acneiform, varioliform, or obtuse eruptions, there are large, acuminate perifollicular pustules, often with polymorphism (see Fig. 200-9). In impetiginoid or ecthymiform eruptions, flat pustules become confluent and covered with a large crust called a *carapace*.

Malignant syphilis (lues maligna, rupial syphilis, pustuloulcerative syphilis) presents with widespread papulopustules or nodules that become necrotic and break down into ulcers covered by layers of rupioid crust resembling an oyster shell (Fig. 200-15). The eruption is associated with toxicity, fever, arthralgias, and, occasionally, hepatitis. Oral ulcers and mucous patches may develop. Most patients are immunocompromised or in poor health. Infected contacts usually have a more benign course, and there is no evidence that the treponemes causing the infection are more virulent. Noduloulcerative syphilis with or without systemic symptoms is more common in immunocompromised HIV-infected persons.

Pigmentary changes may remain after healing of lesions. On the sides of the neck, an interesting pattern consisting of hypopigmented macules superimposed on linear pigmented reticulated patches, has been called *leukoderma colli syphiliticum* or the *Necklace of Venus*. In dark-skinned individuals, intense loss of pigment within the affected areas may resemble vitiligo. Hypopigmentation in syphilis results from partial inhibition of melanogenesis as the number of melanocytes is normal or only slightly reduced. Dermal atrophy, possibly related to inflammation-induced elastin degradation, may lead to an anetoderma-like appearance.

▲ **FIGURE 200-13** Corymbose syphilitic eruptions occur late in the secondary stage, usually after 6 to 8 months of infection. A larger papule or plaque is surrounded by smaller satellite papules.



▲ **FIGURE 200-14** Nodular secondary syphilis on the face of a man. Such lesions are frequently misdiagnosed as lymphoma or a granulomatous disease, such as sarcoidosis, leprosy, or lupus vulgaris.

Mucous membrane lesions are extremely infectious. The three manifestations are condylomata lata, mucous patches, and pharyngitis. The last two heal spontaneously within 2 to 3 weeks, but condylomata may persist for months.[13]

Condylomata lata consist of flesh-colored or hypopigmented macerated papules or plaques (Fig. 200-16). They have been reported in 9 percent to 44 percent of syphilis cases. Their surface may be smooth, papillated, or covered with cauliflower-like vegetations. The common sites are the genital and anal areas and, less frequently, the oral commissures, face, axillae, inframammary folds, and toe webs (Fig. 200-17).[14] Lesions in intertriginous areas may erode or proliferate, forming elevated, brown, velvety plaques or grouped hypertrophic, nodular lesions that resemble raspberries (frambesiform syphilis). Overgrowth of bacteria produces a foul odor.

Mucous patches are painless, shallow, rounded erosions covered with gray macerated scaling (Fig. 200-18). Present in 7 percent to 12 percent of secondary syphilis cases, the lesions may appear anywhere in the mouth but are more common on the tongue and lips.[15] The tonsils and epiglottis may be affected. Confluence of several denuded lesions on the tongue has been termed *plaques fauches en prairie*. Mucous patches also arise on the glans penis, inner vulva, and anus. Split papules are elevated mucous patches with central fissures in the oral commissures (see Fig. 200-18).

Pharyngitis of variable severity may occur in up to one-fourth of cases, al-

▲ **FIGURE 200-15** Sharply marginated, necrotic ulcers covered by "rupioid," thick, dirty crusts (like oyster shells) are the characteristic lesions of malignant syphilis.

▲ **FIGURE 200-18** Mucous patches on the lips. These erosions covered with gray-white, macerated scales are seen on the lips, oral mucosa, tonsils, and larynx. Lesions in the buccal commissure are fissured in the center (split papules).

though soreness is rare. Diffuse redness of the pharynx, palate, and tonsils may be very mild or severe with edema and erosions. Pseudomembranes and necrosis have been reported, and laryngeal involvement may produce hoarseness.

Nail changes in secondary syphilis may result from involvement of either the nail matrix or the nail folds. In the nail plate, brittleness, splitting, onycholysis, pitting, lunular elkonyxis (pits) with fissuring, and dystrophy have been described. The nail plate growing during the infectious episode may become dull, dry, thickened, and Beau's lines or latent onychomadesis (separation) may appear. Paronychia of the lateral and proximal nail folds may develop. The nail bed may become ulcerated, producing an exudate that may cause separation, shedding, and even permanent deformity of the nail plate. Amber-colored plates resembling artificial nails have been reported to be characteristic of late secondary syphilis. Cyanotic, painful toes (the blue toe syndrome) are an unusual manifestation.[16]

Hair loss may be the only sign of secondary syphilis. It has been described in 3 percent to 7 percent of cases, and may be either patchy, diffuse, or both.[17] The more characteristic type consists of small irregular patches of non-scarring alopecia throughout the scalp but predominantly on the occipital and parietal regions. The term *moth-eaten* is often used descriptively (Fig. 200-19). In some cases, the lesions resemble trichotillomania or alopecia areata. Occasionally the eyebrows, beard, and other hair-bearing areas are affected. Diffuse hair loss may occur as a result of scalp involvement by secondary syphilis or as a telogen effluvium, clinically apparent 3 to 5 months after the infection begins.

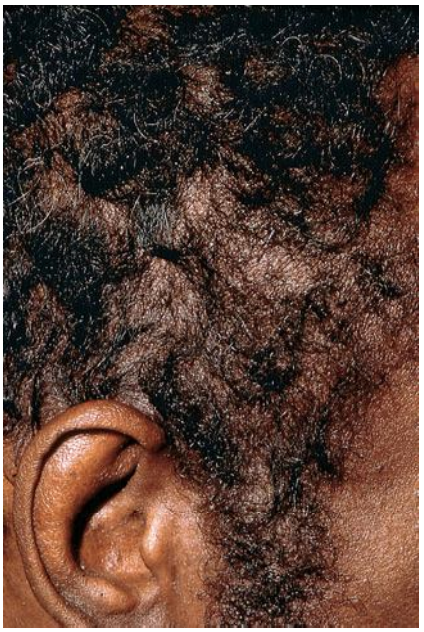
DIFFERENTIAL DIAGNOSIS Secondary syphilis can resemble almost any exanthematous maculopapular but also localized popular eruption; mucous membrane lesions resemble mucosal manifestations of other dermatoses, and syphilitic hair loss has to be separated from a number of alopecias (Box 200-2).

Non-Cutaneous Clinical Findings

LYMPHORETICULAR SYSTEM Enlarged lymph nodes are present in 50 percent to 80 percent of cases. In descending order of frequency, the inguinal, axillary, cervical, epitrochlear, femoral, and superclavicular chains are involved. Typically, the nodes are movable, firm, rubbery, discrete, bilateral, symmetric, and non-tender.[12] Mild splenomegaly is not rare.

▲ **FIGURE 200-16** Rounded, gray, moist, vegetating papules (condylomata lata) develop most frequently on the anogenital area, but may arise on the lips, groin, and toe webs. The lesions are often confused with condylomata acuminata (venereal warts).

▲ **FIGURE 200-17** Coppery, eroded, and crusted papules of secondary syphilis may also be found in the toe webs, where they may be mistaken for tinea, erythrasma, or, as in this case, Kaposi sarcoma.



▲ **FIGURE 200-19** Moth-eaten alopecia is the more common form of hair loss. Irregular, patchy, non-scarring alopecia is present more frequently on the occipital scalp and occasionally affects the eyebrows and beard.

OPHTHALMOLOGIC Iritis, the most common eye complication, occurs in fewer than 3 percent of all cases, late in the course of secondary syphilis, or in relapsing syphilis. The patient presents with injected sclerae and complains of pain, lacrimation, and photophobia. Uveitis, chorioretinitis, and, rarely, vasculitic occlusion of the central retinal vein and artery are also observed. A recent report concluded that 4.3 percent of 552 cases of uveitis were syphilitic.[18] Symptoms include photophobia, lacrimation, pain, and blindness. Topical glucocorticoids without antibiotics are contraindicated.

AUDITORY There are a few reports of sensorineural hearing loss in early acquired syphilis. The condition worsens rapidly and tends to be bilateral. Vestibular involvement with labyrinthitis is uncommon. However, 6 percent of all cases of Ménière disease are caused by congenital or acquired syphilis.[19] The pathogenesis is usually basilar meningitis with damage to the eighth nerve. Immediate treatment with antibiotics and a prolonged course of prednisone preserves hearing in almost all cases.

MUSCULOSKELETAL Because bone and joint involvement are not readily apparent, the impression has been that they are rare. However, clinical and imaging studies have found rates ranging from 0.15 percent to 4.0 percent up to 9.0 percent, respectively. The principal symptoms are local pain, erythema, doughy tumefaction, and warmth. Favored sites are the long bones of the extremities, especially the tibia, and the skull, with resulting persistent headaches. Radiographs and more sensitive bone scans demonstrate various combinations of periostitis, osteomyelitis, bone destruction, and sclerosis. Radiographic changes may take up to 11 months for complete resolution after appropriate therapy. Back pain, arthralgias, arthritis, tenosynovitis, and bursitis may be severe and persist for several months. Patients may experience generalized myalgias and muscle weakness that resembles an inflammatory myopathy.

HEMATOLOGIC Abnormalities include anemia, leukocytosis, relative lymphopenia, and elevated sedimentation rate.

RENAL Acute membranous glomerulonephritis, usually manifested by the nephrotic syndrome, is reversible with treatment.

HEPATIC Although usually sub-clinical, the incidence of luetic hepatitis was 9.7 percent in one study. Jaundice is seldom detected.

GASTRIC Epigastric pain and postprandial vomiting may be caused by eroded, ulcerated, or polypoidal stomach lesions, which heal with antibiotics. Erosive syphilitic gastritis usually affects the antrum of the stomach.

LATENT SYPHILIS

The secondary stage is followed by an asymptomatic stage with no clinical findings; the only evidence of the disease is reactive serologic testing. Latency may remain indefinitely, be interrupted by a relapse of secondary syphilis, or progress to the tertiary stage.[13] Because latent syphilis is a diagnosis of exclusion, careful examination for mucocutaneous lesions and organ involvement is required. In addition, ultrasound evaluation of the aorta to exclude cardiovascular disease and cerebrospinal fluid (CSF) examination for neurosyphilis should be considered if the history or physical findings suggest these diagnoses. Spinal taps are not required unless neurologic symptoms or signs or symptoms are present.

For therapeutic and epidemiologic purposes, the latent stage is divided into early (less than 1 year) and late (1 year or longer) stages. Hence, the duration of infection should be determined by history and previous serologic tests. However, this determination may not always be possible, and the clinician must settle for a diagnosis of indeterminate latency, which is treated in the same manner as late latent syphilis.

In clinical practice, patients who were adequately treated but who continue to have low titers of nontreponemal tests are commonly seen. If adequate previous treatment or lack of reinfection cannot be confirmed, these patients should be assumed to be infected and treated. A record of the nontreponemal test titer and the administered therapy should then be given to the patient. Unfortunately, some patients are unnecessarily retreated repeatedly because such records are not readily available.

RELAPSING SYPHILIS

Approximately 25 percent of untreated patients relapse despite the absence of re-infection. More than two-thirds of the relapses occur within 6 months, 90 percent occur within the first year, and 95 percent occur within 2 years.[13] Relapses may present with the reappearance of chancres or, more frequently, an eruption of secondary syphilis, including mucous patches and condylomata lata. Relapsing syphilis lesions tend to be less extensive

Box 200-2

Differential Diagnosis of Secondary Syphilis

Most Likely

- Pityriasis rosea
- Condyloma acuminata (condyloma lata)
- Drug eruption
- Viral eruption
- Psoriasis
- Reiter syndrome

Consider

- Lichen planus (lichenoid eruption, mucous patch)
- Eczema
- Sarcoid
- Cutaneous T-cell lymphoma
- Erythema multiforme
- Balanitis
- Vulvitis
- Granuloma annulare
- Lupus erythematosus
- Dermatophytosis
- Anogenital molluscum contagiosum (condylomata lata)
- Vulvar vestibular papillae (condylomata lata)
- Anal tags (condylomata lata)
- Squamous papilloma (oral lesions)
- Verruciform xanthoma (mucous patch)
- Leukoplakia (mucous patch)
- Glossitis (mucous patch)
- White sponge nevus (mucous patch)

and are frequently confined to the anogenital and oral areas, but remains highly contagious. Because patients may be unaware of the lesions or insufficiently concerned to seek medical help, relapsing syphilis is particularly of concern from an epidemiologic standpoint. Other presentations include periostitis (usually tibial), iritis, and hepatitis.

TERTIARY SYPHILIS

Approximately one-third of patients with untreated latent syphilis develop tertiary syphilis, while the other two-thirds remain in perpetual latency. The three principal presentations during this stage are late benign syphilis, cardiovascular disease, and neurosyphilis.

Late Benign (Tertiary) Syphilis

Late benign syphilis includes any symptomatic syphilitic manifestation after the secondary and relapsing stages that does not involve the cardiovascular or nervous systems. The lesions are caused by a cell-mediated inflammatory response to a small number of treponemes present in the affected tissues. At the beginning of the twentieth century, the incidence in untreated men and women was approximately 15 per 100,000 population, but now this stage is rare, possibly as a result of widespread use of antibiotics for other infections. The more commonly involved organs are the skin (70 percent), mucous membranes (10.3 percent), and bones (9.6 percent), but gummas may appear in practically any organ, including the parotid glands, thyroid, esophagus, stomach, liver, breasts, pancreas, kidneys, adrenal glands, spleen, bladder, and cervix, as well as the brain and heart. Chronic iritis, chorioretinitis, interstitial keratitis, and atrophy of the optic nerve are rare. Painless, fibrosing interstitial orchitis can lead to infertility.

LATE BENIGN SYPHILIS OF THE SKIN Tertiary skin lesions can be divided into three types: granulomatous nodules, psoriasiform granulomatous plaques, and gummas (Box 200-3). "Precocious" lesions develop within the first 2 years after resolution of the secondary stage, and "late" lesions at any time after that. Most lesions develop within 3 to 7 years, but gummas have appeared as long as 60 years after infection. The longer the interval before the appearance of the skin lesions, the more solitary and destructive the process.[13]

Precocious tertiary syphilis occasionally develops within weeks. Infiltrated grouped papules that tend to ulcerate may be localized to one site or be more widespread. The papules have features of both secondary stage lesions and tertiary stage granulomas. Bacteria are rarely detected. The lesions heal with little or no scarring.

Box 200-3

Differential Diagnosis of Tertiary Syphilis

Consider

- Sarcoid (specially ulcerative)
- Metastatic carcinoma
- Sarcomas
- Lymphomas
- Wegener granulomatosis
- Leishmaniasis
- Vasculitis
- Deep fungal infections
- Lupus vulgaris
- Psoriasis

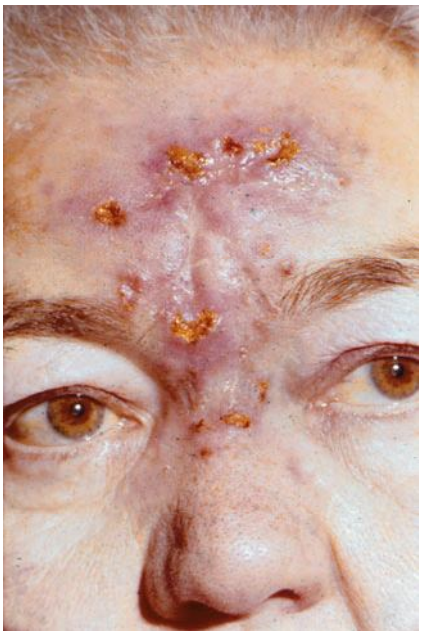
Nodular and noduloulcerative tertiary lesions (Fig. 200-20) are superficial, firm, painless, dull-red, shiny, flat cutaneous nodules that measure several millimeters to 2 cm in size. The nodules appear in a grouped configuration and coalesce into plaques.[20] The skin overlying the lesions breaks down, resulting in irregular ulcers covered with crust. Over weeks or months, central healing and advancing borders produce plaques with annular, arciform, serpiginous, or polycyclic configurations that may grow to more than 30 cm (Fig. 200-21). Some plaques may be psoriasiform (Fig. 200-22). The lesions are most commonly seen on the arms, back, and face. Even without treatment, the granulomas heal after several years, leaving atrophic scars with increased or decreased pigmentation. These lesions are often misdiagnosed as gummas.

▲ **FIGURE 200-20** A noduloulcerative tertiary syphilitic lesion is a sharply defined and irregularly shaped flat nodule of a dull red color, firm consistency, and superficial ulcerations.

▲ **FIGURE 200-21** Crusted and scaly noduloulcerative tertiary syphilis plaques with characteristic serpiginous borders and scarring.

Gummas are non-tender pink to dusky-red nodules or plaques that vary in size from millimeters to many centimeters in diameter.[21] They favor sites of previous trauma and may arise anywhere in the body but are more common on the scalp, forehead (Fig. 200-23), buttocks, and presternal, supraclavicular, or pretibial areas. The nodule is initially firm but develops a gummy consistency due to accumulation of necrotic tissue. Gummas may grow horizontally as well as vertically, and many assume geometric configurations. Small ulcers and abscesses may be present within the lesions (see Fig. 200-23). As the central gumma heals, new lesions may develop on the periphery, forming scalloped borders. In contrast to noduloulcerative lesions, gummas are deeper

▲ **FIGURE 200-22** Plaque of tertiary syphilis may be brick-red in color, covered with scales, and may be indistinguishable from psoriasis.



▲ **FIGURE 200-23** Disfiguring gummatous infiltration of the glabella and forehead with scattered ulcerations in a 60-year-old woman with late benign syphilis.

and more destructive (Fig. 200-24). Tissue necrosis eventuates in cylindrical, punched-out ulcers with clean granulomatous bases covered with adherent yellow-white slough (Fig. 200-25). The ulcer may enlarge, remain unchanged, or heal spontaneously even as the gumma enlarges. Superficial gummas heal with atrophic scars, whereas deeper lesions leave thickened, pitted, ridged scars. The lesions are rarely contagious, but infection following contact with gummas has been reported.

▲ **FIGURE 200-25** Two deep, punched-out ulcers in the popliteal fossa covered with an adherent yellow slough at the base. This is the classical appearance of nodular gummas.

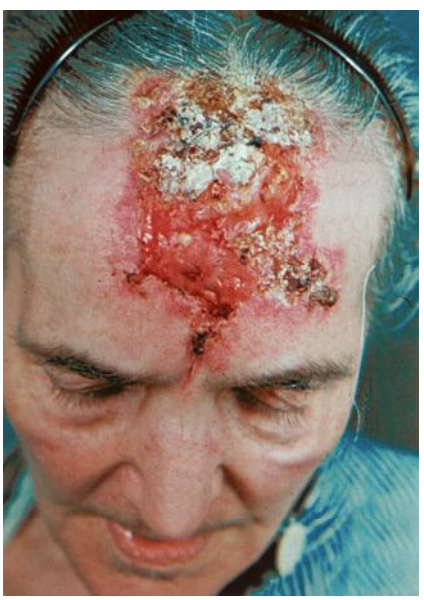
MUCOUS MEMBRANE LESIONS OF LATE BENIGN SYPHILIS Discrete gummas or diffuse gummatous infiltration may involve mucous membranes, especially the palate, nasal mucosa, tongue, tonsils, and pharynx. The lesions ulcerate and are disfiguring. Destruction of the nasal cartilage and bone (saddle nose) (Fig. 200-26A) and perforation of the nose and palate are disease hallmarks (see Fig. 200-26B). Chronic interstitial glossitis even after penicillin treatment and may undergo malignant degeneration (Fig. 200-27). Gummas of the larynx, trachea, and bronchi are rare. Pulmonary findings include chronic infection with miliary lesions, a nodule, or pleural effusion. Pseudochancre redux refers to a solitary gumma of the penis.

Skeletal late syphilis includes gummatous osteitis, periostitis, and sclerosing osteitis. The bones most commonly affected are the tibia, clavicle, skull, fibula, femur, and humerus, but the disease can involve almost any bone. Symptoms include nocturnal pain, swelling, and tenderness.

Cardiovascular Syphilis

Although currently regarded as a medical curiosity, new cases of cardiovascular syphilis continue to be reported. In early syphilis, cardiovascular disease is rare and limited to conduction defects, but it is common in tertiary syphilis. In the Oslo study (see Natural History of Disease in on-line edition), 13.6 percent of men and 7.6 percent of women developed cardiovascular syphilis, which was the primary cause of death in 15.1 percent of affected men and 8.2 percent of affected women. Symptoms and signs usually develop 15 to 30 years after the initial infection, and only 7 percent of patients with cardiovascular syphilis manifest symptomatic disease within 5 years of infection.

Presumably, during the early stages of syphilis, treponemes invade the aortic wall, where they can remain dormant indefinitely. The treponemes have a pre-



▲ **FIGURE 200-24** Aggressive gumma of the forehead causing destruction of the calvarium, mimicking advanced, destructive basal cell carcinoma.

▲ **FIGURE 200-26** **A.** Destruction of the nasal cartilage and bone by a gumma leads to a saddle nose and (**B**) to the perforation of the nasal cartilage and skin and thus to considerable mutilation.

▲ **FIGURE 200-27** Pre-malignant, chronic, interstitial glossitis secondary to gummatous infiltration of the tongue.

dilection for the aortic vasa vasorum and cause chronic, low-grade inflammation that eventuates in an obliterative endarteritis with gradual necrosis of the muscular and elastic tissues and scarring. Fibrous thickening of the adventitia and atherosclerotic plaques in the intima impart the tree bark appearance that is highly suggestive of syphilis.

The most common complications of cardiovascular syphilis are aortitis, aortic aneurysm, aortic valve incompetence, coronary ostial stenosis, and myocardial gummatous disease.

Uncomplicated aortitis comprises between 27 percent and 36 percent of cardiovascular syphilis cases. The changes occur predominantly in the ascending aorta, with fewer than 10 percent of the cases involving the abdominal aorta and only 2 percent affecting the portion below the renal artery.[22] Most cases are asymptomatic and diagnosed inadvertently at postmortem examination. The diagnosis is suspected when linear eggshell calcifications of the antero-lateral aortic wall are present in chest radiographs.

Aortic aneurysms comprise 20 percent of cardiovascular syphilis cases. The proportion is actually 40 percent if cases with coronary ostial or aortic valvular disease are included. Focal weakening of the wall results in a saccular aneurysm, whereas diffuse weakening produces fusiform involvement of the ascending and transverse aorta with subsequent dilation of the aortic ring. The distribution of aneurysms reflects that of the underlying aortitis.

Coronary ostial stenosis constitutes 25 percent to 30 percent of cases of cardiovascular syphilis. Like other forms of ischemic heart disease, the main symptoms are angina pectoris and congestive heart failure. Clues to the syphilitic etiology are the relative young age of the patient, absence of arteriosclerotic changes, reactive syphilis serology, poor response to vasodilators, and concomitant aortic regurgitation. Acute myocardial infarctions rarely occur because the stenosis is gradual and stimulates the development of an adequate collateral circulation.

Aortic valvular incompetence is found in approximately 30 percent of patients with tertiary disease. It is a late complication caused by aortic ring dilation and stretching of the valve. The soft diastolic blowing murmur of aortic regurgitation is best heard over the second right intercostal space. Myocardial disease occurs in only 2.4 percent of cardiovascular syphilis patients. In diffuse gummatous myocarditis, the most common locations are the left ventricle and septum, where gummas can cause heart block and conduction defects.

Neurosyphilis (Table 200-2)

Hematogenous invasion of the meninges by *T. pallidum* occurs early in syphilis. About 25 percent of patients with untreated primary or secondary syphilis do not clear the spirochetes from the CNS, and the organisms presumably remain dormant. After adequate treatment with benzathine penicillin, nearly all patients, including approximately 99 percent of immunocompetent individuals, eradicate the organisms from their CNS. Approximately 9.4 percent of men and 5 percent of women with remaining CNS treponemes (asymptomatic neurosyphilis) are at risk for developing overt neurosyphilis. Although it has been assumed that the development of CNS disease depends primarily on the host's immunologic response to the infection, especially neuroinvasive *T. pallidum* strains have been recently identified. Furthermore, the clinical phenotype of infection varies with the infecting strain.

TABLE 200-2
Classification of Neurosyphilis

- Asymptomatic
- Meningeal
  - Acute meningitis (headache, fever, photophobia, stiff neck, confusion)
    - With hydrocephalus (severe headache, nausea, vomiting, papilledema)
    - With vertex involvement (seizures, aphasia, hemiplegia)
    - With basilar involvement (tinnitus, deafness, Bell palsy)
  - Spinal pachymeningitis (cervical pain, muscle atrophy, sensory loss, spastic paraplegia)
- Meningovascular
  - Cerebral (prodromal symptoms, hemiparesis, hemiplegia, aphasia, seizures)
  - Spinal
    - Meningomyelitis (paresthesia, spastic weakness of legs, sensory loss, sphincter disturbances)
    - Acute transverse meningitis (sudden flaccid paraplegia, hemiparesis, sensory loss, urinary retention)
- Parenchymatous
  - General paresis (impaired judgment, irritability, delusions, dysarthria, tremors, incontinence)
  - Tabes dorsalis (paresthesia, lightning pains, ataxia, incontinence, impotence, papillary disturbances)
  - Optic atrophy (vision loss)
- Gummatous
  - Cerebral
  - Spinal

Symptoms usually develop between 5 and 35 years after the initial infection. The clinical manifestations are protean, but the classification (see Table 200-2) is useful and widely used. Neurosyphilis is divided into asymptomatic, meningeal, meningovascular, parenchymatous, and gummatous disease. Perhaps as a result of the liberal use of antibiotics, which may partially treat CNS infection, the classic forms of neurosyphilis are becoming less common and the presentations more atypical. In clinical practice, an unusual combination of signs and symptoms may be present, resulting in a puzzling neurologic picture. There are reports of patients with blurring of vision accompanied by Argyll Robertson pupils or with isolated bilateral oculo-motor nerve paresis or with tinnitus accompanied by variable auditory deficits. The presentation may be ophthalmic symp-

toms, confusion, personality changes, the Guillain-Barré syndrome, or persistent dizziness. The diagnosis of neurosyphilis should be strongly considered in a young adult with a stroke, new seizure disorder, confusional syndrome, or dementia. Detection relies on a combination of clinical manifestations, serum serologic tests, CSF examination, and radiographic scans.

Asymptomatic neurosyphilis is the presence of CSF abnormalities (reactive serologic or elevated cell counts and protein) in the absence of neurologic signs or symptoms. These findings ultimately disappear in 70 percent of cases even without treatment. Nontreponemal tests may be nonreactive in up to 39 percent of patients, but treponemal tests are usually positive in the serum as well as in the CSF.[22]

Meningeal syphilis may occur early or late. Most cases of acute syphilitic meningitis occur during the first year of infection. Meningitis is the initial presentation of syphilis in up to 25 percent of patients. Fewer than 10 percent of these patients have a concomitant skin eruption. The symptoms, like other aseptic meningitis, include headache, fever, photophobia, stiff neck, confusion, nausea, and vomiting. Up to one-third of patients present with acute hydrocephalus, and one-fourth of all cases of syphilitic meningitis have focal involvement of the cerebral vertex (vertex meningitis) or posterior fossa, possibly resulting in seizures, aphasia, and hemiplegia. Cranial nerve palsies caused by basilar involvement are a common complication of meningitis. The more frequent palsies involve the oculo-motor, auditory, and facial nerves. Reversible sensorineural deafness, with characteristic loss of higher frequencies, develops within days in up to 20 percent of patients, even in the absence of meningitis or other signs of secondary syphilis. Hearing loss is often preceded by tinnitus. Meningeal syphilis usually responds well and rapidly to high doses of intravenous penicillin.

Spinal pachymeningitis with inflammation and thickening of the dura mater usually involves the cervical area and causes pain, muscle atrophy, sensory loss, diminished tendon reflexes, and, ultimately, spastic paraplegia with sensory loss.

Meningovascular syphilis constitutes 10 percent of all neurosyphilis cases. The disease may involve the cerebrum (cerebrovascular) or spinal cord (spinal meningovascular).

Cerebrovascular syphilis is caused by endarteritis of the medium and large arteries (Heubner arteritis) or small arteries and arterioles (Nissl arteritis) that results in thrombotic infarction. The name is rather misleading because the underlying pathogenesis is a chronic meningitis. Because the neurologic signs are focal, the clinical picture resembles atherosclerotic occlusive disease, but the typical patient is between 30 and 50 years of age. Symptoms manifest as early as 2 years, but more commonly develop between 4 and 7 years after the initial infection. Weeks to months before the abrupt onset, approximately one-half the cases experience prodromes, with symptoms such as dizziness, headaches, insomnia, memory loss, and mood changes.[23] Depending on the artery involved, patients may present with almost any neurologic deficit. The most frequent is hemiparesis or hemiplegia, followed in frequency by aphasia and seizures.[23] Therefore, this diagnosis should be considered in anyone with adult-onset epilepsy or strokes.

Spinal meningovascular syphilis is separated into meningomyelitis and acute transverse myelitis. Meningomyelitis, the more common form, usually begins more than 20 years after the initial infection, with paresthesia and spastic weakness of the legs. These symptoms are followed by combinations of sensory loss, sphincter disturbances, pain, and muscular atrophy. Acute transverse myelitis produces sudden flaccid paraplegia, sensory deficits, and urinary retention.

Parenchymatous neurosyphilis encompass three distinct syndromes: tabes dorsalis, general paresis, and optic atrophy.[22]

Tabes dorsalis is caused by infection of the parenchyma of the posterior columns and posterior root of the spinal cord. It once developed in 5 percent of patients with untreated syphilis of 20 to 25 years duration, but is now rare. The three stages are preataxia, ataxia, and paralysis. The early symptoms are recurrent attacks of paresthesia and paroxysms of lightning pain. Stabbing pains in visceral organs such as the abdomen, rectum, and larynx (10 percent to 15 percent of cases) may simulate surgical emergencies. As the disease progresses, the patient may develop impotence, urinary retention, vision loss, rectal incontinence, and locomotor ataxia. Because position sense is lost, the ataxia is more prominent in the dark and is compensated by visual orientation. The Romberg's sign is positive, which means that the patient stumbles when the feet are held close together with the eyes closed. Pupil reactivity becomes sluggish early and is seen in 90 percent of cases. The distinctive Argyll Robertson pupils sign, in which the pupil accommodates to objects but does not react to light, develops later. Hearing loss from eighth nerve damage is found in approximately 25 percent of cases. Charcot joints are enlarged, painless, uninflamed joints in the lower extremities and spine that result from repeated traumatic injury. Serum and CSF serologic tests are reactive in early tabes dorsalis but may be negative late in the course. The course is rarely fatal, but patients become disabled and dependent.

General paresis, a chronic meningoencephalitis that severely disturbs cerebrocortical function, is characterized by gross atrophy of the frontal and temporal lobes, granulations in the ventricles, hydrocephalus, and widened cerebral sulci. Depending on the damaged area, the symptoms may be psychiatric, neurologic, or, more commonly, both.[22] Untreated, the course spirals downward towards death. Symptoms typically begin insidiously 15 to 20 years after infection with changes in personality and behavior. Irritability, forgetfulness, inability to concentrate, and headaches are followed by impaired judgment, emotional lability, and inappropriate social or moral behavior.[22] Delusions of grandeur with marked euphoria occur in 20 percent of the cases. It has been said that everyone in contact with the paretic suffers, but not the patient. Paranoia, tantrums, and alcohol abuse may appear. Full-blown psychosis is followed by a period of neurologic deterioration. Tremors of the hands, lips, or tongue; seizures of any type; and incontinence of urine and feces are common. At this point, a paralytic facies devoid of facial expression is typical. Mental and neurologic deterioration progresses to death typically after 2 to 12 years from pneumonia, infected pressure ulcers, or septicemia. The clinical spectrum is summarized in the clever Holmes mnemonic, paresis: *p*ersonality disorder, *a*ffect (flat), *r*eflexes (hyperactive), *e*ye changes (unequal pupils that react poorly to light), *s*ensorium (delusions), *i*ntellect impairment, and *s*peech dysarthria. Serum and CSF serologic tests are reactive in almost all cases. Adequate antibiotic treatment halts progression of the disease in 80 percent of patients. In the Oslo study, general paresis developed in 2.5 percent of men and 1.4 percent of women.

Optic atrophy may occur as an isolated finding. The vision loss begins in one eye but soon involves the other.

Optic atrophy also results from syphilitic optic neuritis. In both conditions, the CSF is usually abnormal. Penicillin does not restore vision but prevents further loss.

Focal (gummatous) cerebral or spinal meningeal syphilis results from compression of the brain or spine by a gumma, which usually arises from the pia mater. Because serologic tests can be unreactive in the serum and the CSF, a biopsy is invariably needed to establish a diagnosis. Cerebral gummas respond poorly to antibiotics, so surgical resection may be necessary.[24]

CONGENITAL SYPHILIS

In 1854, Paul Diday described the syphilitic newborn as "a little wrinkled potbellied old man with a cold in his head" (Fig. 200-28). The definition of congenital syphilis was recently updated (Table 200-3); however, because most infants have no clinical or serologic evidence of syphilis at birth and develop abnormalities months to years later, all potentially infected infants should be treated with penicillin.[25] Despite the popularity of the term *congenital syphilis*, prenatal syphilis better indicates that the signs and symptoms may develop before or after delivery rather than always being present at birth, and are not hereditary, as congenital implies. Mothers usually transmit the infection to the fetus transplacentally and possibly during delivery through contact with an infectious genital lesion. Syphilis is not transmitted through breast-feeding unless an infectious lesion is present on the breast.[26]

In a recent study, 66 percent of fetuses of women diagnosed with infectious syphilis had hepatomegaly, and some also had abnormal transaminases, thrombocytopenia, and anemia.[27]

Approximately 25 percent of infants from mothers with untreated primary or secondary syphilis die in utero. Of those infants born, almost one-half develop the disease, another one-fourth are seropositive without clinical manifestations, and only one-fourth are not infected. About 40 percent of infants born to mothers with early latent syphilis are infected, and an additional 20 percent are premature, 10 percent stillborn, and 4 percent die perinatally. In late latent syphilis, 10 percent develop congenital syphilis and another 10 percent are stillborn or premature.[26] Without treatment, one out of four newborns with signs and symptoms of congenital syphilis die shortly after birth. Syphilis remains the most common cause of nonimmune hydrops fetalis. Such infants are born with pallor, edema, and a bloated abdomen.

▲ **FIGURE 200-28** Early prenatal syphilis in a newborn. The skin is dry and wrinkled, with a yellowish-brownish hue. There is hemorrhagic rhinitis. This is what Diday described as "a little wrinkled potbellied (not seen here) old man with a cold in his head." Note also the aged appearance of the fingers in this newborn.

Spirochetes have been detected in fetuses as young as 9 weeks, but before the fifth month of gestation, the fetus seems to escape harm, probably as a result of an inability to mount an inflammatory response. Even at birth, the inflammation affects the placenta more than the infant. A fibrosed, large, thick, and pale placenta and a diseased umbilical cord with alternating streaks of red, pale blue, and chalky white may be the only clue to the diagnosis of congenital syphilis. Rarely, infants become infected after birth from colonization by *T. pallidum* in the nasopharynx and gastrointestinal system.

Clinical Findings

Prenatal syphilis is divided into early (first 2 years) and late (after 2 years) stages. It is not unusual for the diagnosis to be missed during the first year of life, and in one study, the average age at diagnosis was 30 years. Most infants are asymptomatic, and even when manifestations develop, these are often subtle and non-specific.

EARLY PRENATAL SYPHILIS Clinical manifestations develop within the first 2 years of life. This stage is comparable to the secondary stage of acquired syphilis because treponemes disseminate throughout the fetus. Without treatment, almost one-half of symptomatic infants die. However, with improved perinatal care and treatment, the prognosis is now good. Infants are born premature or small for dates. They are irritable and cry feebly. In descending order of frequency, the manifestations found are low birth weight, hepatosplenomegaly, anemia, jaundice, thrombocytopenia, skin le-

TABLE 200-3
Definition of Congenital Syphilis[a]

TYPE	DEFINITION
Confirmed	An infant in whom *Treponema pallidum* is identified in lesions, placenta, umbilical cord, or autopsy tissue
Presumptive	Any infant whose mother was untreated or treated with antibiotics other than penicillin before delivery, regardless of findings in the infant *or* Any infant or child with a reactive treponemal test for syphilis and any one of the following: Evidence of congenital syphilis on physical examination or x-ray of long bones Presence in the cerebrospinal fluid of lymphocytosis and elevated protein (without other cause) Reactive cerebrospinal fluid VDRL *or* Infant rapid plasma reagin fourfold higher than mother (both drawn at birth) *or* Reactive immunoglobulin M-treponemal antibody test in serum
Syphilitic stillbirth	A fetal death in which the mother had untreated or inadequately treated syphilis at delivery of a fetus after a 20-week gestation or of a fetus weighing > 500 g

[a]Congenital syphilis includes cases of prenatally acquired syphilis in infants and children, as well as syphilitic stillbirths.

▲ **FIGURE 200-29** Bullous eruptions on the soles of a newborn with early prenatal syphilis. Bullae have ruptured and now present as erosions ("syphilitic pemphigus").

sions, respiratory distress, rhinitis, and pseudoparalysis.[27] Rhinitis ("snuffles") has been reported in as many as 73 percent of infants. It usually develops in the second to third week of life and may be the earliest clinical sign. Initially thin, a mucoid nasal discharge, teeming with spirochetes, can become purulent or bloody (see Fig. 200-28). The nasal septum may become perforated. If untreated, flattening of the nasal bridge results in the characteristic saddle or *fleur de lis* nose.[28]

The skin of the syphilitic neonate is often dry and wrinkled and, in newborns with fair skin, may have a café-au-lait hue (see Fig. 200-28). Mucocutaneous manifestations occur in about one-half of patients younger than 6 months of age and, like secondary syphilis lesions, usually consist of an eruption of copper- to red-colored macules and papules, with or without scale, predominantly on the palms, soles, and diaper area. Condylomata lata and mucous patches may also be present. Annular or corymbiform eruptions have ben reported.[26] Bullae between 1 and 5 cm in diameter are rare but highly infectious and may be generalized or, more often, limited to the extremities particularly the palms and soles (Fig. 200-29). Commonly known as *syphilitic pemphigus*, the presence of blisters is a sign of severe disease. Pustules may appear on the fingers, toes, and at the angles of the mouth. Ulcerations around the mouth, nose, or anus may heal with rhagades (Parrot's lines), depressed linear scars that persist to adulthood and radiate from the orifice like the spokes of a wheel (Fig. 200-30).

Lymphadenopathy occurs in one-half of the cases but may not be prominent. The presence of firm, movable, nontender epitrochlear nodes is especially characteristic for prenatal syphilis. Bone disease, although usually asymptomatic, is the most common early manifestation, having been reported in 97 percent of autopsied infants younger than 6 months of age.[28] The most frequently observed osseous lesion, osteochondritis, is diagnosed by its characteristic radiographic sawtooth appearance in the metaphysis. In the medial aspect of the proximal tibial metaphysis, this defect occurs in one-fifth of early cases and has been called the *Wimberger* or *cat-bite sign*. Longitudinal lines of rarefaction like "celery sticks" may expand into the diaphysis. Pain from osteochondritis of the long bones, or epiphysitis, is exacerbated by movement, so the child keeps the affected limb still, a sign known as *pseudoparalysis of Parrot*. Painful periostitis, commonly observed in the latter half of the first year, may lead to blunting of the scapular spines and anterior tibial margins in later life. The resulting multiple layers of new bone produce the radiographic "onion-peel periosteum" sign. Osteitis of the fingers is uncommon but may produce dactylitis during the first 2 years of life.

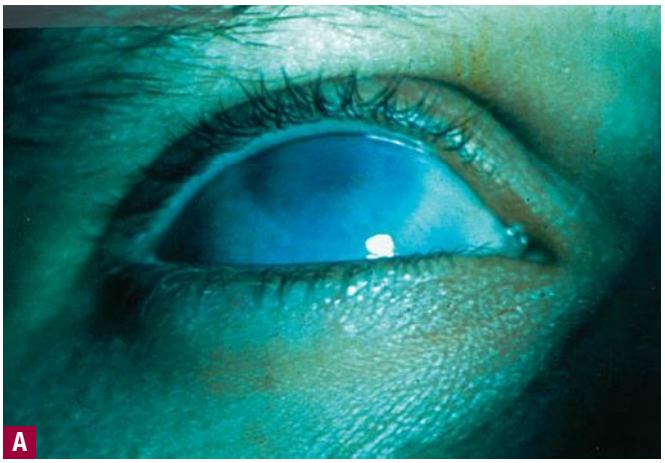
Spirochetes are detected in the CNS of 40 percent to 60 percent of infants with syphilis. However, only 10 percent of these infants develop symptomatic neurosyphilis, which usually does not become clinically evident until the third to sixth month of life.[28] It is essentially meningovascular and can present as various neurologic syndromes.

TABLE 200-4
Clinical Manifestations in Late Prenatal Syphilis

STIGMATA	ACTIVE DISEASE
Ophthalmic	Retinitis
Corneal clouding	Interstitial keratitis
Oral	
Hutchinson teeth	Gummas in nose
Mulberry molars	or palate
High-arched palate	
Ears, nose, throat	
Saddle nose	
Orthopedic	
Frontal bossing	Periostitis
Short maxilla	Dactylitis
Protuberant mandible	Clutton's joint
Saber shins	
Scaphoid scapula	
Thickened medial clavicle	
Neurologic	Eighth nerve deafness
	Neurosyphilis
Mucocutaneous	Gummas
Gastrointestinal	Hepatomegaly
	Splenomegaly

LATE PRENATAL SYPHILIS Manifestations appear after the age of 2 years, but rarely past the age of 30, and can be divided into two groups: malformations (stigmata) and active pathologic processes (Table 200-4). Most manifestations are not specific, with the exception of the Mulberry molars and the characteristic interstitial keratitis. Late congenital syphilis is not infectious. The order of frequency of late syphilis signs varies among reports.

◀ **FIGURE 200-30** Perioral rhagades are linear scars that result from ulcerations that appear during early congenital syphilis and persist to adulthood.



◀ **FIGURE 200-31** **A.** Interstitial keratitis with corneal clouding in late prenatal syphilis. **B.** The presence of small, notched, peg-shaped upper incisors (Hutchinson teeth) is also part of the late congenital syphilis triad.

Interstitial keratitis occurs in 8.8 percent of cases, and the average age of onset is 13.5 years for men and 27.1 years for women. The course eventuates in corneal clouding (syphilitic nebulae) or glaucoma (Fig. 200-31A). Iritis and iridocyclitis may also be found, but usually earlier. Corneal transplantation often restores vision.

Asymptomatic neurosyphilis occurs in 30 percent to 50 percent of patients and is diagnosed only through abnormal CSF findings. Symptomatic neurosyphilis is rare and usually delayed until puberty. Juvenile paresis, the most common pattern, affects 1 percent to 5 percent of all patients with congenital syphilis. The presentation often involves personality and behavior changes such as deteriorating school performance and inappropriate emotional responses. Within 1 year, any combination of ataxia, dysarthria, tremors, and seizures develop. Other CNS complications include mental retardation and cranial nerve palsies. Bilateral eighth-nerve disease with vertigo, tinnitus, and deafness has been reported in 3 percent to 38 percent of patients, usually adolescents. The deafness progresses despite antibiotics, but the response to systemic glucocorticoids has been encouraging. Skin manifestations consist of granulomatous lesions and gummas, just as in late benign syphilis.

Bone manifestations, such as arthritic perisynovitis, chondroosteoarthritis, epiphysitis, and periostitis, may also occur in late prenatal infection. A thickened, prominent forehead produced by localized periostitis of the frontal and parietal bones (frontal bossing of Parrot) is present in approximately 87 percent of patients. A short maxilla, with a shallow dish configuration, results from impaired development caused by syphilitic rhinitis and is present in up to 83 percent of patients. The Higouménakis's sign, which is a rather non-specific finding, is a unilateral, irregular enlargement of the sternoclavicular portion of the clavicle resulting from previous periostitis. Anterior bowing and thickening from periostitis of the midportion of the tibia (saber shins) occur in 4 percent of patients. Scaphoid scapulae, a concavity of the vertebral border of the scapulae, is observed in 0.7 percent of patients. Mandibular protuberance, or bulldog jaw, was found in 25.8 percent of patients. The size is actually normal but appears proportionally larger in comparison to the size of the maxilla. Clutton joints are symmetric, non-tender swellings of the knees, which often follow trauma and produce bilateral hydrarthrosis. Deformities such as painless perforation of the nasal septum or soft palate and deep ulcers of the pharynx and tongue can result from damage by gummas.

Dental abnormalities are caused by treponemal invasion of the tooth buds. The pathognomonic Hutchinson teeth refer to widely spaced, small permanent incisors that are screwdriver or peg-shaped, wider at the gingival margin, and notched at the biting edge because of defective enamel production (see Fig. 200-31B). Mulberry or moon molars, found in 65 percent of cases, are dome-shaped and have numerous diminutive cusps arrayed in a tight circle at the top of the dome. The first lower molars most commonly show these changes. As a consequence of defective enamel, these teeth are predisposed to caries and rarely persist beyond adolescence. Dental abnormalities can be prevented if treatment is initiated before the third month of age.

Congenital syphilis can be a difficult diagnosis in the absence of physical signs and symptoms. Maternal IgG antibodies can cross the placenta, but nontreponemal tests become nonreactive within 3 to 6 months and treponemal tests within 6 to 12 months after birth. There is an interval of 2 to 3 months between the onset of the infection and fetal production of IgM antibodies, so serologic reactivity at birth depends on when the fetus became infected. The presence of reactive IgM tests in the serum of newborns is considered to prove the diagnosis of congenital syphilis, but the fluorescent treponemal antibody-absorption (FTA-ABS) test IgM may be falsely negative in 35 percent of infants. The umbilical cord should be sent for pathologic examination with special stains for treponemes. Nasal secretions and mucocutaneous lesions should be examined by dark-field microscopy. Radiographs showing periostitis of the tibia suggest the diagnosis.

SYPHILIS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION (See Chap. 198)

Infection with syphilis imparts a greater risk for acquiring HIV infection, at least in part because the genital ulceration provides an easier entry to the virus into the systemic circulation. Conversely, numerous studies demonstrate that the prevalence of syphilis is higher in HIV-infected persons. In addition, there is impaired immunity with decreased CD4 counts and elevated viral load titers.[29]

Surprisingly, HIV infection does not significantly influence the clinical course, serologic response, or treatment outcome of most patients with early syphilis.[29,30] The appearance of primary chancres is typical, but patients with primary syphilis present more frequently with multiple ulcers, and their chancres persist up to the secondary stage more often. The course of secondary syphilis is usually unchanged, although rapidly progressive disease and unusual manifestations have rarely been

▲ **FIGURE 200-32** Ulcerated papules in a human immunodeficiency virus–infected man. This was the initial presentation of an human immunodeficiency virus infection.

reported. Nodular and noduloulcerative lesions (Fig. 200-32) are more common, but most of these cases do not have the constitutional symptoms associated with malignant syphilis.[31,32] Posterior chamber uveitis is the most common manifestation.[31] Perforation of the palate has been rarely reported. The incidence of ocular syphilis may be higher in HIV-infected patients treated with highly active antiretroviral therapy.[33]

Although most cases of early syphilis in HIV-positive patients respond to conventional doses of penicillin, serologically defined treatment failures are more common, and for this reason closer evaluation after therapy is mandatory (see Treatment).

In one study, 18 percent of patients treated with intramuscular penicillin had serologically defined treatment failures at 6 months and 14 percent at 12 months.[34] Clinical relapses occurred in 1 percent of patients in a prospective study and more frequently in retrospective studies. Rarely, patients experience multiple relapses.

Neurosyphilis may be the first clinical manifestation of HIV infection. The presence of treponemes from the CSF is not unusual during the primary and secondary stages despite the absence of neurologic symptoms. In the best study published to date, *T. pallidum* was recovered from the CSF of 26 percent of HIV-infected patients with early syphilis before treatment and 20 percent after treatment.[34] However, these percentages are similar to those of HIV-seronegative patients.[34] In a prospective, multicenter, randomized, controlled trial that compared HIV-seropositive and HIV-uninfected persons with syphilis, no differences in neurologic status were apparent.[35] It is important to note that the presence of *T. pallidum* in the CSF in early syphilis does not differ according to HIV status and is not predictive of treatment failure. Hence, performing spinal taps on all patients would not identify those at risk for symptomatic neurosyphilis. Most cases of neurosyphilis in HIV-infected patients comprise asymptomatic or meningovascular neurosyphilis, but focal gummas and other types of neurosyphilis have also been reported. Manifestations include cranial nerve palsies, optic neuritis or neuroretinitis, polyradiculopathy, transient ischemic episodes, and strokes. A rare fulminant form (necrotizing neurosyphilis) is reported more frequently in acquired immunodeficiency syndrome patients.

Not only is the prevalence of neurosyphilis higher in patients co-infected with both syphilis and HIV, but the progression to symptomatic forms of neurosyphilis can be accelerated, even after conventional therapy.[35] In a small but significant study, which included 15 HIV-infected and 25 HIV-seronegative patients with primary or secondary syphilis, *T. pallidum* was isolated from the CSF by rabbit inoculation in a similar proportion from both groups.[36] Only CSF leukocytosis was more common (67 percent vs. 25 percent) in the HIV-seropositive group. Notably, one injection of benzathine penicillin failed to eradicate the CNS infection in three of the four HIV-infected cases with positive treponeme cultures.[36] Since then, several unsettling reports have alluded to the unexpected frequency of neurorelapse after benzathine penicillin therapy in HIV-infected patients. Serologic positivity and CSF abnormalities usually resolve after treatment in HIV-infected patients with neurosyphilis, but 8 percent may remain infected despite even the recommended high doses of intravenous penicillin, and 23 percent have persistent pleocytosis.[36] Of note, however, patients with CSF abnormalities should be cautiously diagnosed as having asymptomatic neurosyphilis, because CSF leukocytosis or elevated protein is present in up to 60 percent of non-syphilitic HIV-infected patients who are not taking effective antiretroviral therapy.

The rate of cardiovascular syphilis may also be increased, with one study from India reporting a 14.3 percent prevalence in 14 HIV-infected persons with syphilis compared with a 2 percent prevalence in 100 HIV-seronegative syphilis patients.[37]

Dysregulation of the humoral immune response may result in uncontrolled production of antibodies with extremely elevated titers. In a study, the median rapid plasma reagin (RPR) titers (see Reaginic Nontreponemal Tests) were four times higher (1:128 vs. 1:32) in HIV-infected patients than in HIV-uninfected patients with their first episodes of early syphilis.[38] Furthermore, B-cell activation results in a higher rate of biologic false-positive nontreponemal serologic tests. Conversely, delayed seroreactivity and false-negative nontreponemal serologic tests have been reported, so the threshold to biopsy suspicious skin lesions should be low. The sensitivity of treponemal tests appears to be decreased in patients previously treated for syphilis if they are HIV infected (80 percent vs. 97 percent).[39]

Manifestations of secondary syphilis may occur more commonly with HIV infection. In general, the characteristic pathologic findings are present, although some cases with lymphoid infiltrate resembling cutaneous T-cell lymphoma have been reported.

DIAGNOSTIC TESTS

Definitive diagnosis of early syphilis requires demonstration of spirochetes in lesional exudate or tissue either by dark-field microscopy or by direct immunofluorescence. Unless the diagnosis is otherwise unequivocal as a result of these examinations or from clinical evaluation of typical lesions coupled with reactive serologic results, skin biopsy is recommended for suspected primary, secondary, and certainly, tertiary syphilis lesions.

Histopathologic Examination

The epidermis of a chancre is acanthotic at the margins and becomes thinner and more edematous towards the eroded center. A dermal infiltrate composed predominantly of lymphocytes, plasma cells, some histiocytes, and a few neutrophils is dense in the center and perivascular in the periphery of the chancre. In untreated cases, the spirochetes stain gray with an impregnated silver dye such as the Warthin-Starry stain (see Fig. 200-1). The spirochetes are most easily found in the epidermis

and around dermal capillaries. By electron microscopy, *T. pallidum* is predominantly found extracellularly. Less commonly, organisms are found within the endothelial cells of capillaries and inside the vacuoles and phagolysosomes of plasma cells, macrophages, and neutrophils; and occasionally within fibroblasts and nerve fibers.

Characteristically, secondary syphilis lesions show dilatation of blood vessels with a proliferation of endothelial cells and a superficial and deep perivascular dermal infiltrate with many plasma cells. The infiltrate often becomes lichenoid, may obscure the dermal epidermal interface, and, in one-third of cases, surrounds adnexal structures and nerves. Specific changes depend on the biopsied lesion.

Macular lesions show mild or no epidermal changes. Papulosquamous plaques show psoriasiform epidermal hyperplasia, parakeratosis, and often, focal spongiosis, basal vacuolar changes, and microabscesses with neutrophils. Other common epidermal changes are epidermal pallor, keratinocyte necrosis, extravasated red blood cells, and exocytosis of mononuclear cells. The dermal vessels show endothelial proliferation and swelling. There is a superficial and deep perivascular infiltrate arranged in a coat-sleeve pattern and composed of lymphocytes, histiocytes, and many plasma cells. The infiltrate assumes a lichenoid pattern that may involve the superficial and deep dermis and, in one-third of the cases, surrounds adnexal, vascular, and neural structures. The infiltrate may also be T-shaped or perivascular. Small epithelioid granulomas, which may have Langhans or foreign-body–type giant cells, may be present, even in early lesions. In lesions of pustular syphilis, neutrophils within the sub-corneal pustules may infiltrate the hair follicles. In ulcerating lesions, there is infarction necrosis of the epidermis and dermis because of occlusion of blood vessels by fibrinoid material. The epidermis may be absent from the specimen.

In nodular tertiary syphilis, there is a dermal lymphohistiocytic and plasma cell infiltrate with small granulomas and islands of epithelioid cells intermingled with some multinucleated giant cells. A mild degree of caseation necrosis may be present. In gummas, the infiltrate contains numerous epithelioid and multinucleated giant cells and extends throughout dermis to the subcutaneous tissues. Extensive caseation necrosis surrounded by epithelioid and giant cells is present in the center of the lesion. Nodular tertiary syphilis may be difficult to differentiate from lupus vulgaris, and gummatous syphilis from scrofuloderma and erythema induratum [all manifestations of mycobacterial infection (see Chap. 184)].

Dark-Field Microscopy

Dark-field examination is the diagnostic test of choice in chancres and moist lesions of secondary syphilis, especially condylomata lata and mucous patches. The test is invalid for oral lesions because saprophytic treponemes that cannot be differentiated from *T. pallidum* are common in the mouth. In such cases, a lymph node aspirate can be examined by dark-field microscopy.

The surface of the lesion should be cleaned and gently abraded with a sterile gauze soaked in 0.9 percent sterile saline, carefully avoiding bleeding, as blood cells obscure detection of the treponemes. After squeezing the base of the lesion with two gloved fingers, a serous exudate accumulates on the surface and can be scraped off with a scalpel or drawn off with a pipette. The exudate is mixed with one or two drops of saline on a glass slide and covered with a plastic cover slip. The slide is examined under a dark-field microscope for the presence of treponemes.

Direct Fluorescence Antibody Test

The lesional exudate is smeared on a glass slide and stained with fluorescein-labeled anti–*T. pallidum* immunoglobulin. In contrast to dark-field microscopic examination, the smear can be held for later evaluation and oral or anal lesions can be examined because only *T. pallidum* is stained. The sensitivity of the test is greater than 90 percent.[40]

Serology

Serologic tests for syphilis are divided into two types. The simpler cardiolipin-based nontreponemal tests are used for screening and to follow therapeutic response. The more elaborate *T. pallidum*-based treponemal tests are used for diagnostic confirmation and to improve diagnosis of early, congenital, and neurosyphilis.[41]

A presumptive diagnosis of syphilis is made by a reactive nontreponemal test, such as the RPR test or the VDRL test, confirmed by a treponemal test, such as the microhemagglutination assay with *T. pallidum* antigen or the FTA-ABS test (Table 200-5).[42] Although treponemal tests have higher specificity and sensitivity, because of their higher cost, they are not used for screening but rather to corroborate the accuracy of reactive nontreponemal tests.

Reaginic Nontreponemal Tests

Reaginic nontreponemal tests are inexpensive and are widely used for screening. The antigen (reagent) is a combination of cardiolipin, cholesterol, and lecithin. The VDRL and RPR become reactive 4 to 5 weeks after infection and revert to negative in 25 percent to 30 percent of cases during late latency. Results are reported as either nonreactive or quantitatively as a titer of the sample diluted with saline in a geometric progression by a factor of 2 (1:2, 1:4, 1:8, and so on). The reported titer represents the highest dilution that gives a positive result. Titers may differ slightly between laboratories. A high titer (≥ 1:32) usually indicates active disease, whereas low titers (≤ 1:8) may remain unchanged

TABLE 200-5
Interpretation of Serologic Tests

RPR	MHA-TP	CAPTIA (IGM) EIA	
–	–	–	No syphilis or incubating syphilis
–	–	+	Early primary syphilis
+	+	+	Primary or secondary syphilis
+	–	+	Early infection
+	+	–	Late secondary or latent syphilis
+	–	–	Biologic false-positive, late syphilis
–	+	–	Late infection, treated syphilis, or false-positive treponemal test

for years after therapy of late disease. Titers decline more slowly in patients with previous episodes of syphilis. After treatment, the titers should decline fourfold (a titer of 1:32 decreases to 1:8) or lower within 6 months in primary or secondary syphilis, and within 24 months in latent syphilis. In patients treated for primary syphilis, the tests become nonreactive in 60 percent by 4 months and in nearly all patients by 12 months. In secondary syphilis, the tests usually become nonreactive in 12 to 24 months after treatment. If therapy is administered in the early latent stage, nontreponemal tests may remain reactive in low titers for up to 5 years or longer. Notably, one study found persistently reactive low titers after 35 years of adequate treatment in 18 percent of secondary syphilis cases and 44 percent of late latent stage cases. In tertiary syphilis, the tests may revert to nonreactive in 20 percent to 30 percent of cases, even without treatment. A titer that neither decreases nor increases fourfold after treatment is referred to as *serofast*. If an initially high titer (≥ 1:32) fails to decrease after treatment, the patient should be evaluated for neurosyphilis and retreated appropriately. A fourfold titer increase indicates reinfection or treatment failure. Weakly reactive qualitative tests should be repeated, because up to one-third will be eventually positive.

False-negative results occur during very early infection or in latent and late syphilis. In 1 percent of secondary syphilis cases, results are falsely reported as nonreactive as a result of the prozone phenomenon. That is, unless the serum is diluted, the high levels of antibody prevent flocculation.

Biologic false-positive results constitute 1 percent to 2 percent of reactive nontreponemal tests, depending on the population studied. In 90 percent of these, the titers are less than 1:8. Biologic false-positive results may be transient and acute (< 6 months) or longer lasting and chronic (> 6 months; Table 200-6). In narcotic addicts, false-positive reactions may persist even after 14 months of drug abstinence.[39]

TABLE 200-6
Causes of Biologic False-Positive Nontreponemal Tests

Other		Drug abuse Dysproteinemias Hepatic cirrhosis Malnutrition Malignancy Lymphoproliferative disorders

Specific Treponemal Tests

These tests use whole or fragments of *T. pallidum* as antigen. Compared with nontreponemal tests, they are more cumbersome to perform but have greater sensitivity in the primary and late stages and slightly higher specificity (Table 200-7). They are widely used to confirm reactive nontreponemal test results.[41]

The FTA-ABS test is the most sensitive serologic test in primary syphilis, and reactivity begins during the third week of infection, but the microhemagglutination assay with *T. pallidum* antigen, which is less expensive and easier to perform, is more popular. In most patients with reactive treponemal tests, the reactivity continues for life even after successful treatment. Only 15 percent to 25 percent of tests become unreactive between 2 to 3 years after treatment of primary syphilis. The tests are highly specific and sensitive during the secondary and the late phases of the disease (see Table 200-7). Because of their high sensitivity, which permits detection of very small amounts of antibody, the tests cannot be used to assess treatment efficacy. False-negative results are very rare. False-positive FTA-ABS results are also uncommon but may result from autoantibodies (rheumatoid factor) or antibodies to other spirochetal infections (Table 200-8).

Treponemal-based enzyme immunoassays (EIAs) are becoming increasingly popular as screening tests for syphilis and may, in time, replace nontreponemal tests for this purpose. These tests are more specific than the RPR and more sensitive than the FTA-ABS in patients with past infection.[43] The tests do not distinguish between patients with incompletely treated or untreated syphilis and those who have been successfully treated. When a screening treponemal test is reactive, a nontreponemal test should be done to exclude a false positive reaction. If the nontreponemal

TABLE 200-7
Sensitivity and Specificity of Serologic Tests

	Sensitivity (%)				
	Primary	Secondary	Latent	Tertiary	Specificity (%)
VDRL	80 (74–87)	100	80 (75–100)	71 (55–94)	98
Rapid plasma reagin	86 (81–100)	100	80 (75–100)	73 (55–96)	98
Fluorescent treponemal antibody-absorption	98 (93–100)	100	95	97 (95–100)	99
Microhemagglutination assay with *Treponema pallidum* antigen	82 (50–95)	100	99	96 (90–99)	99
Captia syphilis (immunoglobulin M) enzyme immunoassay	82	60	53	34	100

Note: For explanation of serologic tests, see text.

test is negative, another test should be performed using a different nontreponemal assay. If this test is also not reactive and the diagnosis of syphilis therefore cannot be established serologically, the clinician needs to be guided by the history (risk factors, former presence of potentially syphilitic lesions). Appropriate management may include a more intense search for diseases that cause falsely reactive treponemal tests or treatment for presumptive syphilis of unknown duration.

IgM EIA tests, such as the Captia syphilis (IgM) EIA, are the serologic test of choice in very early primary infection, assessment of re-infection, and congenital syphilis. IgM antibodies can be detected in the serum toward the end of the second week of infection. The test is the first to become positive and has a 93 percent sensitivity in primary infection. However, because memory cells do not synthesize IgM antibodies, the sensitivity is only 85 percent in secondary infection and 64 percent in early latent infection. Reactivity ceases within 3 to 9 months after therapy of early syphilis but may persist for 12 to 18 months after treatment of late infection. It is important to note that a reactive result indicates almost with certainty the need for therapy, but a nonreactive result does not exclude infection. Persistence of reactivity after therapy indicates treatment failure or false-positive results because of autoantibodies of the IgM class.

TABLE 200-8
Common Causes of False-Positive Treponemal Tests

- Infectious mononucleosis
- Lepromatous leprosy
- Leptospirosis
- Lyme disease
- Malaria
- Relapsing fever
- Systemic lupus erythematosus

Because IgM antibodies do not cross the placenta or the intact blood–CSF barrier, IgM reactivity in the serum of a newborn confirms prenatal infection, and detection of antitreponemal IgM in the CSF indicates neurosyphilis. The sensitivity of the Captia (IgM) EIA is 100 percent in congenital syphilis, but lower in primary (82 percent), neurosyphilis (34 percent), and treated syphilis (11 percent).[42] Immunoblots have a very high sensitivity and near-perfect specificity. Although laborious, they are the tests of choice to confirm a false-positive test and are promising as a replacement of other confirmatory treponemal tests.[41]

Polymerase chain reaction assays have a sensitivity and specificity of more than 95 percent in identifying *T. pallidum* in genital ulcers but remain an investigational tool.[44]

Cerebrospinal Fluid Examination

Examination of the CSF by lumbar puncture to exclude asymptomatic neurosyphilis offers marginal benefits, as the risk of developing neurosyphilis in HIV-seronegative patients after standard parenteral penicillin treatment is very small. However, lumbar puncture should be performed if there is clinical evidence of neurologic involvement. Because no clinical presentation is specific for neurosyphilis, reliable criteria by laboratory examinations are particularly important[45] (Table 200-9). Elevated white blood cell count (5 cells/μL) and total protein (> 400 mg/L) indicate inflammation and presumed infection. Of course, these findings are found in other types of meningitis. Conversely, both parameters may be normal or only slightly elevated in asymptomatic disease as well as in tabes dorsalis.

A reactive CSF VDRL result indicates neurosyphilis. Blood contamination may increase titers, but this only occurs when CSF is visibly bloody. Unfortunately, the CSF VDRL is not reactive in up to 70 percent of patients with neurosyphilis, particularly in asymptomatic patients. A nonreactive FTA-ABS test virtually excludes neurosyphilis, but a reactive result cannot be interpreted because positive tests in the absence of CNS involvement are so common.[46] In certain cases, the diagnosis of neurosyphilis is particularly challenging. Moreover, a patient with adequately treated syphilis and no neurosyphilis may have abnormal CSF serology, cell counts, and protein as a result of a nonsyphilitic CNS infection (HIV, malaria) or a neoplasm.

TREATMENT

Parenteral penicillin is the treatment of choice for all stages of syphilis. A concentration of penicillin above 0.018 mg/L is considered treponemicidal. However, a serum concentration equivalent to the maximally effective in vitro level (0.36 mg/L) is recommended for a minimum duration of 7 to 10 days in early syphilis

TABLE 200-9
Diagnosis of Neurosyphilis through Cerebrospinal Fluid Testing

- Strongly indicative
  - Reactive VDRL (or rapid plasma reagin)
  - Reactive MHA-TP (or FTA)
  - Reactive western blot, polymerase chain reaction, or IgM tests
  - TPHA index > 500
- Strongly suggestive (in absence of other central nervous system disease)
  - Cell count > 5 cells/μL
  - Protein > 40 mg/100 mL
  - IgG index > 0.7
- Practically excluded
  - Nonreactive MHA-TP (or FTA)
  - TPHA index < 70

FTA = fluorescent treponemal antibody; Ig = immunoglobulin; MHA-TP = microhemagglutination assay with *Treponema pallidum* antigen; TPHA = *Treponema pallidum* hemagglutination test.
Note: For explanation of serologic tests, see text.

and longer in late syphilis.[47] The recommended doses of long-acting benzathine penicillin provide treponemicidal levels for 3 to 4 weeks. Oral penicillin can produce adequate serum and tissue levels but is not recommended because of possible lack of compliance.[47] Treatment failures are rare and regularly respond to a second course of penicillin at the same or higher doses.

Parenteral penicillin is the only treatment with documented efficacy in neurosyphilis, HIV infection, and pregnancy. The concentration of penicillin in the CSF is less than 10 percent of the serum level. However, even a single injection of benzathine penicillin produces effective levels in the perivascular areas where treponemes are found in the CSF.[37]

After penicillin therapy, clinical relapse is rare but, as has been noted in Reaginic Nontreponemal Tests, serologically defined treatment failure is relatively common. Tetracyclines, erythromycin, and third-generation cephalosporins have strong antitreponemal activity in experimental and clinical trials but are less effective than penicillin. Although less investigated and more expensive than tetracycline, doxycycline is preferred because of better compliance and absorption, which is less affected by food.[48] Erythromycin is slightly less effective than tetracycline. The results with the macrolide, azithromycin, in a single 2-g dose is comparable to erythromycin and not recommended routinely—certainly not in HIV-infected persons and pregnant women.[49] Ceftriaxone at a dose of 1 g intramuscularly or intravenously daily for 8 to 10 days appears to be effective in primary, secondary, and early latent syphilis, although experience with this treatment is limited.[49,50] Additionally, although not recommended, the drug can be safely administered during pregnancy.[47] HIV serology is recommended for all patients with syphilis and should be repeated in 3 months in patients living in areas with high HIV prevalence.[47]

Primary and Secondary Syphilis (without Neurologic, Ophthalmologic, or Auditory Involvement)[47]

A single dose of benzathine penicillin G, 2.4 million units intramuscularly, is the preferred treatment.

PENICILLIN ALLERGY Patients with uncomplicated syphilis may be treated with doxycycline, 100 mg orally twice daily for 2 weeks. Compliance is better than with tetracycline, 500 mg orally four times daily, or erythromycin, 500 mg orally four times daily. Ceftriaxone, 250 mg daily or 1 g every other day intramuscularly or intravenously for 8 to 10 days, is an alternative, but some patients may also be allergic to this agent. If azithromycin at a single dose of 2 g orally is the only choice, close follow-up is required because of the risk of treatment failure.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION The treatment is the same, but follow-up is closer. Some experts recommend CSF examination in patients with CD4 counts below 350 cells/mm^3 and nontreponemal titers equal or above to 1:32. There is no evidence to support administration of three weekly injections of benzathine penicillin G or enhanced therapy with ampicillin and probenecid after a course of benzathine penicillin injections.[34]

CHILDREN Children should be evaluated for congenital syphilis through examination and review of maternal and prenatal records. If the CNS is abnormal, treatment for neurosyphilis is indicated. If infection was acquired postnatally, a child protection agency should be consulted after treating with a single intramuscular injection of benzathine penicillin G, 50,000 units/kg up to 2.4 million units.

CEREBROSPINAL FLUID EXAMINATION If there are signs or symptoms of CNS, eye, or hearing involvement, the CSF should be examined. A slit-lamp examination is indicated if there is ophthalmologic disease. If CSF findings suggest neurosyphilis, treatment should be modified accordingly.

FOLLOW-UP Patients should be re-examined clinically and serologically at 6 and 12 months (if HIV-seropositive, then at 3, 6, 9, 12, and 24 months).

TREATMENT FAILURES Either a reappearance of lesions or symptoms or a fourfold (or greater) increase in nontreponemal titers indicates failed therapeutic response or re-infection and requires repeat clinical examination and retreatment. HIV serology should be repeated. Unless re-infection can be definitely established, a spinal tap is indicated. If CSF analysis indicates neurosyphilis, treat with intravenous penicillin. If neurosyphilis is excluded, treat with benzathine penicillin G, 2.4 million units intramuscularly for three doses 1 week apart, even if desensitization is necessary.

The management of patients whose RPR titers do not decline by a fourfold factor in 6 months is unclear. Approximately 15 percent of persons treated with the recommended therapies will fail to achieve a twofold dilution in nontreponemal titers 1 year after treatment. At the very minimum, clinical evaluation and HIV testing are indicated. If the patient is HIV seropositive, treatment should be based on the results of a spinal tap. If HIV seronegative but compliance cannot be assured, retreatment (preferably with a single intramuscular benzathine injection of penicillin G on three successive weeks) is recommended. In rare cases, the titers fail to decline even after retreatment and even though CNS infection has been excluded. In this case, only serologic and clinical follow-up evaluations are recommended. The patient should be retreated only if there is a fourfold elevation in titers or new clinical signs develop.

Early Latent Syphilis[47]

A single dose of benzathine penicillin G, 2.4 million units intramuscularly, is the recommended treatment.

PENICILLIN ALLERGY If the patient is neither pregnant nor HIV-infected, treat with doxycycline, 100 mg orally twice daily for 4 weeks.

CHILDREN The treatment is the same as for primary or secondary syphilis.

FOLLOW-UP As in ate latent syphilis (see Indeterminate or Late Latent Syphilis).

Indeterminate or Late Latent Syphilis

Benzathine penicillin G, 2.4 million units intramuscularly 1 week apart for three doses, is the treatment of choice. If the patient misses a dose, the treatment may be resumed as long as the interval between injections has not exceeded 2 weeks.

The regimen does not need to be repeated in patients who are late for a treatment as long as the time interval between injections is less than two weeks, with the exception of pregnant women.

PENICILLIN ALLERGY Doxycycline, 100 mg orally twice daily, or tetracycline, 500 mg orally four times daily for 28 days, may be prescribed.

PREGNANCY Treat with penicillin as discussed in Treatment in Pregnancy.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION Treat with penicillin.

CHILDREN After appropriate evaluation to exclude congenital syphilis and sexual abuse, treat with three weekly intramuscular injections of benzathine penicillin G, 50,000 units/kg (up to 2.4 million units).

CEREBROSPINAL FLUID EXAMINATION In asymptomatic individuals, the yield of positive findings for lumbar punctures is low, but CSF examination is clearly indicated in certain cases:

- Cardiovascular, neurologic, eye, or auditory symptoms or in late benign syphilis
- HIV infection
- RPR titer ≥ 1:32
- Treatment failure
- Treatment other than penicillin

If the CSF examination demonstrates abnormalities, patients should be treated for neurosyphilis. The outcome of treatment has not been conclusively studied, but in 469 treated patients with uncomplicated late latent syphilis who were followed for up to 12 years, the CSF remained normal, and no cases of cardiovascular syphilis were reported.

TREATMENT FAILURES Patients with a normal CSF examination should be retreated for latent syphilis if signs or symptoms of syphilis develop, if a high titer (> 1:32) fails to decline fourfold (to 1:2) within 12 to 24 months, or if titers subsequently increase fourfold or higher.

FOLLOW-UP Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months (and additionally at 18 months if the patient is HIV infected). After treatment, the patient should be reevaluated for neurosyphilis and retreated accordingly if (1) titers increase fourfold, (2) an initially high titer (≥ 1:32) fails to decrease fourfold within 12 to 24 months, or (3) the patient develops signs or symptoms attributable to tertiary syphilis.

Tertiary Syphilis (Cardiovascular, Late Benign Syphilis)[47]

Benzathine penicillin G, 2.4 million units 1 week apart for three doses, is the recommended treatment.

PENICILLIN ALLERGY If the patient is not HIV infected and the CSF is negative, treat with doxycycline, 100 mg orally twice daily for 2 weeks.

CEREBROSPINAL FLUID EXAMINATION All patients should have spinal taps and, if abnormalities are found, treat for neurosyphilis.

PROGNOSIS After treatment of late benign syphilis, gummas heal slowly over several months, depending on the extent of tissue destruction. Gummas of the brain or spinal cord may need surgical excision. Because advanced symptomatic disease in cardiovascular syphilis is associated with poor prognosis even with recommended doses of benzathine penicillin, some experts prefer to treat cardiovascular disease with high-dose intravenous penicillin. The evidence suggests that penicillin has a beneficial effect in the majority of patients, although efficacy is difficult to evaluate, as most symptomatic patients receive therapy to improve cardiac function. In studies, 63 percent of patients with aortic insufficiency, aneurysms, or both, experienced symptomatic improvement from 6 to 12 months after penicillin treatment. The disease progressed in 4 percent of asymptomatic and 4.5 percent of symptomatic patients.

Neurosyphilis[47]

The treatment of choice is aqueous crystalline penicillin G, 18 to 24 million units administered daily as 3.5 to 4.0 million units intravenously every 4 hours for 10 to 14 days.[47]

Alternatively, treatment with a single injection of procaine penicillin G, 2.4 million units intramuscularly daily, and probenecid, 500 mg orally every 6 hours for 10 to 14 days, can be instituted in patients whose compliance can be assured. Treatment of neurosyphilis with ceftriaxone (1 g intravenously daily for 14 days) is not as effective as penicillin.

PENICILLIN ALLERGY Desensitize and treat with penicillin.

FOLLOW-UP Re-examine the CSF every 6 months until normal. Cell counts should decrease by 6 months and CSF VDRL and protein levels by 2 years. If not, retreat with intravenous penicillin. Notably, these CSF abnormalities may persist longer in HIV-infected patients.

PROGNOSIS In one study, penicillin cured, improved, or stabilized the disease in 91 percent of patients with asymptomatic neurosyphilis, 81 percent with meningovascular disease or meningitis (78 percent cured), 75 percent with general paresis (48 percent cured), 72 percent with tabes dorsalis (47 percent cured), and 88 percent with miscellaneous neurologic abnormalities.

If symptoms worsen during treatment, the dose may need to be increased. Optic atrophy, alone or in conjunction with tabes dorsalis, and eighth-nerve–related deafness are notoriously more resistant to treatment. Blindness because of optic atrophy is not reversible with penicillin, although lack of progression or improvement occurs in up to 60 percent of cases. Eighth-nerve–related deafness benefits from the combination of long-term penicillin and prednisone.

RELAPSE Neurosyphilis relapses usually respond to additional courses of intravenous penicillin at equal or higher doses.

Treatment in Pregnancy[47]

The penicillin regimen appropriate for the stage of the infection should be used. In primary, secondary, and early latent syphilis, a second benzathine penicillin injection 1 week later is recommended by some experts.

PENICILLIN ALLERGY Desensitize and treat with penicillin. Erythromycin's ability to cross the placenta is fair to poor. Infants born to mothers who received erythromycin for syphilis during pregnancy should be thoroughly evaluated for active disease, treated with penicillin, and closely followed. Tetracycline is avoided because of dental staining as a result of deposition in enamel.

EVALUATION DURING PREGNANCY Consider sonographic evaluation for signs of fetal syphilis (hepatomegaly, ascites, hydrops) or thickened placenta. If present, refer after initiating treatment to a high-risk obstetrician.

SCREENING Pregnant women should be screened at their initial prenatal visit, and those with seropositive results should be considered infected unless treatment can be verified and sequential serologic antibody titers convincingly demonstrate an appropriate response. In case of doubt, retreatment is warranted, as the potential benefits outweigh the possible risks. Screening should be repeated in the third trimester and again at delivery.

FOLLOW-UP Serologic titers should be repeated monthly in women at high risk of infection or in geographic areas with

high syphilis prevalences, or otherwise at 28 to 32 weeks of gestation, at delivery, and then according to the recommendations for the stage of infection.

COMPLICATIONS A potential adverse effect of penicillin treatment is the Jarisch-Herxheimer reaction, which may precipitate premature labor (placental shock). However, the association of spontaneous abortion with this phenomenon is debatable and should not delay treatment.

PROGNOSIS In 414 pregnant women with early syphilis who were treated with variable doses of penicillin, only 5 percent of their newborns had syphilis, and an expected rate of stillbirths was reported. The injected infants were born to women re-infected or treated late in pregnancy. In another study, the success of therapy in preventing congenital syphilis was also excellent: for mothers with primary syphilis, 27 of 27; secondary syphilis, 71 of 75; early latent syphilis, 100 of 102; and late latent syphilis, 136 of 136.[28]

Prenatal Syphilis[47]

NEONATAL PERIOD Aqueous penicillin G, 50,000 units/kg intravenously every 12 hours for the first 7 days of life and every 8 hours for the next 3 days, or procaine penicillin G, 50,000 units/kg intramuscularly daily for 10 to 14 days.

POSTNEONATAL PERIOD Benzathine penicillin G, 50,000 units/kg (up to 2.4 million units) intramuscularly if CSF examination is negative. If positive, aqueous penicillin G, 50,000 units/kg every 4 to 6 hours intravenously for 10 to 14 days.

PRESUMED CONGENITAL SYPHILIS Infants should be treated for presumed congenital syphilis regardless of evaluation if born to mothers with any of the following:

- Untreated syphilis at delivery
- Treatment other than with penicillin
- Treatment for syphilis within 1 month of delivery
- Inadequate documentation of appropriate treatment
- Serologic evidence of relapse or reinfection after treatment
- No documented fourfold decrease in RPR titers after treatment before or during pregnancy

If the infant has signs of congenital syphilis on physical examination or serologic evidence of syphilis (infant's RPR titer is two dilutions greater than mother's), the evaluation should include complete blood cell count with differential and platelets and CSF examination for cell count, protein, and RPR. Other tests that can be ordered as clinically indicated include long-bone radiographs, chest radiograph, cranial ultrasound, ophthalmologic examination, auditory–brainstem response, and liver function tests.

If the infant's clinical, CSF, serologic, and blood evaluation are normal and the mother's compliance with her prior treatment is indisputable, the infant may be treated with a single intramuscular injection of benzathine penicillin G, 50,000 units/kg.

If the mother was adequately treated and had an appropriate serologic decline in titers, evaluation of an infant with a nontreponemal titer equal to or less than the mother's titer is not necessary, but a single dose of benzathine penicillin is recommended. If the infant's titer is not reactive, no treatment is necessary.

FOLLOW-UP Seropositive infants (or infants born to mothers who were seroreactive at delivery) must be re-examined clinically and serologically every 2 to 3 months until the test becomes nonreactive or the titer has decreased fourfold. If the reactive test result was caused by passive transplacental transfer, nontreponemal antibody titers should decrease by 3 months and disappear by 6 months of age. If the child was infected and treated, the serologic decline may be slower. If the titers are stable or increasing after 8 to 12 months of age, the child should be re-evaluated (including CSF analysis) and retreated with a 10-day course of intramuscular penicillin G. Treponemal tests may remain positive for 15 months if the disease was acquired transplacentally, but if the tests are reactive after 18 months, they indicate congenital syphilis.

Close neurologic follow-up is indicated for infants with initially abnormal CSF examinations. If CSF pleocytosis was present, spinal taps should be done every 6 months until the cell count is normal. If the cell count remains abnormal after 2 years, or if a downward trend is not present at each examination, the infant should be retreated. The CSF VDRL should also be checked at 6 months, and retreatment administered if still reactive.

Treatment of Sex Partners and Persons Exposed to Syphilis

Examine the exposed person and do a serologic test. Treat the contact if there is clinical or serologic evidence of disease; treat prophylactically for primary syphilis if:

- The exposure occurred within 90 days preceding the sex partner's diagnosis of early (primary, secondary, or early latent) syphilis. For purposes of treatment, patients without clinical disease but serologic titers equal or greater than 1:32 are assumed to have early syphilis.
- The exposure occurred more than 90 days before the sex partner's diagnosis of primary, secondary, or early latent syphilis, but serologic tests are not immediately available, and reliability is uncertain.
- The evaluation of a long-term sex partner of a person with latent syphilis demonstrates possible transmission serologically or clinically.

Syphilis in Human Immunodeficiency Virus–Infected Patients

A penicillin regimen should be instituted according to the stage of the disease.

PENICILLIN ALLERGY Desensitize and treat.

CEREBROSPINAL FLUID EXAMINATION Spinal fluid analysis should be performed on patients with indeterminate or late latent disease or with early disease with neurologic symptoms. Some experts recommend CSF examination before treatment of early syphilis as well as 6 months after treatment, but there is no evidence of improved outcomes.

FOLLOW-UP A closer follow-up with clinical and serologic tests is needed for these patients. CSF examination is indicated if there is serologic evidence of treatment failure at any time, or if the serofast response continues after 12 months.

NEUROSYPHILIS Treat according to recommended regimens for neurosyphilis. Neurorelapse is more common in these patients, even after adequate treatment.

Complications of Treatment

The Jarisch-Herxheimer reaction is a clinical syndrome consisting of fever, headache, flare of mucocutaneous lesions, tender lymphadenopathy, pharyngitis, malaise, myalgias, and leukocytosis. It occurs within 12 hours of instituting therapy. The fever peaks in 6 to 8 hours usually around 39°C (102.2°F), but it can

be as high as 42°C (107.6°F). Patients should be warned about the possibility of developing this reaction before receiving treatment. Symptoms are controlled with nonsteroidal anti-inflammatory agents or aspirin. The pathogenesis of the Jarisch-Herxheimer reaction is unknown. It has been proposed that destruction of spirochetes is followed by massive phagocytosis with release of pyrogenic cytokines. Systemic glucocorticoids modify the febrile reaction without affecting the skin lesions or the leukocytosis, and suppress or mitigate the reaction if administered 12 hours before penicillin therapy.

Patients with neurosyphilis can become febrile after treatment with penicillin, especially when the CSF contains high numbers of cells and protein. Convulsions, dementia, psychosis, and meningismus have been reported to occur in up to 2 percent of neurosyphilis patients treated with penicillin. Death is very rare. About 50 percent of infants with early syphilis and 39 percent of those with late disease develop febrile reactions. Rare cases of elevated liver function tests and the nephrotic syndrome have been reported.

Therapeutic paradox, or deterioration of tertiary syphilis after therapy, results from rapid decomposition of gummatous tissue. Worsening of the aortic insufficiency murmur has been reported from this complication.

Hoigne syndrome (pseudoanaphylactic reaction) is a complication associated with intramuscular procaine penicillin treatment and is seen in approximately 1 case per 1000 treated patients. The reaction occurs immediately after the injection and is characterized by tachycardia, elevated blood pressure, fear of imminent death, violent combativeness, unusual taste sensation, auditory or visual disturbances, neuromuscular twitching, occasional seizures, and even loss of consciousness. It rarely lasts longer than 30 minutes. Treatment consists of observation and sedatives or anticonvulsants. Inadvertent intracapillary infusion of procaine or, less likely, penicillin during intramuscular injection resulting in microembolization has been proposed as the mechanism.

Anaphylaxis from administration of penicillin injection is a life-threatening emergency that is managed by intramuscular injection of epinephrine and diphenhydramine with hydrocortisone intravenously.[47]

Vaccines

There is no protective vaccine against syphilis, although efforts are under way to develop one. In one promising study, repeated immunization of rabbits with purified antiendoflagellar antigen over 32 weeks did not prevent re-infection, but the lesions occurred earlier, had a flatter, softer appearance, and resolved more rapidly.[51] Twelve surface proteins that may be suitable components for designing a vaccine were identified after mapping of the genome.[51]

The renowned physician William Osler who wrote, "Know syphilis in all its manifestations and relations, and all other things clinical will be added unto you." The mapping of the *T. pallidum* genome promises a better understanding of syphilis, development of new tests and treatments, and possibly a vaccine to prevent infection.

CHAPTER 201

Endemic (Non-Venereal) Treponematoses

Miguel R. Sanchez

Pinta, yaws, and endemic syphilis constitute a group of distinct spirochetal infections that are known as the *endemic non-venereal treponematoses*. These diseases have remained confined to foci in indigent, remote, rural areas within tropical and sub-tropical regions of selected countries.[1] As many as 2.5 million persons are believed to be infected.[1] However, a significant proportion of infected persons remain asymptomatic. The distinct causative spirochetes are so closely related that they cannot be distinguished histopathologically, immunologically, or serologically from *Treponema pallidum*. Like venereal syphilis, the diseases progress through successive clinical early (primary and secondary) and late stages usually separated by periods of latency.[1,2] Serologic tests for syphilis give reactive results in patients with endemic treponematosis. So far, no subspecies-specific monoclonal antibodies have been found.

In contrast to syphilis in other parts of the world, transmission occurs from skin-to-skin contact rather than sexual contact. Infants contract the infections from their mothers during breast-feed-

ENDEMIC TREPONEMATOSES

AT A GLANCE

- Non-venereal syphilis, pinta, and yaws are non-venereal infections acquired by skin-to-skin-contact.
- They are caused by *Treponema pallidum* or closely related treponemes.
- Like venereal syphilis, these infections are characterized by three successive stages separated by periods of latency.
- Penicillin or, alternatively, doxycycline is highly effective treatment for both the cutaneous and systemic lesions of endemic treponematosis.

ing, and children contract them from direct contact with mucocutaneous lesions of infected family members and playmates. The diseases are not transmitted transplacentally, however. *Hippelates pallipes*, the eye gnat, has been implicated in the transmission of yaws.[1]

Without treatment, patients remain potentially infectious indefinitely, although the skin lesions may become inconspicuous or sub-clinical. Patients do not develop lifelong immune resistance. Cross-immunity is absent in the early stages of endemic syphilis, yaws, and pinta but is variable in late stages. Notably, patients with late pinta are resistant to syphilis, but those with yaws or syphilis at any stage are susceptible to pinta. The level of cross-protection may be proportional to the severity of the initial infection.[1]

In areas of low incidence, health care providers with limited experience in recognizing these diseases frequently misdiagnose them as impetigo, psoriasis, mycobacterial infection, or tropical ulcer, among other diseases. Although the non-venereal treponematoses are not fatal, they are disfiguring and disabling, and patients experience discrimination and social ostracism.

PINTA (CARATE, MAL DE PINTA, AZUL)

Epidemiology and Etiology

Pinta ("colored spot" in Spanish) is caused by *T. carateum*, named after the Colombian word for the disease (*carate*). The organism can be propagated only in primates, and no isolates are known to exist.

The disease affects predominantly poor, undernourished infants, children, and adolescents who live in small, remote, crowded villages in hot, semiarid coastal areas. Twenty years ago, approximately 750,000 cases were estimated, but now only a few hundred new cases are reported each year, mainly in southern Mexico, Brazil, Colombia, Venezuela, Peru, and Ecuador.[1]

Transmission occurs from repeated, direct contact of the exposed skin of a healthy person with a cutaneous or mucous membrane lesion on an infected person.

Pinta is the only treponematosis with clinical manifestations confined to the skin.[1] As in syphilis, there are three distinct clinical stages. Lesions at different stages may be present in a single patient. Because cell-mediated immunity is not completely effective against the organism, the infection persists indefinitely, and people of all ages can be infected. However, half of all patients are younger than 15 years of age.

Primary Stage

After an incubation period of 15 to 30 days, one to three erythematous papules develop at the site(s) of inoculation. These primary lesions may be pruritic and over weeks to months enlarge or coalesce with other lesions to achieve a size of 1 to 3 cm. The resulting plaques are irregular, scaly, lichenified, and centrally paler, and can grow to a diameter of 20 cm (Fig. 201-1).[3] Over time, the centers become hypochromic, grayish, light blue, or pale mauve. Primary lesions usually develop in exposed areas, especially the hands, feet, arms, legs, face, and neck. They can persist for years and eventually heal spontaneously with residual dyspigmentation. Regional lymph nodes may become enlarged.

Secondary Stage

Secondary lesions (pintids) usually arise 1 to 12 months, but sometimes years, after the appearance of the primary lesions. They may encircle the sites of the primary lesions or erupt generally on the body. Pintids may occur on the palms, soles, and groin.[1] Secondary lesions may be indistinguishable from primary lesions but are smaller, usually asymptomatic, and psoriasiform. Some lesions may be circinate or annular with raised borders where the number of treponemes is highest. Gradually, the lesions turn brown or copper colored and eventually slate blue, gray, or black. More than one color may be present within a plaque. Lesions can occur up to 10 years after the initial infection.[3]

Tertiary Stage

Late lesions usually develop between 2 and 4 years after the onset of the disease and 3 months to 10 years after the appearance of the secondary-stage lesions. Typically, patients have dyschromic patches that are hyperchromic, hypochromic, and achromic, which impart a mottled pattern with a variegated palette of white, brown, blue, red, and violet.[4] The lesions have irregular borders and vary in size. The more commonly involved areas are the wrists, palms, ankles, and elbows as well as the skin around and within old lesions (Fig. 201-2). In such areas, the lesions appear

FIGURE 201-1 Lichenified patch in primary pinta with dyschromic changes.

▲ **FIGURE 201-2** Depigmented and hyperpigmented, mottled patches in late pinta.

scarred and atrophic (cicatricial lesions of pinta).[4] Lymphadenopathy may develop during any stage of pinta. Patients with only late-stage lesions may appear to have vitiligo (vitiligo of pinta).

Differential Diagnosis (Box 201-1)

YAWS (FRAMBOESIA TROPICA, PIAN, BUBA, PARU, PARANGI)

Epidemiology and Etiology

Yaws is caused by *T. pallidum* (subspecies *pertenue*). The spirochete can be propagated in laboratory animals, and various strains have been isolated for investigation.[1] Approximately 75 percent of new cases arise in children younger than 15 years of age.[5,6] Yaws is contracted from direct contact with abraded, bitten, or excoriated skin with oozing lesions. Some experts contend, with scant evidence, that the disease can be transmitted by flies or through domestic utensils.[7]

The infection occurs in countries along the tropical belt in lowlands characterized by heavy rainfall, high humidity, and persistently hot temperatures above 27°C (80.6°F).[6] Owing to mass treatment campaigns and improved living conditions, the disease has been eradicated in many areas, and greatly reduced in others.[5] However, yaws is underdiagnosed because fewer physicians have experience with the infection. Over the past three decades, due to relaxed surveillance and control measures and the persistence of poor sanitary conditions, a resurgence of yaws has been documented in regions of Africa and Southeast Asia. Sizable foci have been reported in several tropical regions of western and central Africa (Ghana, Togo, Benin, and the Central African Republic), and residual foci remain in South America (Colombia, Guyana, Peru, Ecuador, and Brazil), Haiti, Dominica, Southeast Asia, Indonesia, Papua New Guinea, and the Solomon Islands.[7] Currently, at least 100 million children are estimated to be at risk of becoming infected.[1] *T. pallidum pertenue* is nearly identical to the spirochete that causes infectious and endemic syphilis, so not surprisingly the diseases share many characteristics.

Box 201-1

Differential Diagnosis of Pinta

Most Likely
- Leukodermas
- Eczema (early lesions)

Consider
- Pityriasis alba
- Pellagra
- Tinea versicolor
- Melasma
- Lichen planus (early lesions)
- Tuberculoid leprosy (early lesions)
- Tinea corporis
- Psoriasis (early lesions)
- Lupus erythematosus (early lesions)
- Yaws (early lesions)
- Syphilis

Always Rule Out
- Vitiligo
- Erythema dyschromicum perstans

Primary Stage

After an incubation period of 10 to 90 days (average, 3 weeks), the primary lesion or mother yaw (buba madre) appears at the site of inoculation, which is usually an exposed body part, generally a lower extremity.[8] Characteristically, the lesion is a non-tender, often pruritic, infiltrated, erythematous small nodule that grows to a size of 1 to 5 cm. Its surface frequently becomes papillomatous and crusted. The primary lesion is usually single, but satellite papules may be present, becoming confluent into a plaque. The lesion eventually becomes an ulcer (chancre of yaws, frambesioma) with a raspberry-like base that may be covered by yellow crust (Fig. 201-3). Regional buboes (enlarged lymph nodes) are common.[1] The mother yaw heals spontaneously in 2 to 6 months, leaving atrophic scarring and central hypopigmentation. Constitutional symptoms are rare.

Secondary Stage

Resolution of the mother yaw is typically followed by a period of latency, which is then interrupted within 10 to 16 weeks, but possibly as long as 2 years, after the onset of the primary stage by an eruption of disseminated skin lesions with generalized lymphadenopathy. Constitutional symptoms such as malaise, fever, and anorexia are often present. The lesions (daughter yaws or pianomas) are reddish, weeping, warty or vegetating, crusted, non-pruritic papules and plaques that are similar to but smaller than (up to 2 cm) the mother yaw (Fig. 201-4A). As the lesions grow, they become eroded and covered by a highly infectious fibrinous exudate, which dries into a crust (see Fig. 201-4B, C). The exudate attracts flies that torture the affected persons.[8] Pianic onychia (paronychia) may develop.

Pianomas may appear in any body area. In addition, dry, papulosquamous patches and plaques (pianides) may be present on any part of the body.[8] In body folds (axillae, anal folds), they are

▲ **FIGURE 201-3** Ulcerated primary-stage nodule (mother yaw). The genital location is unusual.

▲ **FIGURE 201-4** **A.** Early secondary lesions of yaws (daughter yaws) appearing as eroded and crusted papules and plaques. **B.** Warty secondary-stage papillomas (daughter yaws). **C.** Eroded papillomas covered by fibrinous exudate. (**B** and **C** used with permission from H.J.H. Engelkens, MD, J. van der Stek, MD, and E. Stolz, MD.)

resemble condylomata lata; on mucous membranes, they are similar to hypertrophic mucous patches. It is interesting that widespread warty exudative lesions appear during humid times, but in arid, desert regions and during dry spells, the lesions favor or are limited to intertriginous areas and mucous membranes. In addition, a milder, attenuated, less florid form with small, dry, few (even single) lesions that are often limited to skin folds has been reported in areas with low or receding transmission rates. In some cases the lesions are papillomatous but resolve quickly.[1]

Thick, hyperkeratotic plaques of the palms and soles become fissured and ulcerated ("worm-eaten soles"). This painful involvement of the soles is also called *crab yaws* (Fig. 201-5) because patients walk with a deliberate slow, crustacean gait. Lesions may be annular or circinate (tinea yaws). Lesions on the face are often seborrheic or psoriasiform.[8] Painful osteoperiostitis is common in early yaws.[7] The appearance of turnip-like, fusiform soft-tissue swelling of the proximal, but not the distal, phalanges because of periostitis is classic ("ghoul hands"). The metatarsal, metacarpal, and tibial bones are also commonly involved.[8] Infected persons then enter a latent period with serologic reactivity but no signs or symptoms of the disease. All lesions resolve without scarring, but relapses may develop during the initial 5 years of infection. In relapsing yaws, lesions tend to be confined to the perioral, perianal, and periaxillary areas.

Tertiary Stage

In approximately 10 percent of cases, latency is interrupted after 5 to 10 years by a late stage with skin and skeletal lesions, and possibly with ophthalmologic and neurologic involvement. Cuta-

▲ **FIGURE 201-5** Fissured hyperkeratotic plantar keratoderma in secondary yaws (crab yaws).

neous and subcutaneous gummatous nodules (gumma framboesiodes) necrose centrally and ulcerate, causing deep, mutilating lesions.[7] Coalescence of the ulcers may produce circinate, serpiginous tracts that heal with deforming scars and contractures.[6] Palmoplantar hyperkeratosis may lead to chronic keratoderma. Juxta-articular lymphadenopathy may occur on the elbows and knees.

Late skeletal changes include hypertrophic periostitis, hydrarthrosis, gummatous osteitis and periostitis, and osteomyelitis. Considerable bone hypertrophy as a result of chronic osteitis may result in curvature of the tibia (saber shins). Bilateral hypertrophic osteitis of the nasal process of the maxillae with persistent swelling of the nasal bridge (goundou) slowly progresses over 5 to 20 years. The most dreaded consequence of yaws, which occurs in approximately 1 percent of untreated infected persons, is rhinopharyngitis mutilans (gangosa), or extensive destruction of the nose, maxillae, upper lip, and central face with eventual perforation of the nose and palate. Although ophthalmologic, neurologic, and cardiovascular disease is not usually associated with yaws, there are rare reports of optic disk atrophy, myeloneuropathy, and aneurysms.[1]

Differential Diagnosis (Box 201-2)

Box 201-2

Differential Diagnosis of Yaws

Most Likely

- Frambesiform leishmaniasis (pianomas, gangosa)
- Paracoccidiomycosis (pianomas)

Consider

- Psoriasis (pianides)
- Impetiginized eczema (pianides)
- Pyoderma vegetans (pianomas)
- Arthropod bites (pianides)
- Myiasis (pianides)
- Scabies (pianides)
- Dermatophytosis (pianides)
- Pyoderma (pianomas)
- Lupus vulgaris (gangosa)
- Atypical mycobacterial infection
- Deep fungus infection (pianotes, gangosa)
- Tuberculoid leprosy (pianides)
- Ecthyma (pianomas)
- Vitiligo (pintoids)
- Pinta (pintoids)
- Keratodermas

Always Rule Out

- Frambesiform syphilis (pianides, pianomas)

ENDEMIC SYPHILIS (BEJEL, FIRJAL, BELESH, NJOVERA)

Epidemiology and Etiology

Endemic syphilis is a non-venereal infection caused by *T. pallidum* (subspecies *endemicum*) that favors arid climates in rural areas bordering deserts. It has been reported to be a common health problem in children in Burkina Faso and the Bedouin tribes of Saudi Arabia, Iraq, and Syria. Foci also remain in Africa (Sudan, southern Zimbabwe, and South Africa), Southeast Asia, Turkey, and the western Pacific.[3] Approximately 80 percent of cases occur in children and adolescents younger than 15 years of age.[9] Transmission occurs through skin or mucous membranes contact with infected skin lesions or saliva, or by drinking from contaminated flasks or sharing pipes.[1] Anecdotal reports that the common fly, *Musca domestica*, is a disease vector have not been substantiated. The mucocutaneous lesions resemble those of venereal syphilis.

Primary Stage

The incubation period is 10 to 90 days. The primary lesion is an asymptomatic patch that becomes eroded. It is frequently missed, probably because the chancre is often present in the oropharyngeal mucosa. Because of the small inoculum, regional lymphadenopathy is rare. A primary chancre may develop on the nipple of a mother nursing an infected child. Primary lesions heal in 1 to 6 weeks.[3]

Secondary Stage

Usually a few non-tender, oval or round, macerated, eroded mucous patches erupt on the lips, tongue, and tonsils. Vegetating or hypertrophic condylomata lata appear on the anogenital area and the axillae.[5] Split papules are fissured mucous patches in the labial commissures. Occasionally, macular, papular, annular, and circinate eruptions, similar to those seen in secondary syphilis, develop. Non-tender, generalized lymphadenopathy is common. Nocturnal lower extremity pain is caused by periostitis of the long bones.

The secondary stage persists for 6 to 9 months and is followed by a latency period, which may continue for only a few months but usually lasts 5 to 15 years. At this point, a tertiary stage with cutaneous skeletal and systemic manifestations develops.[10]

▲ **FIGURE 201-6** Cutaneous gummas in late endemic syphilis. Note the involvement of the elbow.

Tertiary Stage

Late lesions consist of gummas of the skin, bone, nasopharynx, and larynx.[7] The gummas develop destructive ulcerations, but the lesions are not as mutilating as those of yaws (Fig. 201-6). Lesions eventually heal, leaving atrophic, depigmented scars bordered by hyperpigmentation. Saddle-nose deformity, palate perforation, and gangosa are disfiguring complications.[3]

Skeletal involvement is common, but most patients are not significantly bothered by pain. Clinically apparent tibial bowing and tenderness are exceptions. However, bone defects may be present on radiographs, most commonly in the tibia and fibula, and sometimes in the ulna and radius. Systemic involvement is rare. Uveitis, chorioretinitis, and optic atrophy have been observed. Aortitis and saccular aneurysms of the aortic arch have infrequently been reported.[3]

An attenuated form of endemic syphilis with fewer, more rapidly healing cutaneous lesions but more frequent periostitis has been reported.

Differential Diagnosis (Box 201-3)

DIAGNOSIS OF THE NON-VENEREAL TREPONEMATOSES

The diagnosis of the non-venereal treponematoses is made through clinical

Box 201-3

Differential Diagnosis of Endemic Syphilis

Most Likely

- Condylomata acuminata
- Molluscum contagiosum
- Oral herpes simplex
- Aphthous ulcers

- Lymphomas and sarcomas (gummas)
- Granulomatous diseases (gummas)

Always Rule Out

- Venereal syphilis

evaluation of the lesions (Table 201-1) in inhabitants or former residents of endemic areas and is confirmed by detection of treponemes under dark-field microscopic examination or with a direct fluorescent antibody test. In the absence of positive findings on dark-field examination, histologic or serologic confirmation is required. In yaws and endemic syphilis, nontreponemal tests yield reactive results in 2 to 3 weeks after the onset of the primary lesion. In pinta, these tests give reactive results in 80 percent of cases within 3 months after the appearance of primary lesions and in essentially all patients with the late stage of the disease. Treponemal tests are more specific for spirochetal infection and are used for confirmation of the diagnosis, and results will remain reactive after treatment when serologic titers of the nontreponemal tests fall. Other treponemal tests, including enzyme immunoassays, have not shown greater specificity than the fluorescent treponemal antibody absorption test but may be less expensive.[11] A finger-prick indirect hemagglutination test is advantageous for screening children.[12]

HISTOPATHOLOGIC FEATURES OF THE NON-VENEREAL TREPONEMATOSES

TREATMENT OF THE NON-VENEREAL TREPONEMATOSES

The recommended treatment for pinta, yaws, and endemic syphilis remains a single intramuscular injection of 1.2 million units of benzathine penicillin for adults or children older than 10 years of age and 0.6 million units for younger children.[7] Patients become non-infectious within 24 hours. Children older than 8 years of age who are allergic to penicillin may be treated for 15 days with tetracycline 250 mg four times daily, or, if younger, with erythromycin 8 mg/kg four times daily.[9] Penicillin-allergic adults are treated for 15 days with tetracycline 500 mg four times daily, doxycycline 100 mg twice daily, or erythromycin 500 mg four times daily. Other macrolide antibiotics are also probably effective, despite a dearth of reported experience. In pinta, primary and secondary lesions disappear after treatment, but achromic patches persist for life. Failure of penicillin therapy is exceedingly rare but has been reported in a few cases in Papua New Guinea, Colombia, and Ecuador.[1,14] Seven- to 10-day courses of oral penicillin, at a dose of 50 mg/kg per day in four divided doses up to 1200 mg daily, have provided good results in eradication campaigns. There is concern that such widespread use of penicillin may lead to resistance of other pathogenic bacteria such as streptococci. Concurrent infection with human immunodeficiency virus appears to exacerbate non-venereal treponematosis, and based on the experience with venereal syphilis, it appears prudent to screen persons at risk for human immunodeficiency virus infection and to consider closer follow-up. Recommendations for prophylactic treatment depend on the number of seropositive children younger than 6 years of age (Table 201-2).

EPIDEMIOLOGIC PERSPECTIVE

Eradication of the non-venereal treponematoses should be possible, but history has shown that mass treatment campaigns alone are insufficient.[15] In some areas where the diseases had been thought to be eradicated, new cases are now being reported at a surprising rate.[16] In 1997, the World Health Organization estimated the number of new cases of endemic treponematosis at 460,000 annually.[5] Treatment of those infected and

TABLE 201-1
Non-Venereal Treponematoses—Clinical Manifestations

	Pinta	Yaws	Endemic Syphilis
Causative organism	*Treponema carateum*	*T. pertenue*	*T. pallidum*
Transmission	Skin-to-skin contact	Skin-to-skin contact	Skin or mucosal contact with infected skin or saliva, drinking vessels
Peak ages	1–15 yr	1–15 yr	Months–15 yr
Incubation	15–30 days (average, 1–3 wk)	10–90 days (average, 3 wk)	10–90 days
Primary lesions	Erythematous papules become psoriasiform plaques	Vegetating, soft, ulcerating papule (mother yaws) with satellites	Small eroded papule (often absent)
Secondary lesions	Erythematous scaly and psoriasiform plaques (pintids); increased and decreased pigmentation	Warty or frambesiform nodules, papulosquamous plaques, palmoplantar plaques (crab yaws)	Mucous patches, condylomata lata, syphilis-like eruptions
Tertiary lesions	Dyschromic, hypochromic, achromic, and polychromic patches	Gummas, pintoid dyschromia, juxta-articular nodes, gangosa, goundou, keratoderma	Serpiginous gummas, juxta-articular nodes on elbows only
Reactive serologic test result	2–3 mo after primary lesion	2–3 wk after primary lesion	2–3 wk after primary lesion
Treatment	Penicillin	Penicillin	Penicillin

those at risk must be followed by such sound public health measures as prolonged serosurveillance and periodic screenings.[2,17] Follow-up should begin 6 months after initial treatment and should be repeated at least every 2 years. City dwellers are at lower risk, and the diseases are practically unknown in the West, where a single case usually stimulates a published case report.

CHAPTER 202

Chancroid

Stephan Lautenschlager

EPIDEMIOLOGY

Chancroid is most common in developing countries, especially in Africa and Asia, where the causative organism, *Haemophilus ducreyi*, was isolated from over 50 percent of genital ulcers in patients until the 1990s.[1–3] These endemic regions also have some of the highest rates of human immunodeficiency virus (HIV) infection in the world, and chancroid is common in all 18 countries in which adult HIV prevalence surpasses 8 percent.[4]

Recent epidemics in the industrialized countries have usually been associated with commercial sex work, the use of crack cocaine, syphilis, and an increased risk of HIV infection.[15,16] Lower-class prostitutes appear to be a reservoir in all reported outbreaks of this disease. Men have a markedly higher incidence of chancroid than women.[10] Several studies in Africa showed that chancroid ulcer is an important risk factor for the heterosexual spread of HIV-1.[17] It is still not clear whether there is an asymptomatic reservoir of *H. ducreyi* carriers and what the risks of transmission are.[18,19] The duration of infectivity in the absence of treatment was estimated to be 45 days for women. The transmission rate from females to males is not known, but a transmission rate from males to females of 70 percent per sex act has been reported.[20]

ETIOLOGY AND PATHOGENESIS

Historical Aspects

H. ducreyi is a Gram-negative, facultative anaerobic coccobacillus that requires hemin (X factor) for growth. The organism is small, nonmotile, and non–spore-forming and shows typically streptobacillary chaining, especially in cultures. The exact taxonomy is still controversial. The current classifications list *H. ducreyi* as a true *Haemophilus* sp. However, studies of DNA homology and chemotaxonomy demonstrate substantial differences between *H. ducreyi* and *Haemophilus* sp. *H. ducreyi* will likely be reclassified in the future, but this issue awaits further studies.[24,25]

Biochemistry

Growth Requirements

Genetics and Virulence

Three major factors seem to be important in the pathogenesis of *H. ducreyi* infection: the adherence to the epithelial surface, the rate of production of exotoxins (e.g., cytolethal distending toxin),[30] and the resistance of the host defense mechanism. Many details about pathogenesis are still unclear. Because of the lack of appropriate experimental model systems, attachment factors, in particular, are not well understood.[31]

CLINICAL FINDINGS

The incubation period is between 3 and 7 days, rarely more than 10 days. No prodromal symptoms are known. The chancre begins as a soft papule surrounded by erythema. After 24 to 48 hours it becomes pustular, eroded, and ulcerated (Fig. 202-1). Vesicles are not seen. The edges of the ulcers are often ragged and undermined (see eFig. 202-1.1 in on-line edition). The ulcer is usually covered by a necrotic yellowish gray exudate (Fig. 202-2), and its ground is composed of granulation tissue that

CHANCROID AT A GLANCE

- A sexually transmitted acute ulcerative disease.
- Usually localized to the anogenital area and often associated with inguinal adenitis or bubo.
- *Haemophilus ducreyi*, a Gram-negative, facultative anaerobic coccobacillus, is the causative agent.
- Chancre is common in many developing countries (Africa, the Caribbean, and Southwest Asia) but rare in the United States and Europe.
- Painful soft ulcers with ragged undermined margins develop 1 to 2 weeks after inoculation.
- Chancroid facilitates the transmission of human immunodeficiency virus.
- Azithromycin and ceftriaxone are recommended as a single-dose treatment.

▲ **FIGURE 202-1** Early, sharply circumscribed ulcer in the sulcus coronarius.

▲ **FIGURE 202-2** Enlarging chancroid with gray exudate, which has destroyed the frenulum (kissing ulcer).

▲ **FIGURE 202-3** Vulvar chancroid with undermined edges.

bleeds readily on manipulation. In contrast to those of syphilis, chancroid ulcers are usually tender, not indurated (soft chancre), and painful. The diameter varies from 1 mm to 2 cm. Half of males have a single ulcer, and most lesions are found on the external or internal surface of the prepuce, on the frenulum, and on the glans (see eFig. 202-2.1 in on-line edition). The meatus and shaft of the penis and the anus are involved less frequently. Edema of the prepuce is often seen. Rarely, if the chancre is localized in the urethra *H. ducreyi* causes purulent urethritis.[32]

In females the lesions are mostly localized on the vulva (Fig. 202-3), especially on the fourchette, the labia minora, and the vestibule. Vaginal, cervical, and perianal ulcers have also been described. Extragenital lesions of chancroid have been reported on the breasts, fingers, thighs, and inside of the mouth. Trauma and abrasion may be important for such extragenital manifestations.

Painful inguinal adenitis (bubo) occurs in up to 50 percent of patients within a few days to 2 weeks (average, 1 week) after onset of the primary lesion (see eFig. 202-3.1 in on-line edition). The adenitis is unilateral in most patients, and erythema of the overlying skin is typical. Buboes can become fluctuant and may rupture spontaneously. The pus of a bubo is usually thick and creamy. Buboes are less common in female patients. In addition to the common types of chancroid described thus far, a number of clinical variants have been reported (Table 202-1). Mild systemic symptoms can accompany chancroid in rare cases, but systemic infection by *H. ducreyi* has never been observed. Recently chronic skin infection due to *H. ducreyi* was reported, affecting the lower limb of children visiting Samoa,[33] suggesting that this may be a previously unrecognized form of infection.

LABORATORY TESTS

Bacterial culture of *H. ducreyi* currently remains the primary tool for the diagnosis of chancroid in the clinical setting. However, the advent of more sensitive DNA amplification techniques has demonstrated that the sensitivity of *H. ducreyi* culture is only 75 percent at best.[34–36] The bacillus will survive only 2 to 4 hours on a swab unless refrigerated. Swabbed material from the purulent ulcer base should be inoculated directly onto an appropriate culture medium, because no satisfactory transport system is available.[37]

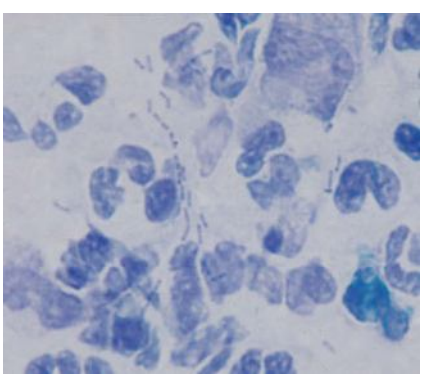
As noted earlier (see Growth Requirements), the simultaneous use of two primary isolation media from a nutritionally rich agar base supplemented with hemoglobin and serum is recommended for high culture sensitivity.[27] Small, nonmucoid, yellow-gray, translucent colonies appear in 2 to 4 days after inoculation. Typically, these colonies remain intact when they are pushed across the agar surface. The identification of *H. ducreyi* is performed following the recommendations of Lubwama[38]: demonstration of hemin requirement, oxidase and catalase test, β-lactamase test, and hydrogen sulfide and indole activity. Testing of antibiotic susceptibility is recommended, because clinically significant antimicrobial resistance of *H. ducreyi* has become common.

Direct examination of clinical material by Gram or Giemsa stain may be helpful, but reported sensitivity and specificity values are low—10 percent to 63 percent and 51 percent to 99 percent, respectively.[39] The bacilli are usually found in small clusters or parallel chains of two or three organisms streaming along strands of mucus. This pattern has been described as a "school of fish" or "railroad track" (Fig. 202-4). This arrangement, said to be characteristic of *H. ducreyi*, is nevertheless not pathognomonic, because most genital ulcers have a polymicrobial flora. Cotton or calcium-alginate swabs are recommended for specimen collection. Some authors do not recommend direct microscopy in the routine diagnosis of chancroid.[21,36,39]

Many attempts have been made to develop serologic tests for chancroid. Due to limited sensitivity in the detection of circulating antibodies to *H. du-*

TABLE 202-1
Clinical Variants of Chancroid

Giant chancroid	Single lesion extends peripherally and shows extensive ulceration.
Large serpiginous ulcer	Lesions become confluent, spreading by extension and autoinoculation. The groin or thigh may be involved (ulcus molle serpiginosum).
Phagedenic chancroid	Variant caused by superinfection with fusospirochetes. Rapid and profound destruction of tissue can occur (ulcus molle gangrenosum).
Transient chancroid	Small ulcer resolves spontaneously in a few days, may be followed 2–3 wk later by acute regional lymphadenitis (French: *chancre mou volant*).
Follicular chancroid	Multiple small ulcers occur in a follicular distribution.
Papular chancroid	Granulomatous ulcerated papule may resemble that of donovanosis or condylomata lata (ulcus molle elevatum).



▲ **FIGURE 202-4** Smear from soft ulcer showing a "school of fish" pattern (Giemsa stain).

Box 202-1

Differential Diagnosis of Chancroid

	DISEASE/CONDITION	ETIOLOGIC AGENT
Most Likely	Genital herpes	Herpes simplex virus types 1 and 2
	Syphilis	*Treponema pallidum*
	Lymphogranuloma venereum	*Chlamydia trachomatis* serovars L1–L3
Consider	Other bacterial sexually transmitted infection: granuloma inguinale (donovanosis)	*Calymmatobacterium granulomatis*
	Other bacterial infections	*Streptococcus* sp., fusospirillary infections, *Mycobacterium tuberculosis*, *Corynebacterium diphtheriae* (very rare)
	Viral infections	
	Acute HIV infection	HIV
	Ulcus vulvae acutum	Epstein-Barr virus
		Cytomegalovirus
	Genital herpes zoster	Varicella-zoster virus
	Parasitic infections	
	Amebiasis	*Entamoeba histolytica*
	Leishmaniasis	*Leishmania* sp.
	Scabies	*Sarcoptes scabiei*
	Inflammatory diseases (e.g., Behçet disease, aphthosis, Crohn disease, pyoderma gangrenosum)	
	Drug adverse effects	
	Fixed drug eruption	For example, trimethoprim-sulfamethoxazole
	Toxic effects	For example, foscarnet
	Traumatic and self-induced genital ulcers and neoplasms	
Always Rule Out	Genital herpes	Herpes simplex virus types 1 and 2
	Syphilis	*T. pallidum*
	HIV infection	HIV

HIV = human immunodeficiency virus.

creyi, serologic testing currently has limited usefulness in the routine diagnosis of chancroid infection but may be useful in population-based epidemiologic research as a method of screening for past infection.[39,40]

Polymerase chain reaction (PCR) procedures using different primers have shown greater sensitivity for the diagnosis of chancroid than bacterial culture.[39] A multiplex PCR assay has been developed (Roche Molecular Systems, Alameda, CA) for the simultaneous amplification of DNA targets from *H. ducreyi*, *Treponema pallidum*, and herpes simplex types 1 and 2,[41] which seems to be a particularly attractive diagnostic tool in the investigation of genital ulcers in patients. Multiplex PCR has a resolved sensitivity and specificity for *H. ducreyi* of 98.4 percent and 99.6 percent, respectively.[41] None of these PCR-based methods is commercially available yet, but their use for routine diagnostic purposes would be clearly advantageous.

In resource-poor settings in which diagnostic facilities are not readily available, the World Health Organization advocates the use of a syndromic management approach for patients with genital ulcer disease.[42]

HISTOLOGY

Characteristic histologic features with three vertically arranged zones (superficial necrotic zone, a zone of new blood vessel formation beneath, and a deep zone consisting of dense lymphocytic and plasma cell infiltrate) have been described in chancroid.[43] Tissue biopsy is not a recommended diagnostic method, but histologic examination may be useful to exclude malignancy in non-healing or atypical ulcers.[39] Staining with *H. ducreyi*-specific monoclonal antibodies demonstrates the organisms chiefly within the granulocytic infiltrate and fibrin of the ulcer.[44]

DIFFERENTIAL DIAGNOSIS (Box 202-1)

The three classic causative agents for genital ulceration are *H. ducreyi*, *T. pallidum*, and herpes simplex. The clinical appearance of the diseases caused by these three agents can be extremely variable in both men and women, and therefore clinical diagnosis of genital ulcer disease can be made with reasonable certainty for only a minority of patients.[45] The cause of genital ulcers[46] also differs considerably by geographic region. In industrialized countries isolated painful chancres are most likely due to herpes simplex virus.[47] In a high percentage of genital ulcers no pathogen can be isolated, but co-infections of *H. ducreyi* with *T. pallidum* (ulcus mixtum) or herpes simplex virus are not uncommon.[5,8]

COURSE AND PROGNOSIS

The disease is self-limited, and systemic spread does not occur. Occasionally, without treatment, genital ulcer and inguinal abscess have been reported to persist for years. Local pain is the most frequent complaint. If no clinical improvement is evident 1 week after the start of therapy, incorrect diagnosis, co-infection with another organism, concomitant HIV infection, poor compliance with the therapy regimen, or a resistant strain of *H. ducreyi* must be considered.

Infection does not confer immunity, and re-infection is possible. To avoid re-infection, patients must be instructed to use condoms properly.

TABLE 202-2
Complications of Chancroid

- Painful inguinal adenitis (up to 50% of cases)[61]
- Spontaneous ruptures of inguinal buboes with occurrence of large abscesses and fistula formation (rare)
- Spreading of *Haemophilus ducreyi* to distant sites (kissing ulcers and/or extragenital lesions due to autoinoculation) (in 50% of male patients)
- Acute conjunctivitis (very rare)[62]
- Bacterial superinfection (including by anaerobes) leading to extensive destruction (rare)
- Scarring leading to phimosis (rare)
- Erythema nodosum (very rare)[63]
- Enhanced transmission of human immunodeficiency virus (3-fold to 10-fold increased risk)

TABLE 202-3
Recommended Treatment Regimens

Antibiotic	Dosage	Limitations	Source of Recommendation
Azithromycin	1 g orally in a single dose	High cost, limited availability, contraindicated in pregnancy	CDC, WHO, IUSTI-Europe
or			
Ceftriaxone	250 mg intramuscularly in a single dose	Parenteral dosing, may perform less well in HIV-positive patients	CDC, IUSTI-Europe (WHO, as alternative)
or			
Ciprofloxacin	500 mg orally bid for 3 days	High cost, compliance problems, contraindicated in pregnancy	CDC, WHO, IUSTI-Europe
or			
Erythromycin base	500 mg orally qds for 7 days	Compliance problems, gastrointestinal intolerance	CDC, WHO, IUSTI-Europe

CDC = Centers for Disease Control and Prevention; HIV = human immunodeficiency virus; IUSTI-Europe = European Branch of the International Union against Sexually Transmitted Infection; WHO = World Health Organization.

COMPLICATIONS

In about half of untreated patients, the course is that of spontaneous resolution without complications. When treatment is delayed, various complications may occur (Table 202-2).

TREATMENT

Based on in vitro susceptibility the most active drugs against *H. ducreyi* are azithromycin, ceftriaxone, ciprofloxacin, and erythromycin. Worldwide, several isolates with intermediate resistance to either ciprofloxacin or erythromycin have been reported. Regimens actually recommended by the Centers for Disease Control and Prevention, the World Health Organization, and the European Branch of the International Union against Sexually Transmitted Infection are listed in Table 202-3.[39,49,50] Antibiotic combinations (e.g., ceftriaxone and streptomycin) showed synergy in an animal model and may be promising to improve single-dose treatment, but clinical evaluation is needed.[51] Local treatment consists of application of antiseptic dressings (i.e., povidone-iodine). Suppurative nodes should not be incised; if necessary, they can be punctured to prevent spontaneous rupture and sinus tract formation. A large syringe should be used and the fluctuant buboes entered laterally through normal skin. In patients with complicating phimosis a circumcision may be necessary when all active lesions have healed.

Even after correct treatment ulcers recur in approximately 5 percent of patients, and retreatment with the original regimen is recommended. Usually reinfection by an untreated sexual partner is the cause of relapse.

HIV infection and lack of circumcision appear to be associated with increased likelihood of infection with *H. ducreyi* and treatment failure.[52] In resource-poor areas of the world, syndromic management can be recommended, but local epidemiology must be considered.[36,42] Flowcharts for the management of genital ulcers have been developed that do not require laboratory identification of the causative pathogen.[36] If a patient complains of one or more small blisters or an ulcer with a history of recent blisters, then herpes management should be followed. If an isolated small ulcer and painful matted lymphadenopathy is present, treatment for lymphogranuloma venereum, chancroid, and syphilis should be initiated. If only an ulcer is present, treatment should be for syphilis and chancroid.[36]

RELATIONSHIP BETWEEN HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND CHANCROID

Renewed interest in chancroid has led to evidence that genital ulcers promote the heterosexual transmission of HIV-1.[53–57] Effective treatment of genital ulcers can thus reduce the incidence of HIV-1, and this strategy has become a cornerstone of HIV prevention programs in many parts of the world.[58] Patients with chancroid should be tested for HIV.

PREVENTION

The exacerbation of the HIV epidemic by *H. ducreyi* infection has made chancroid control an urgent priority. Patients should be advised to abstain from sexual activity until all clinical lesions have cleared. Sexual contacts of the patient should be examined and treated regardless of whether symptoms of the disease are present, because asymptomatic carriage of *H. ducreyi* is possible.[18] Antibiotic therapy may provide some protection from re-infection, because the effects of a single dose of azithromycin may last as long as 2 months after treatment.[59] Chancroid survives in populations in which many men are having sex with a few women. As a result of increased condom use and social programs such as presumptive treatment plans, the cases of chancroid in Kenya have decreased dramatically to less than 10 percent of genital ulcers seen in Nairobi.[4] In Thailand a decrease of 95 percent (from 30,000 to fewer than 2000 cases) was achieved in the 1990s.[4,60] Based on these results, eradication of chancroid seems to be a feasible public health objective.[4]

CHAPTER 203

Lymphogranuloma Venereum

Samer H. Ghosn
Amal K. Kurban

EPIDEMIOLOGY

Lymphogranuloma venereum (LGV) is a rare sexually transmitted disease due to specific *Chlamydia* variants. It is endemic in East and West Africa, India, Southeast Asia, South and Central America, and some Caribbean islands; and accounts for 2 percent to 10 percent of genital ulcer diseases in areas of Africa and India.[1,2] The peak incidence occurs in persons 15 to 40 years old, in urban areas, and in individuals of lower socioeconomic status. Men are six times more likely than women to manifest clinical infection. The incidence of LGV is low in the developed world where cases are usually limited to travelers or military personnel returning from endemic areas. Since 2003, however, outbreaks of LGV have appeared in Europe and North America, particularly in the form of proctitis, among human immunodeficiency virus (HIV)–positive men who have sex with men.[3–10]

LGV is contracted by direct contact with infectious secretions. Transmission efficiency is unknown. Conjugal transmission has been reported.[11,12] Sexual practices such as fisting and sex-toys-sharing may be other routes of transmission.[3] An epidemic of LGV has been reported recently among "crack" cocaine users in the Bahamas.[13]

Due to underdiagnosis and underreporting, the epidemiology of LGV remains poorly understood. Common diagnostic laboratory methods are nonspecific and not readily available in endemic areas. Even in industrialized countries, only a few laboratories offer specific assays to LGV serovars. Without such assays, many LGV cases are misdiagnosed as common chlamydial urogenital infection. Underdiagnosis of LGV is also largely due to the presence of an asymptomatic carrier state.[14] Women, in particular, may harbor asymptomatic persistent infection in the cervical epithelium, thus serving as reservoirs of the infection as they do for other urogenital chlamydial infections and gonorrhea. In contrast, infectivity in men ceases after healing of the primary mucosal lesion. Interestingly, most of the detected cases in the recent outbreaks are in men who practice receptive anal sex, suggesting that a high proportion of men who practice insertive anal sex are mis- or undiagnosed. The reasons behind this are unclear but may be organism-related, host-related (sexual practices such as fisting and the use of sex toys, intravenous drug use, HIV-status, etc.) or physician-related (failure to diagnose genital LGV). The resurgence of LGV as a health problem may simply reflect increased awareness rather than increased incidence.

ETIOLOGY AND PATHOGENESIS

LGV (tropical or climatic bubo, lymphopathia venerea, Nicolas-Favre disease) is caused by *C. trachomatis* serovars L1, L2, and L3. Most of the recent outbreaks are caused by a number of strains of *C. trachomatis* L2 serovar (L2b), suggesting that these outbreaks most likely represent increased awareness of a slowly evolving endemic.[7,8,14–16]

Chlamydiae are obligate intracellular bacteria characterized by two distinct morphologic forms: the small metabolically inactive and infectious elementary body, and the larger metabolically active and non-infectious reticulate body. In contrast to the A-K serovars that remain confined to the mucosa, LGV serovars have a high affinity for macrophages. After being inoculated onto the mucosal surface, the organisms replicate within macrophages, and find their way to the draining lymph nodes (LNs), and cause lymphadenitis. Entry of the LGV strains into host cells involves cholesterol-rich membrane domains.[17] Infection with serovar L2 has been shown to cause caspase-independent apoptosis of host cells.[18] Variable expression of members of the polymorphic membrane protein genes (pmpA to pmpI) has been suggested to play a role in the pathogenesis.[19]

CLINICAL FINDINGS

Cutaneous Lesions and Related Physical Findings

Clinical manifestations are protean, depending on the sex of the patient, acquisition mode, and the disease stage.

PRIMARY STAGE Three to 30 days after infection, 5- to 8-mm painless erythematous papule(s) or small herpetiform ulcers appear at the site of inoculation

LYMPHOGRANULOMA VENEREUM AT A GLANCE

- Rare systemic sexually transmitted disease caused by L serovars of *Chlamydia trachomatis*
- Endemic in Africa, Southeast Asia, and South and Central America
- Outbreaks among men who have sex with men in Europe and North America
- Clinically manifest as inguinal and anorectal syndromes, in three stages
- Hematogenous spread with manifestations of systemic infection
- Diagnosis by identification of organism and by serology or genotyping
- Doxycycline or erythromycin treatment curative if given early

(Fig. 203-1). Painful ulcerations[20] and non-specific urethritis[21] are less common. In males, the lesion is usually found on the coronal sulcus, prepuce, or glans penis; and in females on the pos-

▲ **FIGURE 203-1** Lymphogranuloma venereum: Soft painless erosion on the prepuce.

terior wall of the vagina, vulva, or, occasionally, the cervix. Inoculation may also be rectal or pharyngeal. The primary lesion is transient, often heals within a few days, and may go unnoticed. Other cutaneous manifestations include erythema nodosum, erythema multiforme, urticaria, and scarlatiniform exanthem.[22,23]

SECONDARY STAGE A few weeks after the primary lesion appears, marked LN involvement and hematogenous dissemination occur, manifest by variable signs and symptoms, including fever, myalgia, decreased appetite, and vomiting. Photosensitivity may develop in up to 35 percent of the cases, often 1 to 2 months after bubo formation.[24] Less commonly, patients may develop meningoencephalitis, hepatosplenomegaly, arthralgia, and iritis.[25,26] The lymphadenitis episodes often resolve spontaneously in 8 to 12 weeks. Depending on the mode of transmission, two major syndromes are distinguished:

The acute genital syndrome (GS) or inguinal syndrome is characterized by inguinal and/or femoral LN involvement and is the major presentation in men. Initially, the skin overlying the affected LN is erythematous and indurated. Over the subsequent 1 to 2 weeks, the LN enlarge and coalesce to form a firm and tender immovable mass (bubo; Fig. 203-2), which may rupture and drain through the skin, forming sinus tracts. Bilateral involvement occurs in one-third of the cases (Fig. 203-3). Nodal enlargement on either side of the inguinal ligament, the "groove sign," is pathognomonic of LGV, but only present in 10 percent to 20 percent of cases,[27] and is rarely bilateral.[28] In women, inguinal lymphadenitis is unusual because the lymphatic drainage of the vagina and cervix is to the deep pelvic/retroperitoneal LN. When these nodes are involved, low abdominal/back pain that exacerbates upon lying supine and pelvic adhesions may ensue.

The acute anorectal syndrome (ArS) is characterized by peri-rectal nodal involvement, acute hemorrhagic proctitis, and pronounced systemic symptoms. It is the most common presentation in women and in homosexual men who practice anal sex. The major source of rectal spread in women is the internal lymphatic drainage of the lower two-thirds of the vagina. Patients may complain of anal pruritus, bloody rectal discharge, tenesmus, diarrhea, constipation and lower abdominal pain.

▲ **FIGURE 203-2** Early bubo consisting of unilateral enlargement and coalescence of inguinal lymph nodes. The overlying skin is erythematous and indurated. Note the absence of the primary lesion in this case. (Used with permission from Shukrallah Zeynoun, MD.)

TERTIARY STAGE This stage is more seen in women with untreated ArS, and includes rectal strictures (most common) and abscesses, perineal sinuses, rectovaginal fistulae (leading to "watering can perineum"), and "lymphorrhoids" (perianal outgrowths of lymphatic tissue). Late sequelae of the GS are less common and include urethral strictures and genital elephantiasis with ulcers and fistulas (in 4 percent of cases).[29] Esthiomene (Greek, "eating away") is a rare primary infection of the external genitalia (mostly in women), leading to progressive lymphangitis and genital destruction. Infertility and "frozen pelvis" are potential sequelae of ruptured deep pelvic nodes in women.

Other Unusual Manifestations

Extragenito-anal inoculation of LGV is rare. Oropharyngeal infection may manifest initially as pinhead-sized vesicles on the lip, and later on as cervical lymphadenopathy with constitutional symptoms, closely mimicking lymphoma. Supraclavicular and mediastinal lymphadenopathy and pericarditis rarely occur.[30–33] Ocular autoinoculation of infected discharges may lead to conjunctivitis with marginal corneal perforation, often with preauricular lymphadenopathy.[34] Inhalation of LGV serovars L1 and L2 may accidentally occur in laboratory workers and lead to pneumonitis with mediastinal and supraclavicular lymphadenopathy.[35]

LABORATORY TESTS

Diagnosis of LGV may be difficult, but LGV should be suspected in any patient with infected sexual contacts, genital ulcer, perianal fistula, or bubo. The accuracy of clinical diagnosis may, however, be as low as 20 percent.[36] Laboratory tests are important to establish the diagnosis and are usually divided into two broad categories: non-specific tests that do not distinguish between LGV and non-LGV serovars, and specific LGV tests. In practice, positive test on LN aspirate is considered diagnostic of LGV, in contrast to a positive test on primary genital lesion where further specific testing is required to rule out common chlamydial urogenital infections.

Non-Specific Chlamydial Tests

Frei test, an intradermal skin test assessing delayed hypersensitivity to chlamydial antigens, lacks sensitivity and specificity and is no longer used.

▲ **FIGURE 203-3** Lymphogranuloma venereum: Bilateral, firm, immovable masses above Poupart's ligament.

Serology assays are sensitive but non-specific due to cross-reactivity with other chlamydial infections. In addition, they do not differentiate current from prior infection. The complement fixation test is most commonly used. Titers greater than 1:256 are highly suggestive of LGV and titers below 1:32 exclude the diagnosis unless the disease is in its early stages.[37] The microimmunofluorescence test is more specific but less readily available. Commercially available enzyme immunoassays lack data regarding their sensitivity and specificity for LGV serovars.[38]

Culture studies do not distinguish between LGV and non-LGV serovars; however, a positive culture without centrifugation is highly suggestive of LGV.

Direct fluorescent microscopy uses conjugated monoclonal antibody against *C. trachomatis* on smears from bubo material or genital swab.[39]

Nucleic acid amplification testing (including polymerase chain reaction) may be performed on almost all specimens; however, its sensitivity and specificity in detecting LGV serovars remain unknown.

Specific Tests for Lymphogranuloma Venereum

Only the Centers for Disease Control and Prevention and a few U.S. laboratories have the capacity to sequence DNA to identify L serovars.[7] Recently, a technique combining polymerase chain reaction and restriction fragment length polymorphism has been reported to have adequate specificity in identifying LGV serovars.[20] Other newly introduced biomolecular techniques exploring immune-mediated lysis,[21] heparin sulfate lysis,[40,41] use of pooled antibody,[15] and structural genetic differences[42] are promising.

Other Non-Specific Laboratory Findings

Mild leukocytosis, false-positive VDRL, cryoprecipitins, rheumatoid factor, and high serum levels of immunoglobulin A and immunoglobulin G may be present.[43]

DIAGNOSTIC PROCEDURES

Bubo aspiration to obtain material for culture and direct microscopy should be performed through a lateral approach, and may require injection of 2 to 5 mL of sterile saline before the aspiration due to the paucity of milky fluid.[39] Proctoscopic examination reveals, in the setting of the ArS, multiple discrete and irregular superficial ulcerations and friable granulation tissue, usually confined to the distal 10 cm of the anorectal canal.[44,45]

HISTOPATHOLOGIC EXAMINATION

Primary lesions reveal non-specific ulceration with granulation tissue, and endothelial swelling. Organisms are rarely demonstrated using Giemsa stain. Biopsy of affected LN reveals suppurative granulomatous inflammation. Necrotic foci may enlarge into stellate abscesses which, in turn, may coalesce into discharging sinuses. These findings are not specific to LGV and can be found in chancroid, cat-scratch disease, and tularemia, and in some deep fungal infections. The pathology of LGV-proctocolitis is similar to that of Crohn disease and includes crypt distortion, submucosal fibrosis, and follicular inflammation with occasional granuloma formation.[44]

DIFFERENTIAL DIAGNOSIS (Box 203-1)

In contrast to LGV primary stage, chancroid ulcers are usually larger and more painful, and granuloma inguinale ulcers have abundant friable granulation tissue without associated lymphadenitis. Acute GS may be hard to differentiate from chancroid. Buboes containing little or no pus are, however, more likely to be caused by LGV.[39] Suspecting LGV proctitis in HIV-positive men who have had sex with men with signs and symptoms of Crohn disease is important, even in the absence of LGV pathognomonic findings. Both conditions have similar proctoscopic findings; however, Crohn disease is more proximally localized.

COMPLICATIONS

In addition to the complications seen in the tertiary stage, the ulcerative nature of LGV may facilitate the acquisition and transmission of blood-borne pathogens such as HIV.[48] LGV may also lead to immune disturbances ranging from mild gammaglobulinemia to rare but fatal immunoblastic lymphoma.[49]

PROGNOSIS AND CLINICAL COURSE

Antibiotic treatment, if given early, is curative, with the acute ArS responding more dramatically than the acute GS.

Box 203-1

Differential Diagnosis of Lymphogranuloma Venereum (Stage-Specific)

- Primary stage
  - Ulcerogenital diseases (herpes simplex virus, chancre, chancroid, granuloma inguinale)
  - *Neisseria gonorrhoeae* and/or common chlamydial urogenital infection
  - Non-infectious causes: Trauma, Zoon balanitis, fixed drug eruption
- Secondary stage
  - Acute genital syndrome
    - Ulcerogenital diseases with lymphadenopathy (syphilis, chancroid, herpes simplex virus)
    - Incarcerated inguinal hernia
    - Reactive inguinal lymphadenitis to a lower extremity focus of infection
    - Bubonic plague (in endemic areas)
    - Acquired immunodeficiency syndrome[46]
    - Kaposi sarcoma[47]
  - Acute anorectal syndrome
  - Inflammatory bowel disease
  - Oropharyngeal lymphogranuloma venereum
    - Lymphoma
    - Infectious mononucleosis
    - Cat-scratch disease
- Tertiary stage
  - Malignancy
  - Filariasis and other parasitic infections
  - Pseudoelephantiasis (no lymphadenitis) of tuberculosis and granuloma inguinale
  - Deep fungal infection
  - Hidradenitis suppurativa
  - Trauma

TREATMENT

Oral doxycycline, 100 mg twice daily for 3 weeks, is the treatment of choice. When contraindicated, oral erythromycin base, at a dose of 500 mg four times a day for 3 weeks, may be given. Treatment with azithromycin (1 g once weekly for 3 weeks or in a single dose[50]) is likely curative but still lacks data regarding its efficacy and safety in pregnancy. Therapy may be prolonged in HIV-positive patients and, in general, should not be stopped until the complete resolution of all signs and symptoms (Box 203-2).

Surgery is often required in late stages and includes lateral aspiration of buboes through intact skin (direct incision has a high risk of fistula formation), rectal stricture dilatation, abscess drainage, rectovaginal fistula repair, genital reconstruction, and colostomy. Avoidance of

Box 203-2

Treatment of Lymphogranuloma Venereum

First line	Oral doxycycline	100 mg bid	3 wk
Second line	Oral erythromycin	500 mg qid	3 wk
Third line	Oral azithromycin	1 g/once weekly	3 wk

sexual activity until complete resolution of signs and symptoms is important.[51]

PREVENTION

Effective control should include periodic evaluation of high-risk individuals; reinforcement of health education aiming at early recognition, and counseling; improving community and clinician awareness of LGV; and increasing the availability of specific diagnostic tests. All sexual contacts should be traced and treated. LGV case reporting should be mandatory by law for more reliable monitoring of prevalence trends.[7]

CHAPTER 204

Granuloma Inguinale

Abdul-Ghani Kibbi
Myrna El-Shareef

EPIDEMIOLOGY AND MODE OF TRANSMISSION

The mode of transmission of granuloma inguinale (GI) is controversial. It is generally considered sexually transmitted, but fecal contamination and autoinoculation remain a possibility, especially in the setting of infected children and adults without sexual activity and primary involvement of remote extragenital sites.[1,2] Transmission rate between sexual partners is low compared with other sexually transmitted diseases and was found to be not more than 50 percent. The incidence of GI is also relatively low among both prostitutes and their conjugal partners. Nevertheless, this disease predominantly affects sexually active individuals.[3] Moreover, donovanosis, being an ulcerative disease, increases the risk of human immunodeficiency virus (HIV) transmission.[4–6] Transvaginal transmission of donovanosis during delivery has been reported, with an apparent predilection to ear structures of the newborn.[7,8] Patients tend to belong to the low socioeconomic classes. No racial predilection has been proved,[9–11] and both male and female predominance have been reported.[5,6,11] Afflicted people are likely to delay seeking medical attention due to the painless nature of the ulcers and the possible embarrassment or fear from medical or surgical intervention. Late cases can be very debilitating and are much more difficult to manage.[12]

GI is endemic in warm, moderately humid areas like South Africa, India, Southern China, and Brazil.[5,13] There are new endemic areas of donovanosis, mainly South and Central America, India, and Papua New Guinea,[12] but the overall incidence of GI seems to be decreasing, especially in Papua New Guinea.[1] The disease has nearly been eradicated from Australia, with only five cases reported in 2004,[14] and is rare in North America and Europe.[15–17]

ETIOLOGY

Donovanosis is caused by the organism *Klebsiella granulomatis*, previously called *Calymmatobacterium granulomatis*. The name has been changed after sequencing the phoE and 16S ribosomal RNA genes and demonstrating close homology with *K. pneumoniae* and *K. rhinoscleromatis*.[5,12]

K. granulomatis is a Gram-negative, nonmotile, pleomorphic bacterium that stains well with Giemsa, Wright's, or silver stains but is periodic acid-Schiff–negative. The mature form is encapsulated, while the immature form is not. The immature non-encapsulated form may assume a closed-safety-pin appearance due to bipolar chromatin densities.

It is difficult to culture and store this organism; however, it may be cultured using embryonic chick heart or chick embryo amniotic fluid. It has also been cultured in human peripheral blood mononuclear cells after decontaminating the specimen with amikacin, vancomycin, and metronidazole,[12] and in HEp-2 cells after adding gentamicin and cycloheximide.[5]

K. granulomatis is a facultative organism that resides in the cytoplasm of large mononuclear cells. It is pathogenic only to humans and the developing chick embryo. It was isolated from the feces of two out of four patients with

GRANULOMA INGUINALE AT A GLANCE

- Granuloma inguinale or donovanosis is a chronic ulcerative debilitating disease that mainly affects the genital organs.
- Caused by the Gram-negative bacteria *Klebsiella granulomatis*.
- Affects mostly people of lower socioeconomic status living in the tropical and sub-tropical areas.
- Diagnosis is made by demonstrating intracellular Donovan bodies on histology.

▲ **FIGURE 204-1** Granuloma inguinale on the inner prepuce. Two beefy red erosive plaques that bleed easily. (Used with permission from Shukrallah Zeynoun, MD.)

▲ **FIGURE 204-3** Granuloma inguinale. Large ulcerovegetative type.

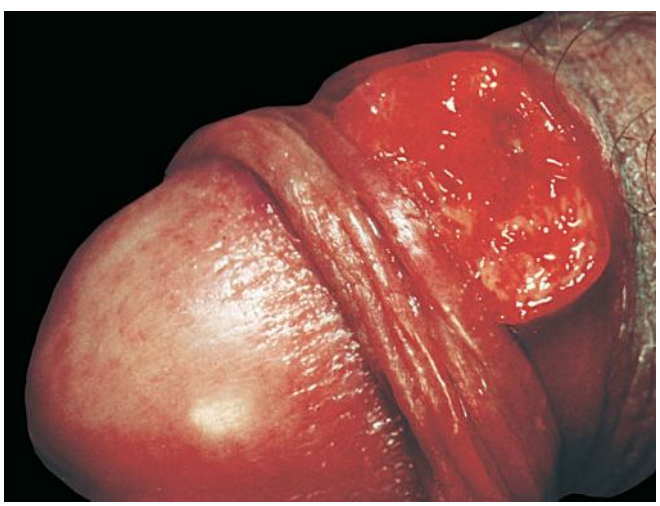
donovanosis, although it has not been successfully cultured from feces. It is still unknown if this organism has a natural habitat.[18]

CLINICAL FINDINGS: HISTORY AND CUTANEOUS LESIONS

The incubation period extends from 3 days to 3 months but is usually 2 to 3 weeks. Single or multiple papules or nodules later develop and grow into a painless ulcer that may extend to the adjacent tissues and moist folds, forming "kissing lesions." The penis, scrotum, and glans are the most commonly affected sites in males; and the labia and perineum are most commonly affected in females.[11] Vaginal and cervical involvement has also been reported and sometimes mistaken for squamous cell carcinoma.[5] The anus and colon may be infected, especially in homosexual males.[5,19]

GI most commonly presents as beefy red, easily bleeding, foul-smelling ulcers with granulation tissue[5] (Fig. 204-1). The ulcers may have hypertrophic or verrucous borders resembling condylomata acuminata.[16] It may also present as soft, red nodules that eventually ulcerate (Fig. 204-2). In long-standing donovanosis, the lesions may be necrotic, quite destructive of tissue, and have a copious gray, foul-smelling exudate[5,16] (Fig. 204-3). The tissue overlying the regional lymph nodes may evolve into an abscess or pseudobubo that later ulcerates.[5] The lymph nodes per se are rarely involved unless there is a bacterial superinfection.[16] In the rare dry cicatricial form, the nonbleeding ulcers form band-like scars and lead to digital lymphedema due to constriction.[16]

HIV co-infection may alter the clinical presentation of GI. The natural history is usually more rapid, and ulcers may persist for longer periods, lead to more tissue destruction, and need more prolonged antibiotic treatment. Extragenital dissemination of GI has been reported in HIV-positive patients.[15]

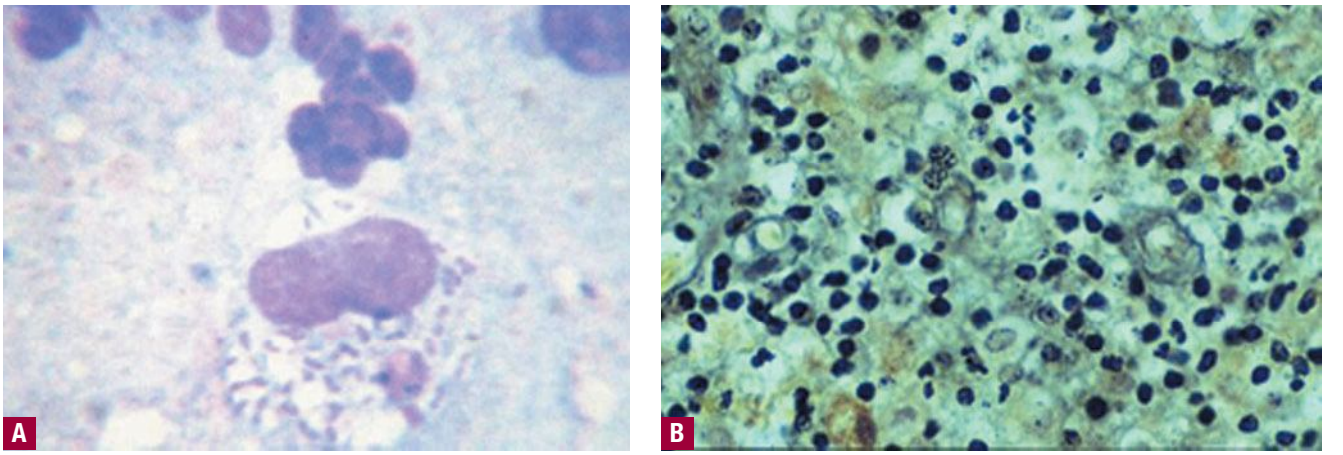


▲ **FIGURE 204-2** Granuloma inguinale. Nodular variety evolving into a large, exuberant ulcer. (Used with permission from A. Eichmann, MD.)

DIAGNOSIS AND LABORATORY TESTS

Demonstrating the Donovan bodies on smear or biopsy specimen makes the diagnosis of GI, although they are more easily visualized with properly done smears rather than biopsy[16] (Fig. 204-4). Secondary bacterial infection and debris may affect the smear result; thus it is recommended to wipe the ulcers gently with cotton swabs first before taking the smear but not to clean the ulcers with saline first.[1] Tissue for smear or crush preparations are better taken from the advancing edge of the ulcer, and tissue preparation should be made immediately, before the desiccation of histiocytes.

Serology is not helpful in making the diagnosis. Polymerase chain reaction has so far only been used for research purposes.[20]



▲ **FIGURE 204-4** Granuloma inguinale. Tissue smear showing Donovan bodies, which are Gram-negative (**A**) and readily stained with Giemsa stain (**B**).

Histologically, the epidermis may exhibit pseudoepitheliomatous hyperplasia and/or ulcerations, depending on the site biopsied. In the dermis, a dense mixed inflammatory cell infiltrate is usually seen composed of polymorphonuclear cells, plasma cells, histiocytes, and rare lymphocytes. Edema and endothelial cell swelling are often noted. The hypertrophic and the cicatricial forms of GI may exhibit fibrosis.[3,19] Clusters of Donovan bodies are seen in the vacuolated cytoplasm of the large mononuclear cells. Using Giemsa, Wright's, or silver stains, these Donovan bodies appear as safety-pin–like structures measuring 1 to 2 μm × 0.5 to 0.7 μm. These Donovan bodies may also be occasionally found extracellularly or within neutrophils.[19]

The differential diagnosis of Donovan bodies (Box 204-1) includes the Frisch bacilli in Mikulicz cells of rhinoscleroma, the amastigotes of leishmania, the chlamydial inclusion bodies of lymphogranuloma venereum, histoplasmosis, and the Michaelis-Gutmann bodies of Malakoplakia.[19]

Box 204-1

Differential Diagnosis of Granuloma Inguinale

Most Likely

- Ulcerative disease of the genital area
  - Primary syphilis (hard indolent ulcer) with indolent lymphadenopathy
  - Secondary syphilis (pale, white, moist plaques)
  - Lymphogranuloma venereum (prominent inguinal lymphadenopathy)
  - Chancroid (painful ulcers with painful lymphadenopathy)
- Note that the above diseases may co-exist.

Always Rule Out

- Long-standing necrotic lesions of the penis, vulva, or cervix
  - Squamous cell carcinoma
  - Genital amebiasis
  - Chronic herpes simplex of the immunosuppressed
- Extragenital involvement
  - Leishmaniasis
  - Scrofuloderma
  - Deep mycosis
- Disseminated form with bone involvement
  - Tuberculosis

COMPLICATIONS

Genital complications of donovanosis include genital swelling that may progress to pseudoelephantiasis, phimosis, paraphimosis, and progressive tissue destruction that may lead to the destruction of the whole penis or other involved organs.[6] There is also an increased risk of squamous cell carcinoma in long-standing cases.[5,11]

Extragenital involvement has been reported in around 6 percent of the cases, occurring either as a primary infection or by spreading from a genital site by autoinoculation or systemic hematogenous dissemination.[6,13] Primary extragenital sites reported include particularly the oral mucosa, and also the neck, scalp, chest, arms, and legs. Oral involvement usually presents as swelling, ulcerations, and bleeding of the gum and palate. Bone involvement may lead to loss of teeth. Long-standing infection results in fibrosis, gum and cheek adhesions, and microstomia.[5,6] Hematogenous dissemination may present with fever, anorexia, and weight loss. It may lead to the involvement of bones, notably, and other visceral organs like the abdominal cavity, bowel, liver, spleen, and lungs. The most commonly affected bone is the tibia, comprising more than 50 percent of reported cases. There are few reported cases of GI manifesting as otitis media with mastoiditis, psoas abscess, and cervical lymphadenopathy.[2,7,21]

In addition, the fact that GI ulcers are painless and bleed easily upon contact increases the risk of HIV transmission remarkably.[9,22]

PROGNOSIS AND CLINICAL COURSE

GI shows no tendency for spontaneous healing. If left untreated, GI may extend to internal organs, including the ovaries, adnexa, uterus, epididymis, and bladder. Fistulas may form and lead to genital fibrosis and deformity.[5,11] Systemic dissemination may be fatal, especially in cases of misdiagnosis.[6]

TREATMENT

Untreated ulcers do not resolve spontaneously. On the contrary, they tend to worsen with time, and antibiotic treatment is better started early (Box 204-2).

The patient should continue treatment until all clinically visible ulcers have completely healed. Serial biopsy specimens may be needed.[11] If the patient does not improve within the first few days of treatment, the addition of gentamicin 1 mg/kg intravenously every 8 hours needs to be considered.

The Centers for Disease Control and Prevention recommends the same treatment regimens for HIV-positive patients with GI, although there have been few reports of failure of such treatment.[23] The Centers for Disease Control and Prevention also strongly recommends gentamicin 1 mg/kg intravenously every

Box 204-2

Treatment of Granuloma Inguinale

First line	Azithromycin[1,14]	1 g once followed by 500 mg daily *or* 1 g weekly for 4–6 wk *or* 500 mg once daily for 1 wk
Second line	Doxycycline	100 mg once or twice daily for at least 3 wk
	Trimethoprim/sulfamethoxazole	800 mg/160 mg twice a day for at least 3 wk
	Ciprofloxacin	750 mg twice a day for at least 3 wk
	Erythromycin base[23]	500 mg orally four times a day for at least 3 wk

8 hours for HIV-infected patients with GI if there was no improvement within the first few days.

Relapse may occur 8 to 16 months after apparently effective treatment, requiring follow-up by the physician. Long-standing cases may be complicated by secondary bacterial infections or by fistulas and abscess formation, which require surgical intervention and render antibiotic treatment alone ineffective.[13]

Pregnant or lactating patients with GI are to avoid doxycycline and ciprofloxacin in their treatment regimens.

PREVENTION

All partners who had sexual contact with a patient with GI within 60 days before the onset of symptoms need to be examined. Sexual partners need not be treated unless they develop signs and symptoms of GI.

Children born to mothers with untreated donovanosis need to receive prophylactic azithromycin at a dose of 20 mg/kg for 3 days.[8]

CHAPTER 205

Gonorrhea and Other Venereal Diseases

Annabelle L. Garcia
Vandana K. Madkan
Stephen K. Tyring

GONORRHEA

Epidemiology

More than 700,000 people are reported to acquire new gonorrheal infections in the United States every year. Yet, only one-half of these infections are reported to the Centers for Disease Control and Prevention (CDC). The rate of new infections declined after the implementation of a national gonorrhea control program in the United States during the mid-1970s and has continued to decrease slightly since 1999. The prevalence of infection may have decreased due to screening programs that have incorporated immediate, on-site, single-dose treatment, if needed. Safer sex practices in response to the human immunodeficiency virus (HIV) epidemic may also be a contributing factor to the decline of new gonorrheal infections. The highest rate of reported gonorrheal infections is among sexually active teenagers, young adults, and African Americans. Such racial disparity is multifactorial and may be due to differences in accessibility to health care, lack of use of resources available, crowded living environments, and sexual partner preferences. Risk factors for acquisition of new gonorrheal infection include new or multiple sex partners, young age, unmarried status, minority ethnicity, substance abuse, lower socioeconomic and educational levels, and previous infection.

Overall, since the 1980s, prevalence rates among men and women have been similar. The highest rates in women are for those between the ages of 15 and 19 years old and in men between the ages of 20 and 24 years old.[1] A higher rate of new infections among men having sex with men has been reported recently in some major cities.[2,3]

Etiology and Pathogenesis

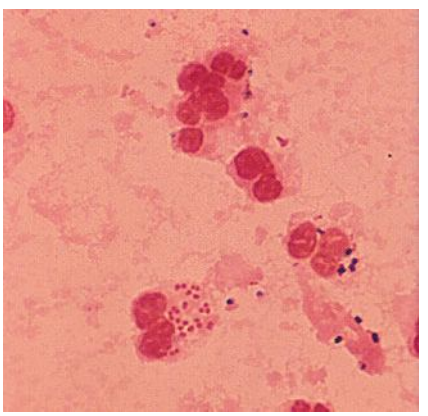
Albert Ludwig Sigismund Neisser first discovered the causative agent of gonorrhea in 1879. Gonorrhea is caused by infection with *Neisseria gonorrhoeae*, a Gram-negative, aerobic coccus-shaped bacterium found in pairs. The organisms are usually visualized intracellularly in polymorphonuclear leukocytes (Fig. 205-1). Gonorrhea is acquired through sexual contact, or, less commonly, as a result of poor hygiene or medical use of urine. It can also be transmitted vertically from mother to child during birth. Pathogenesis involves attachment to columnar epithelial cells via pili or fimbriae. The most common sites of attachment include the mucosal cells of the male and female urogenital tracts. Outer membrane proteins, PilC and Opa, on the bacteria aid in attachment and local invasion. Invasion is mediated by adhesins and sphingomyelinase, which contribute to the process of endocytosis. Certain gonococcal strains produce immunoglobulin A proteases that cleave the heavy chain of the human immunoglobin and block the host's bactericidal immune response. Once inside the cell, the organism undergoes replication and can grow in both aerobic and anaerobic environments. After cell invasion, the organism replicates and proliferates locally, inducing an inflammatory response. Outside the cell, the bacteria are susceptible to

GONORRHEA AND OTHER VENEREAL DISEASES

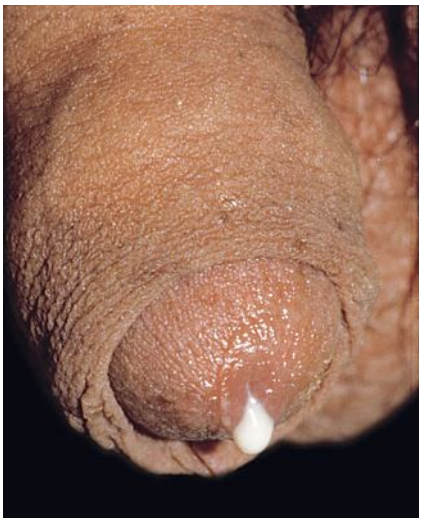
AT A GLANCE

- More than 19 million new sexually transmitted infections occur annually in the United States.
- In the United States, chlamydia is currently the most common reported sexually transmitted disease (STD). It is also the most common cause of pelvic inflammatory disease in women.
- Urethritis is a common presenting symptom of STDs in both men and women.
- Diagnosis can usually be made through culture and/or newer diagnostic methods such as nucleic acid amplification tests.
- Early and appropriate antimicrobial therapy of STDs results in good prognosis.
- Prevention of STDs includes sexual abstinence or safe sex practices.

temperature changes, ultraviolet light, drying, and other environmental shifts. The outer membrane contains lipooligosaccharide endotoxin, which is released by the bacteria during periods of growth and contributes to its pathogenesis in disseminated infection. Delays in proper antibiotic treatment, physiologic changes in host defenses, resistance to immune responses, and highly virulent strains of bacteria contribute to hematogenous spread and disseminated infection. Humans are the only natural hosts of *N. gonorrhoeae*.[4,5]



▲ **FIGURE 205-1** Diagnostic Gram-stained smear of urethral discharge of a man with acute gonorrhea. Gonococci (*red*) within a polymorphonuclear leukocyte. There are also some Gram-positive cocci in this smear (*dark blue*). (Used with permission from Angelika Stary, MD.)



▲ **FIGURE 205-2** Acute gonorrhea in a male manifesting as creamy purulent discharge from the urethra.

Clinical Findings: History and Physical Findings

N. gonorrhoeae infection tends to involve mucous membranes consisting of columnar epithelial cells. The urethra, cervix, rectum, pharynx, and conjunctiva are the areas most commonly involved.

LOCALIZED DISEASE (MEN) The incubation period for the bacteria in men ranges from 2 to 8 days, with most infections being symptomatic after 2 weeks. Only about 10 percent of infections are asymptomatic in men. The most common manifestation of gonococcal infection in men is urethritis, characterized by cloudy or purulent discharge from the penile meatus, which may be indistinguishable from other non-gonococcal causes (Fig. 205-2). Mucosal membrane inflammation in the anterior urethra leads to painful urination and surrounding redness and swelling (Fig. 205-3). Testicular pain and swelling may indicate epididymitis or orchitis and may be the only presenting symptom. However, epididymitis is more commonly caused by *Chlamydia trachomatis* or by combined infection with *N. gonorrhoeae*.

Proctitis is another manifestation of gonococcal infection with symptoms including rectal mucopurulent discharge, pain on defecation, constipation, and tenesmus. Proctitis usually occurs in individuals who engage in anoreceptive intercourse and more commonly in men who have sex with men. As a result of gonococcal proctitis, men who have sex with men are at a higher risk of acquiring HIV infection due to damaged epithelial integrity.[6]

Pharyngitis caused by *N. gonorrhoeae* is rare and usually asymptomatic, although it may serve as a source for disseminated disease. Symptoms range from cervical lymphadenopathy and pharyngeal erythema to severe ulceration with pseudomembrane formation.[7]

LOCALIZED DISEASE (WOMEN) Fifty percent of women infected with *N. gonorrhoeae* are asymptomatic. Appropriate screening, prompt diagnosis, and treatment is crucial in women due to serious complications that can result in sterility. The endocervix is a common site of local infection and invasion by organisms. Symptoms of urethritis include mucopurulent discharge, vaginal pruritus, and dysuria. However, vaginitis does not occur except in prepuberal girls or post-menopausal women because the vaginal epithelium of sexually mature women does not support growth of *N.*

◀ **FIGURE 205-3** Acute gonorrhea in a non-circumcised male. There is a purulent discharge from the urethra and concomitant inflammation of the prepuce and glans.

gonorrhoeae. Other sites of infection include Bartholin's and Skene's glands. Organisms may invade the upper genital tract, including the uterus, fallopian tubes, and ovaries, resulting in pelvic inflammatory disease (PID).

PID occurs in about 10 percent to 40 percent of uncomplicated gonorrheal infections in women and is characterized by fever, lower abdominal pain, back pain, vomiting, vaginal bleeding, dyspareunia, and adnexal or cervical motion tenderness on physical examination. Sequelae of untreated infection include tubo-ovarian abscesses, subsequent ectopic pregnancies, chronic pelvic pain, and infertility due to chronic inflammation with resultant scarring. Symptoms tend to occur at the time of menses and cannot be distinguished from non-gonococcal etiologies.[8] Fitz-Hugh–Curtis syndrome, involving inflammation of the liver capsule, is associated with genitourinary tract infection and may be present in up to one-fourth of women with PID caused by either *N. gonorrhoeae* or *C. trachomatis*. Presenting symptoms include right upper quadrant pain and tenderness with abnormal liver function tests.[9]

Women may also develop proctitis through autoinoculation from cervical discharge or as a result of direct contact from an infected partner's penile secretions. Symptoms may include rectal mucopurulent discharge, pain on defecation, constipation, and tenesmus.[4]

The incidence of gonococcal pharyngitis is similar to that in men.[7]

NEWBORNS AND CHILDREN Neonates may acquire *N. gonorrhoeae* during passage through the birth canal from contact with infected secretions. Such ocular infections are known as *ophthalmia neonatorum* and can lead to severe corneal perforation or scarring.[4] Most states, by law, require the prophylactic use of silver nitrate drops, erythromycin, or tetracycline ophthalmic ointment for prevention of ophthalmia neonatorum.[10] Pharyngeal or genital gonococcal infection in children is often a sign of sexual abuse and warrants further investigation.[11]

DISSEMINATED DISEASE Spread of infection from the site of inoculation to other parts of the body through the bloodstream leads to disseminated gonococcal infection (DGI). Disseminated disease occurs in 0.5 percent to 3 percent of cases and is associated with the classic triad of dermatitis, migratory polyarthritis, and tenosynovitis. Pain and swelling may occur in a single joint or in multiple joints asymmetrically, with upper extremity joints affected more commonly than lower extremities. Skin findings consist of small macules or hemorrhagic pustules on an erythematous base located on palms and soles (Fig. 205-4) or on the trunk and elsewhere on the extremities (see eFig. 205-4.1 in on-line edition). Skin lesions may develop necrotic centers; occasionally lesions may be similar in appearance to erythema nodosum or erythema multiforme. On the palms and soles, lesions may be tender, but in other sites they tend to be non-pruritic and painless and disappear after initiating appropriate treatment. Skin lesions may be present in 40 percent to 70 percent of cases of disseminated disease. Primary skin lesions as a result of localized gonorrheal infection are rare. Histologically, perivascular neutrophilia, dermal vasculitis, and epidermal neutrophil infiltration may be seen.[5]

◀ **FIGURE 205-4** Disseminated gonococcal infection. Tender, hemorrhagic, and necrotic pustules on the fingers and palms.

Laboratory Tests

Bacterial culture has been the "gold standard" diagnostic test for years, although newer and more specific tests are now being used in many laboratories. Culturing *N. gonorrhoeae* requires media containing heme, nicotinamide adenine dinucleotide, yeast extract, carbon dioxide, and other supplements required for isolation. Culture can be performed on modified Thayer-Martin medium. Organisms are Gram-negative, intracellular diplococci visualized microscopically inside polymorphonuclear cells. In men, culture and Gram's stain are performed on secretions or urethral swabs (see Fig. 205-1).[4] Endocervical and endourethral specimens for culture and Gram's stain have yielded more accurate results than testing vaginal secretions in women. Cultures on pharyngeal and rectal swabs may also be performed if infection is suspected in these areas.[5]

The U.S. Food and Drug Administration has approved certain chemiluminescent DNA probes that can be used on endocervical or urethral specimens for diagnosis of gonorrhea. However, distinguishing gonococcal from non-gonococcal infection may be difficult with DNA probes. Newer techniques include the use of nucleic acid amplification tests, such as polymerase chain reaction (PCR), transcription-mediated amplification, and strand displacement amplification on urine or urethral specimens. Overall, nucleic acid amplification tests are highly sensitive and specific and may be able to detect even the presence of one organism.[12,13]

In DGI, cultures should be done on blood, joint fluid, and skin lesions. Synovial fluid from affected joints must be analyzed for cell count, Gram's stain, and culture. Diagnosis should be based on clinical suspicion and pertinent findings because tests for DGI yield positive results only in a small number of cases.[5]

Differential Diagnosis

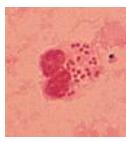
Box 205-1 shows the differential diagnosis for all venereal diseases.

Complications

Permanent sequelae of gonococcal infection in women may be infertility as a result of untreated PID. Untreated DGI can lead to septic arthritis, resulting in permanent joint damage. Meningitis and endocarditis are rare manifestations of DGI. Additional symptoms may include fever, malaise, and perihepatitis (Fitz-Hugh–Curtis syndrome).[5]

Prognosis and Clinical Course

Prognosis is excellent if infection is treated early with appropriate antibiotics. Previously treated gonococcal in-



Box 205-1

Differential Diagnosis for All Venereal Diseases

LOCALIZED	SYSTEMIC	ALWAYS RULE OUT

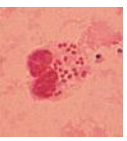
Endometriosis		
Mycoplasmal infection		
Orchitis		
Epididymitis		



fection does not reduce the risk of reinfection. DGI has a good prognosis if treated appropriately and before permanent damage to joints or organs occurs.[14]

Treatment

Ten percent to 30 percent of people with gonococcal infection are co-infected with *Chlamydia*. Thus, routine dual therapy with doxycycline and azithromycin has been recommended and shown to be cost effective. Dual therapy also decreases the development of antimicrobial resistance in bacteria. Box 205-2 shows CDC recommendations for uncomplicated cervical, urethral, pharyngeal, and rectal gonococcal infections. Due to the increased prevalence of antimicrobial resistance, quinolones should not be used for infections acquired in California, the Pacific islands, including Hawaii, or Asia. Patients with DGI may need to be hospitalized due to septic arthritis, meningitis, or endocarditis. The recommended regimen for DGI is ceftriaxone, 1 g intramuscularly (IM) or intravenously (IV) every 24 hours, continuing for 24 to 48 hours after improvement is noted. Treatment may then be switched to oral doses of the antibiotics listed in Box 205-2. Sexual partners should also receive appropriate treatment.[15]

Disseminated gonococcal infection requires longer treatment periods as shown in Table 205-1.

Treatment of gonococcal meningitis should consist of ceftriaxone, 1 to 2 g IV every 12 hours for 10 to 14 days, and of gonococcal infections in neonates as shown in Box 205-3.

Gonococcal ophthalmia neonatorum should be treated with ceftriaxone, 25 to 50 mg/kg IV or IM, not to exceed 125 mg in a single dose.

Box 205-2

Treatment of Localized, Uncomplicated Gonococcal Infection

- Single dosage of any of the following:
  - Cefixime, 400 mg PO
  - Ceftriaxone, 125 mg IM
  - Ciprofloxacin, 500 mg
  - Ofloxacin, 400 mg PO
  - Levofloxacin, 250 mg PO
- Patients allergic to cephalosporins or quinolones may be treated with spectinomycin, 2 g in a single IM dose.
- In dual therapy for chlamydia, add:
  - Azithromycin, 1 g orally in a single dose
  - Doxycycline, 100 mg orally twice a day for 7 days

TABLE 205-1
Management of Disseminated Gonococcal Infection

Recommended regimen	
Ceftriaxone	1 g IM or IV every 24 h
Alternative regimens	
Cefotaxime	1 g IV every 8 h
or	
Ceftizoxime	1 g IV every 8 h
or	
Ciprofloxacin	400 mg IV every 12 h
or	
Ofloxacin	400 mg IV every 12 h
or	
Levofloxacin	250 mg IV daily
or	
Spectinomycin	1 g IM every 12 h
All of the preceding regimens should be continued for 24–48 h after improvement begins, at which time therapy may be switched to one of the following regimens to complete at least 1 wk of antimicrobial therapy:	
Cefixime	400 mg PO twice daily
or	
Ciprofloxacin	500 mg PO twice daily
or	
Ofloxacin	400 mg PO twice daily
or	
Levofloxacin	500 mg PO once daily

Box 205-3

Treatment of Gonococcal Infection in Neonates

- Ceftriaxone, 25–50 mg/kg/day IV or IM in a single daily dose for 7 days, with duration of 10–14 days if documented meningitis

or

- Cefotaxime, 25 mg/kg IV or IM every 12 h for 7 days, with duration of 10–14 days if documented meningitis

Contraindications

Women who are pregnant should not be treated with tetracyclines or quinolones due to possible damage to the fetus. A cephalosporin or a single 2-gram dose of spectinomycin can be used for gonococcal infection, and erythromycin or amoxicillin for chlamydia.[10]

CHLAMYDIA

Epidemiology

Infection with *C. trachomatis* is the most common reported sexually transmitted disease (STD) in the United States, with more than 900,000 reported cases in 2004. Due to a high rate of asymptomatic infection, the prevalence of infection may be more than 2.8 million cases per year, according to the CDC. This is two and one-half times more than the reported cases of gonorrhea. The rate of infection increased about 5.9 percent between 2003 and 2004. This may be as a result of higher screening with more sensitive and specific tests. The overall rate of reported cases in 2004 was 485 per 100,000 and 147 per 100,000 among women and men, respectively. This trend relates to higher screening in women and a greater number of infections in men not being diagnosed or reported. The highest rates of infection reported are in men and women between the ages of 19 and 24 years old. Infection rates among African American women have been seven times higher than those reported in white women; the infection rate in African American men have been eleven times higher than those in white men. Risk factors are similar to those of gonorrhea and include young age, new or multiple sex

partners, unprotected sexual intercourse, and low socioeconomic status.

Etiology and Pathogenesis

The Greek-derived word *chlamys* means "cloak draped around the shoulder." This refers to the draping of intracytoplasmic inclusions containing *C. trachomatis* around the nucleus of an infected cell.[16] *C. trachomatis* is a nonmotile, Gram-negative, obligate intracellular organism with 15 serotypes: A through C cause chronic conjunctivitis and are endemic in Africa and Asia, D through K cause urogenital tract infections, and L1 though L3 cause lymphogranuloma venereum (see Chap. 203). The bacteria have a two-phase life cycle. The infectious form is known as the *elementary body*, which enters host cells through endocytosis. Replication through binary fission occurs inside the host cell, using host-derived adenosine triphosphate, with formation of reticulate bodies. Large intracytoplasmic inclusions inside cells are made up of hundreds of reticulate bodies, which then convert back to infectious elementary bodies to be released from the cell.

Urogenital tract infection is the area most commonly affected in men and women. Transmission is through oral, anal, or vaginal intercourse with symptoms occurring 1 to 3 weeks after exposure. However, asymptomatic infection occurs in up to 80 percent of women and 50 percent of men. Co-infection with other STDs occurs frequently, most commonly with gonorrhea. Serotype G has been associated with an increased risk of squamous cell carcinoma.[17] Newborns can be infected from passage through the birth canal of an infected mother.[18]

Clinical Findings: History and Physical Findings

The most common manifestation of disease is urethritis, characterized by a watery or mucoid discharge from the urethra that may be accompanied by dysuria in both men and women. Rectal infection may result in proctitis in both men and women. Infection may also present as lymphogranuloma venereum (see Chap. 203).[19,20]

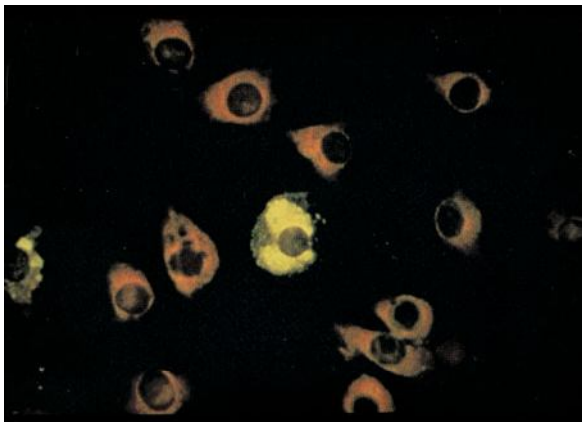
In men younger than age 35 years, *C. trachomatis* is the most common cause of epididymitis. Besides urethral discharge, men may also present with unilateral scrotal pain and swelling. It remains questionable whether chlamydia causes prostatitis. Some studies have linked chronic prostatitis to *C. trachomatis* infection.[19]

In women, the columnar epithelium of the endocervix is commonly affected. Other symptoms beside those of urethritis include intermenstrual or postcoital bleeding and lower abdominal pain. As with gonococcal infection, a severe complication in women that can result in sterility is PID, with ascending infection to the uterus and fallopian tubes. In the United States, chlamydia is currently the most common cause of PID. Symptoms may include fever, lower abdominal pain, back pain, vomiting, vaginal bleeding, dyspareunia, and adnexal or cervical motion tenderness on physical examination. Sequelae of untreated infection include tubo-ovarian abscesses, ectopic pregnancies, chronic pelvic pain, and infertility due to chronic inflammation with resultant scarring. Five percent to 10 percent of women with PID may develop perihepatitis (Fitz-Hugh–Curtis syndrome).

Newborns may develop conjunctivitis and pneumonia after being infected from passage through the birth canal of an infected mother. Signs of ophthalmia neonatorum may include injected conjunctivae, purulent discharge, or swollen eyelids. Pneumonia as a consequence of neonatal chlamydial infection can first present after 1 to 3 months. Symptoms may include cough and fever with wheezing or crackles on pulmonary ascultation.[14]

Laboratory Tests

Traditionally, chlamydial infection was diagnosed by tissue culture with specimens obtained from the endocervix in women, urethra in men, rectum, or conjunctivae. More rapid and sensitive tests have replaced culture in the past few years. A direct fluorescent antibody test, which is highly specific, can be performed on cervical and penile urethral specimens with rapid results (Fig. 205-5). Enzyme immunoassays, which are less specific than the direct fluorescent antibody test, can be used to detect chlamydial antigens through the formation of a color change. Less invasive tests involving nucleic acid amplification, such as PCR and ligase chain reaction, are more commonly being used to detect even small amounts of chlamydial DNA in urine samples.



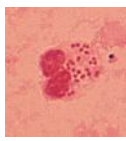
◀ **FIGURE 205-5** Detection of *Chlamydia trachomatis* by direct immunofluorescence with monoclonal antibodies.

Complications

Reactive arthritis (see Chap. 20) can occur up to 1 month after symptoms of non-gonococcal urethritis (NGU). The classic triad associated with this syndrome is NGU, arthritis, and conjunctivitis. Additional symptoms may include fever, malaise, myalgias, asymmetric joint stiffness, lower back pain, cutaneous lesions involving the genitals, and aortic regurgitation as a result of inflammation around the aortic valve. Individuals with the haplotype HLA-B27 are at increased risk of developing the reactive arthritis syndrome.[21]

Prognosis and Clinical Course

Early treatment with appropriate antibiotic therapy results in excellent prognosis and reduces the risk of long-term complications, such as infertility from PID. It is important to complete an appropriate course of antibiotics. First-time therapy with antibiotics has been shown to be up to 95 percent effective in eradicating infection. It is important to counsel patients on the risks of co-infections with other STDs and to arrange for partner referral. Sexual contact should be avoided until treatment is completed (Box 205-4).[18]



Box 205-4

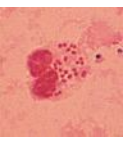
Treatment of *Chlamydia* Infection

- Azithromycin, 1 g PO in a single dose

or

- Doxycycline, 100 mg PO twice a day for 7 days
- Recommended treatment for pregnant women:
  - Erythromycin, 500 mg PO four times a day for 7 days
  - Amoxicillin, 500 mg PO three times a day for 7 days

GENITAL MYCOPLASMAS



Epidemiology

Species of *Mycoplasma* are some of the smallest, free-living organisms with the ability to colonize the respiratory and urogenital tracts of humans. *M. hominis* and other *Ureaplasma* sp. are referred to as the *genital mycoplasmal organisms* and may be found in the lower urogenital tracts of sexually active adults. Forty percent to 80 percent of sexually active women in the United States have urogenital colonization with *Ureaplasma* organisms. *M. hominis* has also been isolated in 20 percent to 50 percent of sexually active women. Rates of colonization tend to be lower in men. *Ureaplasma* organisms have been found to be the cause of 20 percent to 30 percent of NGU, and *M. genitalium* accounts for 10 percent to 20 percent of causes of non-chlamydial NGU. The rates of colonization in children and nonsexually active adults are much lower. Newborns may be infected by passage through the birth canal of an infected mother.

Etiology and Pathogensis

Genital mycoplasmas tend to self-replicate extracellularly, colonizing the respiratory and urogenital tracts. Disseminated infection is rare and tends to occur in immunocompromised hosts or in cases of epithelium traumatized by instrumentation.

M. genitalium and *Ureaplasma* sp. have been isolated from the lower urogenital tracts of men with urethritis and women with cervicitis and PID, as well as from healthy individuals. *M. hominis* has been isolated from cases of salpingitis. In cases of bacterial vaginitis, coinfection with mycoplasmal species may worsen the condition. Whether *Ureaplasma* sp. cause infertility remains controversial. *Ureaplasma* sp. and *M. hominis* have been isolated from the blood of febrile women postpartum and post-abortion. Invasion of placental membranes by *Ureaplasma* sp. has been attributed to preterm labor.

Clinical Findings: History and Physical Findings

Patients with genital mycoplasmal infections may go undiagnosed as such because these organisms may produce symptoms that are usually attributed to other more common causative agents such as chlamydia. This may also be due to the high rate of co-infection with such organisms. As with chlamydia, genital mycoplasmal infections can result in urethritis, cervicitis, PID, endometritis, salpingitis, and chorioamnionitis. Other species can cause respiratory infection, septic arthritis, surgical wound infections, neonatal pneumonia, and meningitis. Infection with these organisms needs to be considered if workup for the more commonly isolated organisms is negative. Physical findings are similar to those of NGU.

Laboratory Tests

Laboratory tests for genital mycoplasmas may be limited because most specimens must be sent to reference laboratories. Some species, such as *M. hominis* and *U. urealyticum*, can be cultured on special media with proper collection and handling from urethral swabs. A PCR assay may be used to detect *M. genitalium*.

Complications

Invasion by different species of *Mycoplasma* and *Ureaplasma* can cause disseminated disease, especially in immunocompromised hosts who have deficiencies in antibody production. Disseminated disease may result in respiratory tract invasion, osteomyelitis, or infectious arthritis. Bacteremia as a result of *M. hominis* has been shown after renal transplantation. *M. hominis* has also be found in surgical wound infections, pericardial effusions, prosthetic heart valves, subcutaneous abscesses, and in synovial fluid of people with rheumatoid arthritis. Some studies have shown certain mycoplasmal species to be more prevalent in those infected with HIV, although this remains questionable.

Prognosis and Clinical Course

Prognosis in immunocompetent hosts is excellent with appropriate treatment and prompt diagnosis.

Treatment

Treatment for genital mycoplasmas is similar to treatment for chlamydia. Fluoroquinolones may also be used as an alternative treatment against *M. hominis* and *Ureaplasma* sp. in cases of resistance to other antibiotics.[22]

TRICHOMONAS VAGINALIS

Epidemiology

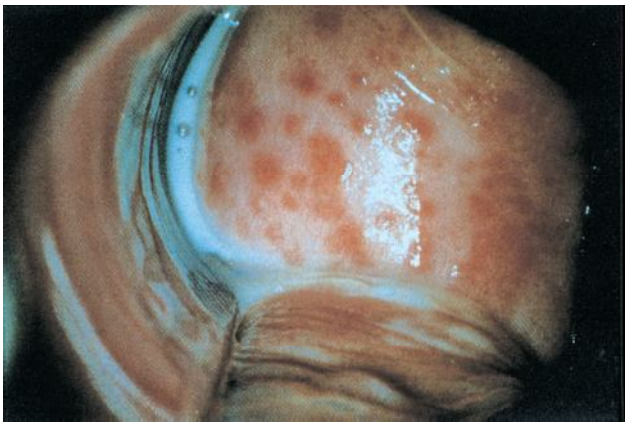
Trichomonas vaginalis causes a condition called *trichomoniasis*, which affects about 2 million to 3 million women annually in the United States. Worldwide, it has been estimated to affect more than 180 million women. It is difficult to estimate the number of men infected because most infections in men are asymptomatic. Yet, 30 percent to 40 percent of men who are exposed have detectable organisms. It is currently not a reportable disease.

Etiology and Pathogenesis

T. vaginalis is an STD caused by parasitic protozoa, which infect vaginal and urethral epithelium, causing microulcerations. In women, organisms may be isolated from the vagina, urethra, cervix, Bartholin and Skene glands, and bladder. In men, organisms may be found in the external genital area, anterior urethra, epididymis, prostate, and semen. The incubation period before symptomatic infection is usually between 4 and 28 days. In women, manifestation of infection ranges from an asymptomatic carrier state to inflammatory vaginitis. Due to the increase in vaginal acidity, symptoms tend to occur during or after menstruation. Most men are asymptomatic carriers.

Clinical Findings: History and Physical Findings

Women who are infected may complain of a malodorous, yellow-green vaginal discharge, vulvar pruritus and erythema, dyspareunia, lower abdominal discomfort, or dysuria. Infection tends to occur in sexually active women and men. Men are usually asymptomatic, yet



▲ **FIGURE 205-6** *Trichomonas vaginalis* infection: "Strawberry" appearance of cervix with punctuate bleeding erosions. (Used with permission from U. Lauper, MD.)

some may complain of urethral discharge and burning on urination with increased frequency. Both men and women may be asymptomatic carriers. Newborns may become infected from passage through the birth canal of an infected mother. Infection in a child may be a sign of sexual abuse.

On physical examination, punctate hemorrhages may be seen on the vaginal wall and cervix. A term commonly associated with such hemorrhages is *colpitis macularis* or *strawberry cervix* (Fig. 205-6). This is a specific sign of trichomoniasis, yet is only seen in 1 percent to 2 percent of women during a regular pelvic exam. It may be visualized in up to 45 percent of cases through the use of colposcopy. Findings of balanitis, epididymitis, and prostatitis may be present in men. Coinfection with other STDs may produce a more complex case.

Laboratory Tests

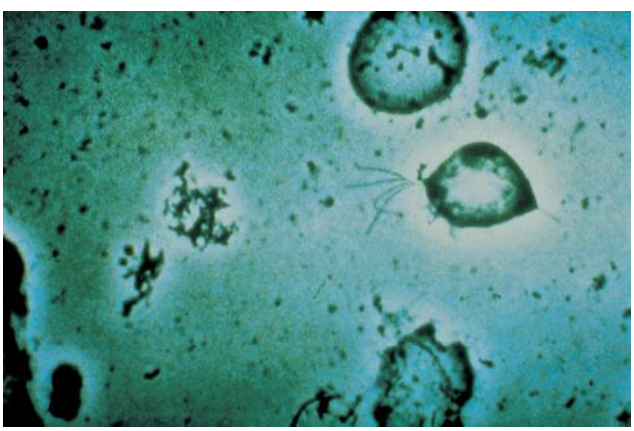
Vaginal pH tends to be elevated above 5.0 in trichomoniasis. A saline wet mount of a vaginal swab specimen is a common diagnostic test. The ovoid-shaped protozoa can be visualized microscopically, best by phase contrast or dark-field examination (Fig. 205-7). The most sensitive test is anaerobic culture, which usually is positive within 48 hours, and is the preferred method for diagnosing infection in men. PCR methods have been shown to have high sensitivity and specificity; however, availability of these tests is limited.[23]

Complications

Recently, studies have shown a link between *T. vaginalis* infection and complications in pregnancy, such as premature delivery, early rupture of membranes, and low birth weight in newborns. Trichomoniasis has also been associated with an increased risk of HIV transmission.[24] Less commonly, it has been linked to atypical PID.[25]

Prognosis and Clinical Course

Prognosis is excellent with resolution of infection occurring after appropriate treatment. Treatment of sexual partners is important to avoid re-infection.[26] Persistent infection despite appropriate treatment with metronidazole may require susceptibility testing (Box 205-5).[23]



▲ **FIGURE 205-7** *Trichomonas vaginalis*, phase contrast microscopy. (Used with permission from U. Lauper, MD.)

Box 205-5

Treatment of Trichomoniasis

- Metronidazole, 2 g PO in a single dose

or

- Metronidazole, 500 mg PO twice a day for 7 days[a]
- Alternative recommendations
  - Tinidazole, 2 g PO in a single dose

[a]Although the use of metronidazole in pregnancy remains controversial, some studies support its use in pregnancy.[27]

BACTERIAL VAGINOSIS

Epidemiology

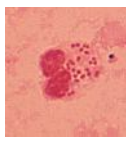
Bacterial vaginosis (BV) is the most common vaginal infection in women of childbearing age. It is estimated that approximately 16 percent of pregnant women in the United States may have bacterial vaginosis at a given time. Some studies have shown an increased prevalence among women who have sex with women. Incidence rates are difficult to determine due to the high prevalence of asymptomatic infection and lack of screening methods.

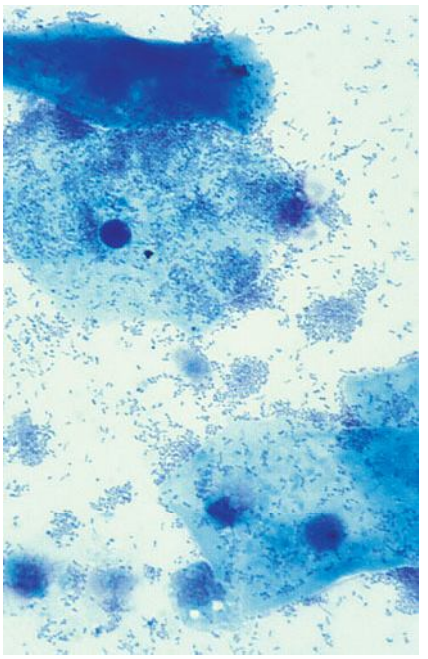
Etiology and Pathogenesis

BV occurs when there is an imbalance of the bacterial flora normally present in the vagina. The shift occurs from hydrogen peroxide–producing lactobacilli to a greater concentration of bacterial organisms including *Gardnerella vaginalis*, *Mobiluncus* sp., *M. hominis*, anaerobic Gram-negative rods belonging to the genera *Prevotella*, *Porphyromonas*, and *Bacteroides*, and *Peptostreptococcus* sp.[28] It is not known to be transmitted through sexual contact. Risk factors for infection include new or multiple sexual partners, early age of first sexual intercourse, use of intrauterine device, douching, and cigarette smoking.[24,29]

Clinical Findings: History and Physical Findings

As many as 75 percent of women with BV may be asymptomatic.[30] Women with BV may complain of a fishy odor and thin, white or gray vaginal discharge. Vaginal pruritus and inflammation are rare. On physical examination,





▲ **FIGURE 205-8** Bacterial vaginosis. Clue cells are large epithelial cells covered with bacteria. (Used with permission from Angelika Stary, MD.)

a milky, homogenous vaginal coating may be seen adhered to the vaginal wall.

Laboratory Tests

According to the Amstel criteria for diagnosing BV, three of the following four must be present: (1) thin, homogenous vaginal discharge; (2) a positive whiff test, which involves the production of a fishy odor when mixing vaginal fluid with 10 percent potassium hydroxide; (3) vaginal fluid pH greater than 4.5; and (4) the presence of clue cells (epithelial cells covered with bacteria) on microscopic examination (Fig. 205-8). Clue cells, being the most reliable indicator of BV, must make up at least 20 percent of the epithelial cells on saline wet mount. Another diagnostic test involves the use of Gram staining to distinguish between the normal bacterial flora of Gram-positive rods and lactobacilli from the Gram-negative morphotypes seen in BV. Due to the variety of bacterial species, culture is not a feasible diagnostic test.

Box 205-6

Treatment of Bacterial Vaginosis

- Metronidazole, 500 mg twice daily for 7 days

or

- Metronidazole gel, 0.75%, 5 g intravaginally once daily for 5 days

or

- Clindamycin cream, 5%, 5 g intravaginally qhs for 7 days

In pregnant women:

- Metronidazole, 250 mg three times daily for 7 days

or

- Clindamycin, 300 mg twice daily for 7 days

Alternative regimen

- Metronidazole, 2 g in a single dose

or

- Clindamycin ovules, 100 g intravaginally qhs for 3 days

Complications

BV has been shown to be a risk factor for preterm birth in pregnancy.[31] BV has also be associated as a risk factor for transmission and acquisition of HIV.[32] Studies have produced conflicting data as to whether BV is associated with a higher risk of acquiring cervical intraepithelial neoplasia.[33,34] Some studies have linked BV to postpartum fever, postoperative gynecologic complications, and postabortal infections; however, more studies are needed to investigate the relationship between BV and possible sequelae.[35]

Prognosis and Clinical Course

BV has a good prognosis with appropriate treatment.[36] Some infections may resolve on their own without therapy. A large number of infections are asymptomatic, and complications are rare. Many of the reported complications remain debatable as to true sequelae of BV. However, recurrent infections have been reported, and a longer treatment regimen may be warranted in such cases (Box 205-6).

Prevention

The best prevention from acquiring STDs is sexual abstinence. The U.S. Preventive Services Task Force recommends screening all sexually active women for chlamydia and gonorrhea, including pregnant women, who are at high risk of infection. Risk factors for infection include new or multiple sex partners, young age, unmarried status, minority ethnicity, substance abuse, lower socioeconomic and educational levels, and previous infection. There is no universal screening recommendation for *T. vaginalis*, genital mycoplasmal infections, or bacterial vaginosis in asymptomatic individuals.[37] It is important for clinicians to educate patients on safe sex practices, risks of acquiring STDs, and possible outcomes from infection.

INFESTATIONS, BITES, AND STINGS

CHAPTER 206

Leishmaniasis and Other Protozoan Infections

Samer H. Ghosn
Amal K. Kurban

LEISHMANIASIS

Epidemiology[1]

Leishmaniasis, a truly ancient disease,[2] was named after W.B. Leishman who identified organisms in smears taken from the spleen of a patient who died from Dumdum fever in 1901. The disease burden remains important in the twenty-first century,[3] with a worldwide prevalence of 12 million and annual incidence of 2 million cases, 25 percent being of the visceral type.

The various types of leishmaniasis are confined primarily to Central and South America (New World); the Mediterranean basin, southern Europe, central Africa, and parts of southern and central Asia (Old World). The infection is endemic in 88 countries, 72 of which are developing countries. In Western countries, the incidence is increasing due to human immunodeficiency virus (HIV)-leishmania coinfection and tourism.[4,5] New Zealand, Antarctica, and the Pacific islands are leishmania-free. Over 90 percent of cutaneous leishmaniasis (CL) cases occur in Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, Syria, Brazil, and Peru.[3] In the United States, most CL cases are imported except for one endemic form in Texas caused by *Leishmania mexicana*.[6,7]

The World Health Organization has classified leishmaniasis as a category 1 disease (emerging and uncontrolled). The recent geographic spread is attributed to massive rural-urban migration and agroindustrial development projects that bring nonimmune urban residents into endemic rural areas. Other incriminated factors include natural disasters, cessation of malaria spraying leading to an increased sand fly population, reconstructions, global warming, wars, and deforestation.

See Box 206-1 for various forms of leishmaniasis and their abbreviations.

Etiology and Pathogenesis[8]

ETIOLOGY AND LIFE CYCLE The genus *Leishmania* consists of parasitic protozoa of the phylum Sarcomastigophora, order Kinetoplastida, and family Trypanosomatidae. Approximately 20 species are pathogenic for humans and all are transmitted by the bite of an infected female phlebotomine sand fly. Cases of venereal[9] and vertical[10,11] transmission, as well as transmission from infected blood transfusion[12] or needles[13–17] have, however, been reported.

Leishmania are dimorphic parasites. In the gut of the sand fly or in culture, they exist in the promastigote form (10 to 20 μm, spindle-shaped, and motile with a single anterior flagellum). In the cells of the host reticuloendothelial system, leishmania exist in the amastigote form (2 to 6 μm, round/oval, nonmotile, and with a relatively large basophilic nucleus and a smaller rod-shaped kinetoplast of extra-nuclear DNA at the base of the lost flagellum). Infected macrophages are ingested by the fly during a blood meal and the amastigotes are released into the stomach of the insect, where they immediately transform into the promastigote form. The latter migrate to the alimentary tract of the fly, multiply extracellularly by binary fission, and, in a few days, reach the esophagus and the salivary glands where they change into the infective metacyclic promastigote form. When the now infectious sand fly feeds on a fresh source of blood, its proboscis pierces the skin, allowing the metacyclic forms to attach to host macrophages.[18]

Box 206-1

Abbreviations Used for Various Forms of Leishmaniasis

- CL: cutaneous leishmaniasis
- CCL: chronic cutaneous leishmaniasis
- DCL: diffuse cutaneous leishmaniasis
- MCL: mucocutaneous leishmaniasis
- VL: visceral leishmaniasis

LEISHMANIASIS AT A GLANCE

- Caused by the protozoan leishmania and transmitted by the bite of infected phlebotomine sand flies.
- Four major human diseases determined mainly by interaction between *Leishmania* sp. and the host:
  - Cutaneous leishmaniasis
  - Diffuse cutaneous leishmaniasis
  - Mucocutaneous leishmaniasis
  - Visceral leishmaniasis
- Diagnosis by organism isolation or serology, but species identification only possible with isoenzyme analysis and molecular techniques.
- Management ranges from observation to systemic therapy, primarily with antimonials; vaccines are in development.

TABLE 206-1
Major Vectors and Reservoir Hosts in Cutaneous Leishmaniasis (CL)

	Leishmania Species	Vector	Main Reservoir Hosts	Geographic Location
Old World–CL	*L. major*	*Phlebotomus*	Great gerbil *Rhombomys opimus*	Central Asia
			Sand fat jird *Psammomys obesus*	West Asia (Jordan, Israel, Palestine, Syria, Saudi Arabia), and North Africa (Libya)
			Meriones sp.	Pakistan, India
			Rodents	Sub-Saharan Africa
	L. tropica		Humans	West and Central Asia
			Hyraxes?	East Africa
			Unknown	West Mediterranean basin
	L. aethiopica		Hyraxes	East Africa (Kenya, Sudan, Ethiopia)
	L. infantum		Domestic dogs	Mediterranean basin
New World–CL	*L. Mexicana* complex	*Lutzomyia*	Forest rodents	Belize and Yucatán peninsula in Mexico, Central America
		Psychodogygus (only for *L. b. braziliensis*)	Wood rat Neotoma micropus	Texas
	L. braziliensis complex		Forest rodents, sloths	Brazil, Colombia, Costa Rica, Guiana, Honduras, Surinam, Panama, Venezuela, the western slopes of the Andes, and the Argentinean highlands

From Saliba EK, Oumeish OY: Reservoir hosts of cutaneous leishmaniasis. *Clin Dermatol* **17**:275, 1999.

After phagocytosis, the metacyclic forms transform into amastigotes that can survive and multiply by binary fission within the acidic phagolysosomes. Macrophages ultimately burst, releasing their amastigotes which in turn infect other macrophages.

RESERVOIR HOSTS[19,20] Leishmaniasis is mostly zoonotic, being incidentally transmitted to humans from wild and domestic animals (primary reservoir hosts) (Table 206-1). Visceral leishmaniasis (VL) caused by *L. d. donovani*, and Old World–CL (OW–CL) caused by some *L. tropica* strains are however anthroponotic diseases (i.e., humans are the primary reservoir hosts).

INSECT VECTORS[21] The insect vector of leishmaniasis, the female phlebotomine sand fly, is grouped under the suborder Nematocera of the order Diptera. Three genera (*Phlebotomus* in the Old World, and *Lutzomyia* and *Psychodopygus* in the New World) and approximately 70 species are implicated as vectors.[22] They are widely distributed and have predilection to intertropical and warm temperate zones. Only the female sand fly is hematophagus. Phlebotomine sand flies are less than 3 mm long and do not fly far from their breeding site. Their activity is mostly crepuscular or nocturnal while the host is asleep. They rest during the day and lay their eggs in dark, humid, and organic matter–rich places such as rodent burrows, bird's nests, and house wall fissures. Being exophilic and exophagic, they prefer to rest and to have their meal outdoors, which limits their control by house spraying.

PATHOGENESIS[22] The resulting disease depends on the fate of the phagocytosed amastigotes. This in turn is a function of numerous parasite- and host-related factors, as well as other factors that may account for geographic differences.[3,23] The latter include vasodilators, anticoagulants, and immunomodulators present in the sand fly saliva,[24] and inoculum size. In general, the parasites interfere with the signaling pathways, intracellular kinases, transcription factors, and gene expression of macrophages, compromising their ability to generate leishmanicidal substances. In addition, they impair dendritic cell activation, migration, and ability to secrete T helper 1 (Th1) cytokines.

PARASITE-RELATED FACTORS[25] Parasite-related factors include infectivity, pathogenicity, virulence, and tissue tropism.[26–30] Lipophosphoglycan and gp63 are 2 important promastigote virulence factors that functionally impair infected cells. Species-specific amastigote virulence factors include A2 gene locus products (*L. donovani*), cysteine proteases (*L. mexicana*) and leishmania homolog of activated C kinase receptor (*L. major*). In general, viscerotropic species spread to the reticuloendothelial system, in contrast to dermotropic species, which only spread to adjacent skin/lymph nodes. Some species involve mucous membranes, leading to mucocutaneous leishmaniasis (MCL). These divisions are not absolute. *L. tropica*, classically dermotropic, may cause visceral disease,[31,32] and viscerotropic species may become dermotropic as a consequence of treatment such as seen in post-kala-azar dermal leishmaniasis,[33] or in the setting of HIV co-infection.[34]

HOST-RELATED FACTORS[22,35] Acquired T-cell immunity, the net effect of opposing Th1 and Th2 responses, largely determines the course and therapeutic response of leishmaniasis. A dominant Th1 response resulting in the production of interferon-γ and nitric oxide leads to a leishmanicidal state of macrophages and accounts for sub-clinical infection or self-healing CL. A dominant Th2 response accounts for progressive disease such as diffuse CL (DCL). In general, T-cell immunity is intact in CL, defective in VL, and pathologically exuberant in MCL. Humoral immunity seems to play little or no role in determining the course of the infection. High titers of antileishmanial immunoglobulin G are associated with chronic, nonhealing, and visceral disease.

Clinical Findings

The clinical spectrum includes cryptic infection, localized cutaneous disease (CL), and disseminated infection (DCL, MCL, and VL).[22]

CUTANEOUS LEISHMANIASIS[36] CL constitutes 50 percent to 75 percent of all incident cases, and is the mildest form of

the disease. It can be caused by any *Leishmania* sp. Most cases heal spontaneously within 1 year and are characterized as acute CL. Disease lasting more than 1 year is termed *chronic CL* (CCL).

Old World Cutaneous Leishmaniasis. OW–CL (also known as *Aleppo boil, Baghdad boil, Oriental sore, leishmaniasis tropica, Biskra button, Delhi boil, Bouton d'orient, Lahore sore, rose of Jericho, Kandahar sore, the little sister*) is caused mainly by *L. major, L. tropica, L. ethiopica,* and to a lesser extent *L. infantum* (see Table 206-1). Two major types are identified.

Moist or Rural Type. The moist or rural type is classically caused by *L. major* and is characterized by multiple lesions, short incubation period (1 week to 3 months), rapid and mild course, and good response to therapy. Rodents are the main reservoirs. After bite(s) from an infected sand fly, one or numerous (up to 100) insect bite–like lesions appear, often on exposed body parts such as the face, arms, and legs. Most of them resolve within 1 to 2 weeks, and only a few evolve into CL (Fig. 206-1). The latter lesions are painless and heal often within 6 months, leaving atrophic scars.

Dry or Urban Type. The dry or urban type is classically caused by *L. tropica* and is characterized by a longer incubation period and course (twice as long as in the moist type) and by a worse response to therapy. The infection is largely anthroponotic and has the potential to persist/progress, recur, and visceralize.[37,38] A single "dry" ulcer over the face is characteristic.[39]

These two types may co-exist in the same patient.[33] *L. aethiopica* may cause a similar cutaneous disease but carries a high risk of evolving into DCL. *L. infantum*, the causative agent of Mediterranean VL in children, may cause a self-limited skin disease in adults.[40–42] Species identification cannot be made clinically and requires biochemical/molecular techniques.

The morphologic spectrum of OW–CL is wide. Lesions start as erythematous papules that enlarge over a few weeks to form nodules/plaques and often ulcerate and become crusted (Figs. 206-2 to 206-4). The "volcanic" noduloulcerative morphology is characteristic and consists of a painless crateriform ulcer with a rolled margin and a necrotic base that is often covered with an adherent crust (Fig. 206-5). Other presentations include

▲ **FIGURE 206-1** **A.** Acute cutaneous leishmaniasis: Multiple nodules on the arm caused by *Leishmania major*. **B.** Multiple, nodular, ulcerated lesions on the trunk at the site of sand fly bites. Note that the ulcerated nodules look similar to volcanoes seen from above ("volcano sign").

"iceberg nodules,"[43] and eczematoid, psoriasiform,[39] erysipeloid,[44,45] zosteriform, paronychial, chancriform, annular, palmoplantar,[46] verrucous, and keloidal[47] lesions. Satellitosis (Fig. 206-6), regional lymphadenopathy, localized lymphadenitis,[48] sporotrichoid lymphatic spread (see

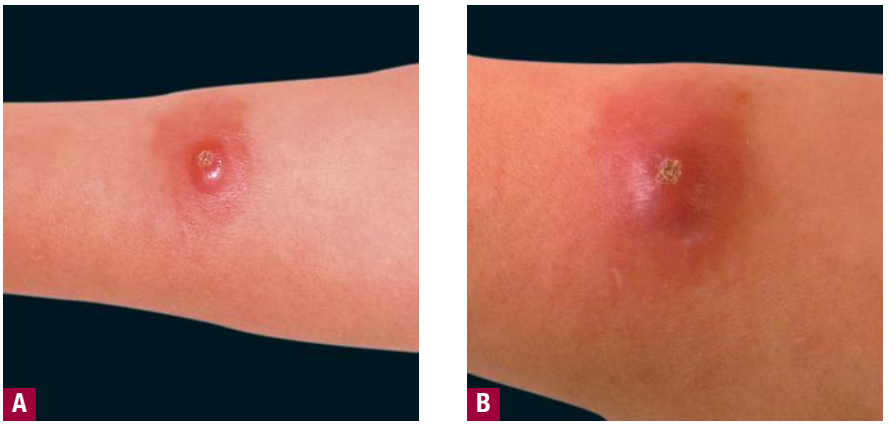
▲ **FIGURE 206-2** Acute cutaneous leishmaniasis. Single crusted erythematous plaque over the cheek.

▲ **FIGURE 206-3** Acute cutaneous leishmaniasis. Crusted erythematous nodule over the right perioral area in a young Middle Eastern girl.

eFig. 206-6.1 in on-line edition), subcutaneous lymphatic nodules[43,49] and localized hypoesthesia[50] may occur. Mature lesions may be elongated and oriented parallel to skin creases.[43] Secondary bacterial infection is common.[51]

New World Cutaneous Leishmaniasis. New World–CL (NW–CL; also known as *valley sickness, Andean sickness, white leprosy, chiclero ulcer, uta, pian bois*, and *bay sore*) is caused by *L. mexicana* and *L. braziliensis* complexes (see Table 206-1). Infection with *L. mexicana* and *L. b. guyanensis* causes only cutaneous disease in contrast to infection with *L. b. braziliensis* and *L. b. panamensis*, which may, in 40 percent to 80 percent of the cases, progress to MCL. Pure cutaneous disease is very similar to OW–CL and isolated ulcers are the most common presentations. Unusual clinical pictures have been reported.[52] One-half of the lesions caused by *L. mexicana* heal within 3 months, whereas those caused by *L. brazilienesis* persist much longer and are often associated with lymphadenop-

▲ **FIGURE 206-4** Acute cutaneous leishmaniasis. Crusted and ulcerated erythematous papule over the scalp.



▲ **FIGURE 206-5** **A** and **B.** Acute cutaneous leishmaniasis. Classical "volcaniform" noduloulcerative lesion over the forearm.

athy.[53,54] However, *L. mexicana* is the causative organism of chiclero ulcer, a chronic mutilating infection of the pinna of the ear of forest workers in Mexico and Central America. *L. flaviscutellata* is the major vector. The Andean cutaneous form of leishmaniasis (uta) is caused by *L. braziliensis* and predominantly affects exposed areas in children. Its principal vector is *L. peruensis*. An atypical nodular form of NW–CL caused by *L. d. chagasi*, has been reported from Honduras[55,56] and Nicaragua.[57]

Complications of Cutaneous Leishmaniasis. The major complications of CL are evolvement into DCL, CCL, and MCL (in NW–CL). Acquired immunodeficiency syndrome (AIDS) and other immunosuppressive conditions increase the risk of mucocutaneous and visceral dissemination,[58–61] and of recurrence after therapy.[62] Other complications include scarring, disfigurement, and social stigma.

Chronic Cutaneous Leishmaniasis/ Leishmaniasis Recidivans. In general, the lesions evolve from papules to chronic disfiguring nodules/plaques that are larger than average lesions and may exhibit variable degrees of scaling, ulceration, verrucosity, and scarring (Fig. 206-7). The diagnosis may be challenging due to the paucity of organisms seen on histologic examination. Leishmaniasis recidivans (LR), also known as *leishmania recidiva cutis*, is a rare form of CCL caused mostly by *L. tropica* in the Old World, and less commonly *L. braziliensis* in the New World. Erythematous, scaly papules, often with apple jelly appearance at the borders of a completely or partially healed lesion, are characteristic. It may complicate vaccination with a live strain of leishmania[63] and usually occurs in the setting of hyperactive T-cell immunity and low antibody titers. Reactivation of dormant infection (after up to 15 years) accounts for most of the cases, but re-infection with different strains may occur. Lupoid leishmaniasis shares similar etiology and clinical picture with LR; however, the former is not a recurrent lesion.[51]

Diffuse Cutaneous Leishmaniasis. DCL is a rare anergic form of CL that occurs in the setting of deficient cell-mediated immunity. It mimics clinically and histologically lepromatous leprosy and is usually caused by *L. aethiopica* in the Old World and *L. m. amazonensis* in the New World. Immunosuppressed patients, typically with HIV infection, may develop DCL with no species-specific relation.[64,65] Disseminated non-ulcerated and parasite-laden nodules gradually develop after a classical CL lesion with predilection for exposed areas of the body such as the extremities (see eFig. 206-7.1 in on-line edition) or the face, where lesions may coalesce leading to leonine facies. Viscera are not involved. A progressive/chronic course with relapse after therapy is classic.

Diagnosis of Cutaneous Leishmaniasis.[66,67] Given the potential treatment toxicity, confirmation of the diagnosis is always recommended (Box 206-2). Even when smear, histology, and culture results are combined, in 10 percent to 20 percent of cases, the parasite may not be detected.[33,43] The diagnostic challenge is often greater in New World disease, particularly in lesions more than 6 months old.[53,68] The best approach is to use several diagnostic methods.

Diagnostic Procedures. ***Skin Biopsy.*** Taken from the infiltrated margin, the skin biopsy may be divided into three parts for an impression smear, histologic examination, and culture.

Smears. Several techniques may be used and have a success rate ranging from 50 percent to 80 percent.[33] Smears, easily obtainable from fine needle aspirates or tissue scrapings, are air-dried, fixed with methyl alcohol, stained with Giemsa stain, and viewed under oil-

Box 206-2

Differential Diagnosis of Cutaneous Leishmaniasis (CL)

- Acute CL
  - Arthropod bite
  - Infections [pyoderma, dermatophyte (Majocchi) granuloma, tuberculosis, atypical mycobacterial and deep fungal infections]
  - Cancers (basal cell/squamous cell carcinoma, keratoacanthoma)
  - Lymphoma/pseudolymphoma
  - Foreign body granuloma
- Chronic CL/leishmaniasis recidivans
  - Lupus vulgaris
  - Sarcoidosis
  - Discoid lupus
  - Lymphoma/pseudolymphoma
  - Leprosy
- Diffuse CL
  - Lepromatous leprosy
  - Xanthomas
  - Deep fungal infections
  - Lymphoma

immersion microscopy for optimal results. Impression smears, made by gently pressing the skin biopsy against a glass slide two to five times, provide better sensitivity than of histologic sections.[69]

Histopathology.[70] In both OW– and NW–CL, early lesions exhibit a dense and diffuse mixed inflammatory cell infiltrate composed predominantly of histiocytes and scattered multinucleated giant cells, lymphocytes, and plasma cells (sometimes with intracytoplasmic homogenous eosinophilic immunoglobulin material called *Russell bodies*). Sparing of the papillary dermis (grenz zone), presence of eosinophils and neutrophils, and perineural inflammation[50] are less common. The hallmark of the disease (observed in approximately 70 percent of the cases) is the presence of numerous amastigotes within histiocytes (termed *Leishman-Donovan bodies*) and extracellularly (Fig. 206-8A).[33] Giemsa stain stains the parasite non-metachromatically and the kinetoplast bright red.

The histologic differential diagnosis includes diseases characterized by parasitized macrophages. Features distinguishing other diseases include: in histoplasmosis, the presence of halo surrounding the yeasts; in granuloma inguinale, safety pin–like encapsulated Donovan bodies; and in rhinoscleroderma, Mikulicz cells. Other considerations are blastomycosis, paracoccidioidomycosis, toxoplasmosis, and trypanosomiasis. As the lesion evolves, the number of amastigotes per section decreases and the histology approaches that of CCL in which the predominant histologic pattern is nodular/diffuse noncaseating tuberculoid granulomatous dermatitis (see Fig. 206-8B). Epidermal hyperplasia and ulceration are variable. Scarring with marked loss of elastic fibers may be seen. In DCL, a diffuse infiltrate composed of vacuolated macrophages with numerous intra- and extracellular amastigotes is characteristic. The major differential diagnosis is lepromatous leprosy.

Other Diagnostic Procedures. Laboratory animal inoculation (xenodiagnosis) is useful when the parasite load is low.[33] Electron microscopy offers no advantage over light microscopy and its use is limited.[33]

LABORATORY TESTS. ***Monoclonal Antibodies.*** Monoclonal antibodies directed against specific leishmania antigens may identify, with high sensitivity and specificity, amastigotes and promastigotes in smear, biopsy, or culture specimens. G2D10 antibody has broad *Leishmania* sp. recognition and constitutes a rapid screening test for leishmaniasis,[71] but is not readily available for routine use.

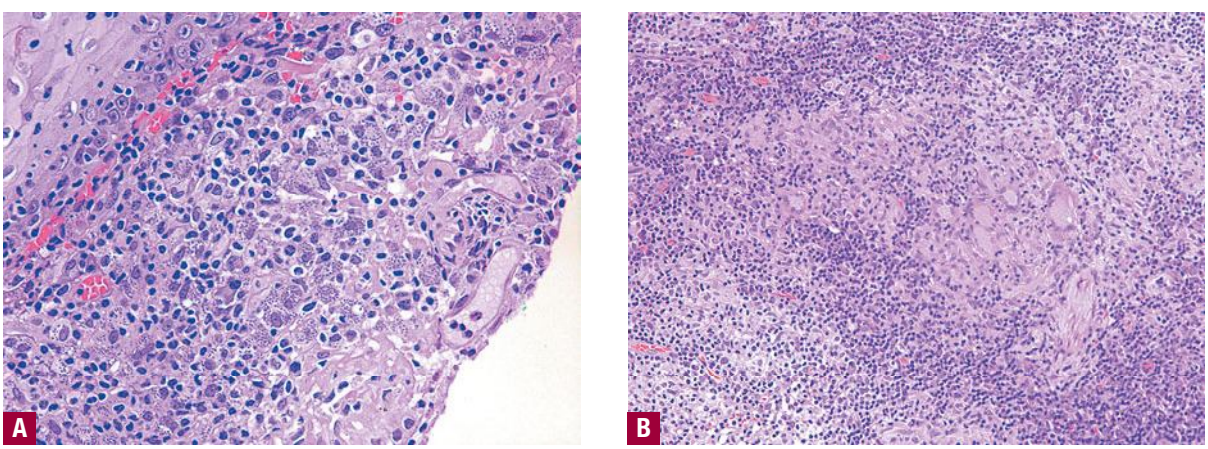
Culture. Culture (at room temperature) using a biphasic medium such as Novy-MacNeal-Nicolle is the gold standard of diagnosis, with a sensitivity of 50 percent.[33] Promastigotes often appear after several days but occasionally may take a few weeks. Species identification is not possible based on their morphology.

Isoenzyme Analysis. Isoenzyme analysis allows for species identification and consists of enzyme electrophoresis of cultured promastigotes. It is based on the fact that morphologically similar promastigotes of different species have different enzyme profiles.

Serology. Serology is not useful due to its low sensitivity (antibodies present in low titre[72]) and specificity (due to cross-reaction with leprosy, malaria, and other trypanosomal infections).

Leishmanin Skin Test. Leishmanin skin test is analogous to the tuberculin test and detects exposure to *Leishmania* without distinguishing between past and active infection.[73] Up to 50 percent of people living in endemic areas may test positive without history of previous or active disease. The test is positive once crusting has developed and negative in anergic states.

Molecular Techniques. Molecular techniques use species-specific oligonucle-



▲ **FIGURE 206-8** Histologic examination (hematoxylin and eosin). **A.** Acute cutaneous leishmaniasis. Moderately dense lymphohistiocytic infiltrate with numerous parasitized macrophages containing amastigotes (Leishman bodies). **B.** Chronic cutaneous leishmaniasis. otide probes for kinetoplast DNA and may be used on all specimens. Polymerase chain reaction (PCR) methods are particularly useful and offer high specificity and improved sensitivity over microscopy and culture, especially in cases in which organisms are scarce.[74–77] False-positive reactions and species identification in NW–CL may be at times problematic. Ethanol-fixed specimens are preferred to formalin-fixed and frozen specimens.[78]

Other Forms of Leishmaniasis

CRYPTIC LEISHMANIASIS Both cutaneous and visceral infection can remain subclinical or manifest with mild, non-specific, and transient symptoms.[3,22,79,80]

MUCOCUTANEOUS LEISHMANIASIS MCL is characterized by the chronic, progressive spread of CL to the nasal, pharyngeal, and buccal mucosa several years after resolution of the primary lesion(s) or, less commonly, while they are still present. It is often a complication of NW–CL caused by *L. b. braziliensis* and *L. b. panamensis* in Central and South America. Ninety percent of cases occur in Bolivia, Brazil, and Peru.[81] In the Old World, similar mucosal lesions caused by *L. aethiopica* may be seen but carry a better prognosis.[82,83] MCL results from direct extension or hematogenous/lymphatic spread to the upper respiratory tract; and rarely ocular and genital mucosa and liver.[33] Bony structures are usually spared. Epistaxis, corrhyza, hyperemia, and nasal septum crusting and ulceration are frequent presenting symptoms and signs. If untreated, the disease evolves into either septal perforation with resulting collapse of the nasal bridge and free hanging nose (tapir nose or parrot beak) or partial/total naso-oropharyngeal mutilating ulceration (espundia) (Fig. 206-9). Secondary infection, pharyngeal obstruction, and respiratory failure are the major causes of mortality. The differential diagnosis includes leprosy, syphilitic gumma, yaws, tuberculosis, deep fungal infections, Wegener granulomatosis, nasopharyngeal carcinoma, and lymphoma. Histopathologic findings are similar to those of CL but organisms are usually sparse. The diagnosis is confirmed by culture and serologic studies. Cure rates decrease in advanced disease.

VISCERAL LEISHMANIASIS VL (*Sikari disease, Burdwan fever, Shahib disease, tropical splenomegaly, kala-azar, death fever, Dumdum fever*) is endemic in the tropical and sub-tropical parts of the world, with 90 percent of cases in Bangladesh, India, Nepal, Brazil, and Sudan.[81] The causative agents belong to the *L. donovani* complex (*L. d. donovani, L. d. infantum*, and *L. d. archibaldi* in the Old World; and *L. d. chagasi* in the New World). Infection with *L. d. donovani* occurs in India and Sudan, is anthroponotic (human host reservoir) and highly endemic, and involves *Phlebotomus argentipes* as a vector. Other infections are zoonotic and dogs are the major reservoir hosts. *L. d. infantum* afflicts mainly malnourished children in China, Africa, the Middle East, and the Mediterranean countries. In the New World, *L. longipalpis* is the only sand fly vector.

▲ **FIGURE 206-9** Mucocutaneous leishmaniasis, South American. Painful, mutilating ulceration with destruction of portion of the nose.

Hematogenous dissemination usually follows skin inoculation, but congenital transmission can occur.[11] Most infections remain sub-clinical. The incubation period and the duration of the disease are variable. The cardinal features of VL are persistent high undulating fever, leukopenia, anemia, splenomegaly, and hypergammaglobulinemia. Other findings include emaciation, "burning feet" (peripheral neuropathy), hepato-gastrointestinal disturbances, epistaxis, thrombocytopenia, and lymphadenopathy. Skin lesions develop later in the course of the disease and consist of ashy hyperpigmented patches on the temple, around the mouth, and on the abdomen, hands, and feet in light-skinned persons; hence, the name kala-azar (in Hindi, black sickness). Other findings include hair and skin depigmentation (in Kenyan patients),[33] cutaneous nodules and mucosal ulcers (in Sudanese patients),[33] trichomegaly (Pitalugo's sign), petechiae, and jaundice.[33]

Without treatment, the fatality rate in developing countries approaches 100 percent in 2 years, with the major complications being cachexia and secondary infections. Hemolytic anemia, acute renal damage, and severe mucosal hemorrhage are less common. Identifying the parasite in the spleen (most sensitive), sternal marrow, lymph nodes, blood, liver, nasopharynx, or skin (even non-lesional) is diagnostic.

Visceral Leishmaniasis and Human Immunodeficiency Virus Co-Infection.[84] Most co-infection cases have intravenous (IV) drug use as a common denominator[85] and represent diagnostic and therapeutic challenges because VL precipitates the onset of AIDS and HIV increases the risk of VL. The problem is mostly described in Spain, Italy, France, and Portugal.[34,81,85–87] *L. d. infantum* is the major causative agent. MCL-, post-kala-azar dermal leishmaniasis (PKDL; see Post-Kala-Azar Dermal Leishmaniasis)– and DCL-like pictures may result,[88] and cutaneous lesions are highly variable.[59] Multiple dermatofibroma- and Kaposi sarcoma–like papulonodular lesions may occur[85] and should be differentiated from parasitic colonization of Kaposi sarcoma.[89] The presence of amastigotes in atypical locations tend to correlate with the degree of immunosuppression.[90] Other *Leishmania* sp. that do not normally affect the viscera have been isolated.[64,65,91]

POST-KALA-AZAR DERMAL LEISHMANIASIS[92] PKDL is extremely rare in the New World and is mostly seen in Sudan and India. In India, PKDL is the most common skin manifestation of leishmaniasis (see eFigs. 206-9.1 and 206-9.2 in on-line edition). Affected patients are the major reservoirs of the infection.[93] The lesions may seldom develop during the treatment of VL.[93,94] High blood concentration of interleukin-10 in VL patients is considered predictive of PKDL development.

VISCEROTROPIC LEISHMANIASIS[31] Caused by *L. tropica*, viscerotropic leishmaniasis has been described among American veterans of Operation Desert Storm. Visceral infection manifests as fever, malaise, and variable hematologic and hepato-gastrointestinal findings. Classic signs of VL are absent and the skin is not involved. Positive culture from bone-marrow aspirates and good response to antimonials are typical.

LEISHMANID Leishmanid was used to describe an id reaction consisting of a papular eruption in the setting of LR.[95]

Prognosis and Clinical Course[22]

The clinical course is disease dependent. In general, life long species-specific im-

TABLE 206-2
Treatment Options Based on *Leishmania* Species

TYPE	SPECIES	TREATMENT
Old World–CL	*L. major*	Expectant observation; local therapy
	Multiple, progressive, or sporotrichoid	Systemic therapy
	L. tropica, L. aethiopica, L. infantum	Systemic therapy
New World–CL	*L. mexicana* complex	Expectant observation; systemic therapy
New World–mucoCL	*L. braziliensis* complex	Systemic therapy

CL = cutaneous leishmaniasis.

munity follows drug-induced cure or natural resolution.[96] Cross-species immunity may also develop.[97] Sterile immunity does not occur and persistent low-grade tissue infection seems to be the rule even after adequate therapy.[30,98–100]

Treatment[101–104]

Given the clinical diversity of leishmaniasis and the lack of adequately controlled therapeutic trials, each case needs to be individualized based on the parasite species (Table 206-2), extent of the disease, host immune and nutritional status, presence of intercurrent diseases, geographic region, and cost and availability of the various therapeutic options. In general, NW–CL tends to be more severe and progressive than OW–CL. In addition, NW–CL caused by *L. braziliensis* may evolve into "espundia," thus necessitating systemic therapy. As a rule, patients should be monitored until the lesions have completely healed. Follow-up at 6 months is then appropriate.

Because most lesions caused by *L. major* and *L. mexicana* heal spontaneously within 4 months, an expectant approach is favored as it may confer protective immunity. Multiple, persistent, progressive, deep, sporotrichoid, and secondarily infected lesions should, however, be treated, as well as lesions on cosmetically or functionally important sites.

Local therapy (Table 206-3) is appropriate for small, noninflamed lesions that are not at risk to progress to MCL. Topical imiquimod alone is ineffective.[105] Systemic therapy is reserved for complicated CL such as DCL and CCL, MCL, VL, relapsing disease, or disease complicated by HIV co-infection. In general, OW–CL requires shorter courses than NW–CL. Sodium stibogluconate (Pentostam) and meglumine antimoniate (Glucantime) are pentavalent antimony derivatives with slightly differing antimony concentrations and comparable efficacy and safety profiles. By presumably inhibiting the glycolysis and fatty acid oxidation in leishmania, they are the mainstay of systemic treatment.[106] Indian VL is treated with 20 mg/kg/day intramuscularly or IV once daily for 40 days versus 28 days if the disease is contracted elsewhere. Antimony resistance[107] is a substantial problem in India[108,109] and in Iran.[110] Resistant cases may benefit from combining antimonials with allopurinol,[111–114] paromomycin,[115,116] azithromycin,[117–119] interferon-γ,[120–122] granulocyte-macrophage colony-stimulating factor,[123] and topical imiquimod.[124,125] Amphotericin B[126,127] and its lipid formulation,[128–130] and paromomycin,[131,132] are other alternative monotherapies. Oral miltefosine is promising in the treatment of Indian VL[133–135] and NW–CL.[136] Non-antimonial systemic therapies are summarized in Table 206-4.

TABLE 206-3
Local Therapy for Leishmaniasis

- Excision or laser ablation[209]
- Cryotherapy,[210] local heat,[27] or electrotherapy[211]
- Intralesional antimonial,[212–215] combined with cryotherapy[216]
- Paromomycin ointment[212,217,218]
- Topical azoles[219]
- Others: Ethanolic formulation of amphotericin B,[220,221] topical glyceryl trinitrate,[222] hypertonic sodium chloride,[223,224] intralesional metronidazole[225]

TABLE 206-4
Non-Antimonial Systemic Therapy for Leishmaniasis

- Amphotericin B[126,127] and its lipid formulation[128–130]
- Paromomycin[131,132]
- Miltefosine[133–135]
- Azoles[5,226–231]
- Terbinafine[232]
- Metronidazole [225,233,234]
- Dapsone[235,236]
- Interferon-γ[237]
- Pentamidine and/or allopurinol[238–241]
- Trimethoprim-sulfamethoxazole[242,243]
- Rifampin[244]
- Nifurtimox[245,246]
- Quinolones[247]
- Pyrimethamine[248]
- Oral zinc sulfate[249,250]
- Anti–interleukin-10[99] (experimentally lead to sterile cure)

Prevention and Vaccines

Essential to prevention is the promotion of personal protective measures through the use of protective clothing, insect repellents containing 30 percent to 35 percent DEET, permethrin-treated bed nets and clothing; and the avoidance of endemic areas.[137] Mapping of leishmania and sand fly genomes[138–140] and good understanding of the epidemiology of reservoir hosts and vectors are important for effective control. Targeting anthroponotic foci that are at the origin of deadly epidemics, suspecting leishmaniasis in persons with skin lesions or febrile illnesses returning from endemic areas, and deferring prospective blood donors from donating blood for at least 1 year after their return are other measures.

New diagnostic tests, drugs, and vaccines[97,141,142] are in development, although limited by the poor prospect for financial return.[143] "Leishmanization," the self-inoculation of the live parasite in inconspicuous areas of the body, has been practiced in endemic areas to prevent disfiguring facial lesions, but was later abandoned due to its complications. Killed promastigotes vaccines with and without adjuvant bacille Calmette-Guérin seem to be useful in endemic areas.[97,144] Adjuvants such as bacille Calmette-Guérin are important to prime a Th1 response. Attenuated live parasites and plasmid DNA–based vaccines using leishmanial antigens have shown efficacy in mouse models.[97] Experimental vaccines containing a component of sand fly saliva proteins appear to be promising.[145]

AFRICAN TRYPANOSOMIASIS[146,147]

Epidemiology

African trypanosomiasis (Af-T; sleeping sickness) affects up to one-half of a million people every year in the middle latitudes of Africa where the vector is found. Fatality rate approaches 100 percent in untreated patients. The disease is very rare in the United States.[147]

Etiology and Pathogenesis

Trypanosoma brucei, the causative organism, enters the bloodstream of a mammalian host via the bite of a blood-feeding infected male or female tsetse fly of the genus *Glossina*. After the bite, infectious metacyclic forms transform into trypomastigotes, which multiply and mature locally in the skin and later invade most tissues. These flies are attracted by dust clouds of moving objects and animals, and by black color. They bite most during early daylight and at dusk, and ingest trypomastigotes from infected blood meals.

Af-T presents in two distinct forms. West African or Gambian trypanosomiasis (GT) (caused by *T. b. gambiense*) is a chronic, predominantly anthroponotic disease present in rural areas west of the Rift Valley. East African or Rhodesian trypanosomiasis (RT) (caused by *T. b. rhodesiense*) is an acute fatal disease (within weeks, if untreated) that infects mainly livestock/game animals east of the Rift Valley, and sporadically herdsmen and tourists.[148–150] Water requirements of the *palpalis* group of tsetse flies and the savannah habitat of *G. morsitans* determine the geographic distribution of GT and RT, respectively.

Clinical Manifestations

Similar to syphilis, three clinical stages characterize Af-T. As a rule, the skin is more involved in RT and in light-skinned patients. The first stage consists of a painful chancre that develops at the site of the tsetse-fly bite and resolves within 1 to 3 weeks, leaving no scar. It consists of a circumscribed, rubbery, indurated, 2- to 5-cm dusky red nodule, often with a central eschar (Fig. 206-10). It is rarely seen in native Africans. The second stage is characterized by hemolymphatic spread. Local lymph node involvement progresses to generalized lymphadenopathy in virtually all African natives and in approximately one-half of European patients. Involvement of the posterior cervical (Winterbottom's sign) and supraclavicular lymph nodes is characteristic only of GT. In the lymph nodes, trypanosomes stimulate antibody production and undergo antigenic variations to evade the host immune response. Hepatosplenomegaly, irregular spiking fevers, constitutional symptoms, anemia, thrombocytopenia, and pruritus (especially presternal) develop, and may be related to circulating immune complexes. The reaction is more severe in RT, in which myocarditis and rarely fatal disseminated intravascular coagulopathy develop.[147] Trypanids are distinctive eruptions that develop 6 to 8 weeks after the onset of fever in approximately one-half of light-skinned patients and consist of poorly defined, centrally pale, evanescent, annular, targetoid or blotchy erythematous macular, hemorrhagic, urticarial, or erythema nodosum–like lesions, commonly on the trunk. A sensation of formication may be associated. The eruption waxes and wanes over weeks with accentuation on exposure to cold, heat, or sweat. Painless swelling of the face (imparting a sad look), and of the hands and feet may occur. Other findings include ichthyosis, acroparesthesias, icterus, petechiae, and generalized flushing. The third stage is characterized by central nervous system involvement weeks to months after exposure in RT, and months to years after exposure in GT. Chronic meningoencephalitis, with an irresistible urge to sleep, is followed by coma and death. Delayed bilateral pain out of proportion to a sharp squeeze applied to soft tissues, known as *Kerandel's deep delayed hyperesthesia*, is characteristic. The skin is not involved.

Diagnosis

Diagnosis of Af-T is via detection of trypanosomes in blood film, chancre/lymph node aspirate, buffy coat, bone marrow, or cerebrospinal fluid. Histologically, long, thin trypanosomes are best seen using Giemsa stain, in the midst of a perivascular lymphoplasmacytic infiltrate. Due to antigenic variability, serologic tests lack sensitivity and specificity.[148] Differentiation of RT from GT is usually based on epidemiology. PCR is the method of choice, but cost limits its use in African countries.[151] New diagnostic tools are being developed.[152–154]

▲ **FIGURE 206-10** East African trypanosomiasis. The trypanosome chancre consists of erythematous nodule with central bulla and ulceration. This patient was treated with Suramin and survived. (From Case Records of the Massachusetts General Hospital, Case 20-2002, *N Engl J Med* **346**:2069, 2002, with permission of the Massachusetts Medical Society.)

Treatment and Prevention

Control of Af-T in endemic areas is highly cost-effective and entails case detection and treatment, keeping tsetse populations at low levels,[154] and mass screening of at-risk populations. Regarding therapy,[104,152] four registered drugs are currently provided free of charge by the World Health Organization. Suramin and pentamidine are the drugs of choice for early stage RT and GT, respectively. Melarsoprol, an arsenical, is a powerful trypanocide able to cure both RT and GT in all stages; however, due to its toxicity, its use is restricted to late-stage disease of both forms. Eflornithine is cytostatic and can only be used in GT. Of concern, HIV-positive patients receiving treatment for RT may succumb to full-blown AIDS.[151]

CHAGAS DISEASE (AMERICAN TRYPANOSOMIASIS)[155]

Epidemiology

American trypanosomiasis (Am-T) is a zoonotic disease caused by *Trypanosoma cruzi* and transmitted to humans by blood-sucking triatomine bugs (kissing bugs, assassin bugs, reduviid bugs). It is endemic in many rural areas of Central and South America and Mexico. In the United States, up to 100,000 Latin-American immigrants are affected.[156]

Etiology and Pathogenesis

Triatomine bugs are large (3 to 4 cm), "cone-nosed" bedbugs that become infected with *T. cruzi* by feeding, usually at night, on contaminated blood. The ingested trypomastigotes transform into epimastigotes, multiply in the vector's midgut, and differentiate into infective metacyclic trypomastigotes in the hindgut. An infected triatomine bug takes a blood meal and releases trypomastigotes in its feces near the site of the bite wound, usually a mucocutaneous junction. Human infection occurs when mucous mem-

branes, especially the conjunctiva, or breaks in the skin are contaminated with the feces on rubbing or scratching. The trypomastigotes invade host cells, where they differentiate into intracellular amastigotes that multiply by binary fission and differentiate again into trypomastigotes, which are then released into the circulation to infect a variety of tissues. Congenital transmission[157] and transmission by blood transfusion and organ transplantation[155,158–160] may occur.

Clinical Manifestations and Treatment

Am-T progresses in three stages (Table 206-5). Diagnosis and treatment are problematic. In the first stage, diagnosis involves microscopic demonstration of trypomastigotes in blood specimens, hemoculture, or xenodiagnosis. Thereafter, detection of organisms becomes difficult, and diagnosis relies more on serologic testing or PCR. Benznidazole (not available in the United States) and nifurtimox are toxic[161] and only effective when given during the first stage of the infection. Later, management is directed to complications, as neither drug is effective. Preventive measures seek to eradicate the vectors, improve diagnostic tests, develop less toxic and more efficient drugs, and implement serologic screening of organ donors and recipients. Control programs have reduced the incidence of Am-T by 70 percent in some countries of South America.[162]

TABLE 206-5
Clinical Stages of Chagas Disease

Acute phase (first stage)	• Transient parasitemia: usually asymptomatic or associated with fever, lymphadenopathy, mild hepatosplenomegaly, and morbilliform/urticarial rash; duration ~8 wk. • Chagoma: painful inflammatory reaction at the site of inoculation: 1- to 3-cm erythematous, often ulcerated nodule with a surrounding pale halo. Local lymphadenopathy often present. • Romana's sign: Unilateral conjunctivitis with palpebral edema (from conjunctival inoculation).
Indeterminate phase (second stage)	• Low levels of the parasite in blood and other tissues → chronic asymptomatic and infectious state. • Reactivation of the infection after organ transplantation (disseminated painful subcutaneous and/or ulcerated nodules[155,251,252]).
Symptomatic chronic phase (third stage)	• In 10%–30% of patients, often many years after initial infection. • Lethal dilated cardiomyopathy, arrhythmias, megaesophagus, and megacolon. • Pathogenesis: molecular mimicry?[253,254]

CUTANEOUS AMEBIASIS[163]

Etiology and Epidemiology

Entamoeba histolytica, of the class Sarcodina and genus *Entamoeba*, is a pathogenic ameba that can cause intestinal and extraintestinal diseases. Amebiasis is the second leading cause of death from parasitic diseases, with higher incidence in Mexico and developing tropical countries.[164] In developed countries, risk groups include male homosexuals, travelers, immigrants, and institutionalized patients. *Entamoeba* exists in two forms: the capsuled cyst (10 to 15 μm) or infective stage, and the mobile trophozoite or tissue-invasive stage. Both forms are passed in the feces. Human beings are the only natural hosts and infection generally occurs by ingestion of mature cysts from fecally contaminated food, water, or hands. Anal sex and contaminated enema equipment are other modes of transmission.[163]

Trophozoites have marked phagocytic, proteolytic, and cytolytic capabilities, invading human colonic mucosa, and occasionally penetrating through to the portal circulation, reaching the liver and other organs, and causing fatal lesions. Some mammalian cells appear resistant to trophozoites adherence,[163] but most cases of asymptomatic non-invasive "luminal amebiasis" are caused by *E. dispar,* rather than *E. histolytica*.[165]

Clinical Manifestations, Diagnosis, and Treatment

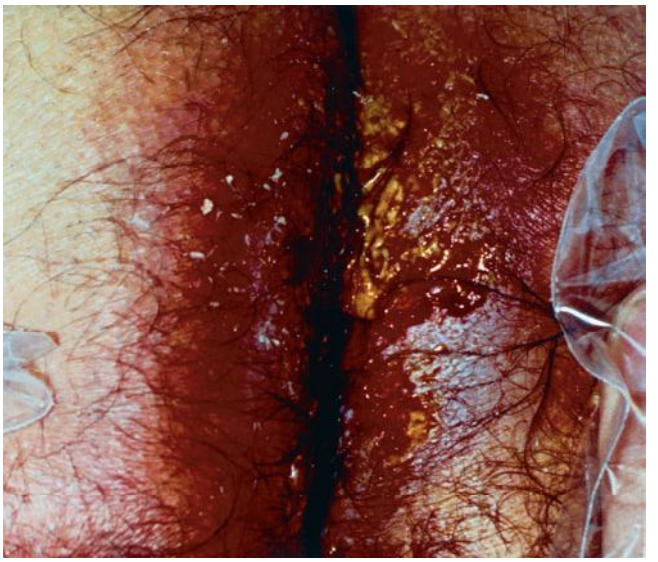
Depending on the transmission mode and extent of invasion, the clinical spectrum includes three major presentations:

1. Invasive intestinal disease (dysentery, colitis, and amebomas).
2. Invasive extraintestinal disease (liver abscess, peritonitis, and pleuropulmonary abscess). Indirect cutaneous extension may occur, often in the setting of an underlying/contiguous abscess, fistula, colostomy, or laparotomy incisions.[164,166]
3. Direct cutaneous transmission of the trophozoites results from spread through contaminated stool to the anal/perianal or perineal/genital skin. Penile lesions are often acquired through anal intercourse. Autoinoculation via contaminated hands may account for more non-anogenital lesions.[167–169]

Both direct and indirect cutaneous transmissions are rare and result in rapidly progressive, foul-smelling, and painful punched-out ulcers with glairy, hemopurulent, raw beef–like base; necrotic, cord-like and undermined borders; and surrounding erythema (Fig. 206-11). Lesions may reach up to 20 cm in diameter and are often destructive if untreated. Chronic urticaria may be associated[170] and local lymphadenopathy is common. The diagnosis relies on identification of cysts and/or trophozoites in infected stool, mucosa, or skin. This method, however, cannot distinguish between *E. histolytica* and *E. dispar*. Enzyme-linked immunosorbent assays are useful in this regard. Stool culture and PCR are only available as research tools. Serology may be helpful but false negativity may occur in early infection. Skin biopsy reveals ulceration, mixed inflammatory cell infiltrate, and areas of necrosis where trophozoites may be identified as round or oval cells (20 to 50 μm) with basophilic cytoplasm, an eccentric nucleus with central karyosome, and often displaying erythrophagocytosis (sign of pathogenicity).[171] For symptomatic intestinal or extraintestinal disease, the drug of choice is metronidazole (750 mg three times a day for 10 days), followed by treatment with one of the luminal agents iodoquinol, paromomycin, or diloxanide furoate.[104]

OPPORTUNISTIC AMEBAS

The free-living amebas belonging to the genera *Naegleria*, *Acanthamoeba*, and *Leptomyxida* (*Balamuthia*) are ubiquitous in air, soil, and water, and cause only few diseases in immunocompetent patients such as acanthamebic keratitis (in contact lens wearers) and primary amebic meningoencephalitis (caused by *N. fowleri*). Immunocompromised patients, primarily those with AIDS and organ transplant recipients, are at risk of disseminated disease.[172] Skin lesions are the



▲ **FIGURE 206-11** Cutaneous amebiasis. A painful, ragged, foul-smelling ulcer with an erythematous halo in the perianal region.

most common (75 percent to 90 percent of the cases[173,174]) and sometimes the sole manifestation of the disease. The extremities and face are commonly involved. Papules, plaques, nodules, pustules, cellulitis, non-healing ulcers with rolled borders, eschars, and palatal ulceration have been described.[173] A rare slowly progressive, fatal neurologic process—granulomatous amebic encephalitis—is caused by *Acanthamoeba* and *Leptomyxida*.[175–178]

Histopathologically, a dermal and/or subcutaneous predominantly neutrophilic infiltrate is present, sometimes with vasculitic, and granulomatous changes.[173,179] The identification of 20 to 30 μm trophozoites with abundant vacuolated cytoplasm, and central nuclear karyosome is diagnostic but may be difficult due to their macrophage-like appearance.[173] The disease is often fatal but early treatment using a combination of IV pentamidine and oral fluconazole, sulfadiazine, and flucytosine may improve the outcome. HIV-positive patients may benefit from antiretroviral therapy.[172]

TOXOPLASMOSIS[180–183]

Toxoplasmosis, caused by the parasitic protozoan *Toxoplasma gondii* (class Sporozoa), is one of the most common human infections worldwide. The main reservoirs of *T. gondii* infection are members of the cat family (Felidae) which are thought to become infected by eating infected mice. Viable organisms invade the feline intestinal epithelium where they undergo an asexual transformation, followed by a sexual cycle, and then form oocysts, which are excreted in large numbers and are resistant to harsh environmental conditions and disinfectants. Human infection results mainly from ingestion of cyst-containing undercooked meat, but can also result from ingestion of the oocysts from fecally contaminated hands or food, organ transplantation,[184] blood transfusion,[185] and transplacental transmission.[186] The parasites form tissue cysts, mostly in skeletal muscle, myocardium, and brain and may remain asymptomatic. Invasion of the reticuloendothelial/endothelial systems results in suppuration and granuloma formation. Three major clinical forms are identified:

1. Congenital toxoplasmosis[186] may manifest as abortion, stillbirth, microcephaly, tram-track intracerebral calcifications,[187] and chorioretinitis.[188] Skin lesions include purpura, jaundice, blueberry muffin lesions (dermal erythropoiesis), and erythroderma. Untreated sub-clinical infection may reactivate during the second and third decade of life, mostly in the form of retinochoroiditis.[189]
2. Acquired toxoplasmosis in immunocompetent persons is asymptomatic in 80 percent to 90 percent of cases.[190,191] However, 10 percent to 20 percent of patients develop cervical lymphadenopathy and a flu-like illness. Clinical manifestations are protean, reflecting heterogeneous immune responses to the organism,[180] mimicking among others dermatomyositis[192–197] or pityriasis lichenoides (Table 206-6).[191,198–201]
3. Toxoplasmosis in immunodeficient patients is often secondary to reactivation of latent infection and presents as disseminated disease. Toxoplasmic encephalitis is the most common cause of intracerebral lesions in AIDS patients. Disseminated papular/nodular eruption may occur.[84,80,202–204]

TABLE 206-6
Cutaneous Lesions Seen in Acquired Toxoplasmosis in Immunocompetent Persons

- Dermatomyositis-like syndrome[192–197]
- Pityriasis lichenoides[191,198–201]
- Sweet syndrome[255]
- Cold urticaria[256]
- Erythroderma[257]
- Palmoplantar maculopapular rash[183]
- Cellulitis[195–197]
- Morphea[258]
- Mastocytosis[259]
- Others: Lichen planus pilaris, pityriasis rubra pilaris, capillaritis, papular acantholytic dermatosis, keratosis lichenoides chronica,[260] chronic prurigo,[195] scarlatiniform eruption, panniculitis,[261] erythema multiforme[205]

Diagnosis is routinely made by serology. Protozoa may be identified in bronchoalveolar lavage, lymph node specimens, or skin biopsies. Tachyzoites, visualized with Wright or Giemsa stain, are crescent-shaped and have a prominent, centrally placed nucleus. The most common histologic finding is subacute histiolymphocytic vasculitis with demonstration of trophozoites within macrophages.[205] Epidermotropic infection and neural infiltration may occur.[206] Other methods include PCR[207] and xenodiagnosis. Toxoplasmosis should be sought in patients with a dermatomyositis-like picture. Sulfadiazine and pyrimethamine act synergistically and provide together effective therapy.[104]

CHAPTER 207

Helminthic Infections

Mary Elizabeth Wilson
Eric Caumes

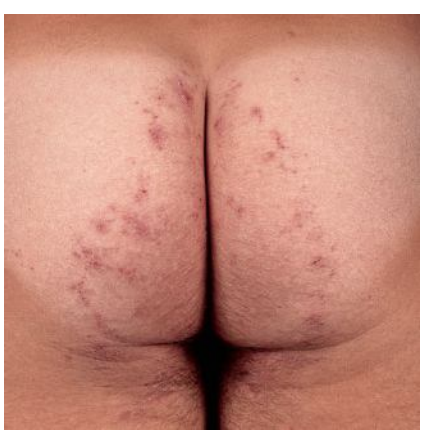
OVERVIEW: RELATIONSHIP BETWEEN HELMINTHS AND CUTANEOUS SIGNS

Helminths are worms. Those that infect human beings and produce cutaneous signs belong to three groups: nematodes (round worms), trematodes (flukes) and cestodes (tapeworms; Fig. 207-1). They have complex life cycles.[1–3] The helminths that are well adapted to humans (i.e., human helminths) accomplish a complete cycle from larval stage to adult in the human host, whereas animal helminths cannot reach the adult stage in humans (who are dead-end hosts), although infection can still cause tissue damage and clinical findings.

Helminths induce a dramatic expansion of the T helper 2 (Th2) lymphocyte subset with hyper immunoglobulin E (IgE), eosinophilia, and an increase in tissue mast cells. It is unclear whether these Th2-derived responses are important in the protective immune response to the parasite, are responsible for immune-mediated pathology, or both.[4] Despite high levels of IgE and other features of Th2 cell activation, allergic responses are rarely observed in infected individuals except during the invasive phase of infection. Helminths can survive for years. Infected hosts have evolved elaborate immune evasion strategies to allow these long-lived infections, including the induction of tolerance to parasite antigens.

The cutaneous manifestations of these helminthic diseases are varied and can be seen at every phase of the helminth cycle: penetration (if cutaneous), invasive (or acute), and chronic (or focal).

- During the penetration phase of the cycle, cutaneous signs are observed only for helminths that infect by penetrating human skin. In such cases, the signs last a short time for human helminths or a longer time for animal helminths, such as animal hookworms, the cause of the cutaneous larva migrans (CLM) syndrome.
- During the acute phase of the disease (invasive phase of the helminthic cycle), the primary cutaneous finding is urticaria. Again, the duration of the urticarial episode is short when the helminths are well adapted to humans, whereas it may last for weeks or even months when they are not, as is the case with the helminths that cause the visceral larva migrans syndrome.
- During the chronic phase, cutaneous manifestations vary according to the type of helminth, and they are related to the presence of the adult worm or the eggs or the larvae in the subcutaneous tissue or skin. The most common clinical presentations are creeping dermatitis (Table 207-1), panniculitis, papules, or nodules (Table 207-2).



▲ **FIGURE 207-1** Larva currens. Multiple, pruritic, serpiginous, inflammatory lesions on the buttocks in chronic strongyloidiasis.

HELMINTHIC INFECTIONS AT A GLANCE

- A common cause of morbidity and mortality in tropical and developing countries. Skin and soft-tissue findings accompany many of these infections.
- Some parasites can survive for years in the human host with first symptoms and signs developing days to years after infection.
- Eosinophilia and other manifestations of immediate hypersensitivity often occur during the tissue migration phase.

APPROACH TO A PATIENT WITH SUSPECTED HELMINTHIC INFECTION

Clinical Approach

Helminthic skin diseases may lead returning travelers and immigrants to consult a physician.[5,6] To properly diagnose skin lesions, a thorough history and physical examination are essential. The patient history should include geographic location(s) and durations of stay; activities, including occupational exposures; type of accommodations; dietary habits (food and water); exposures (beach, fresh- or saltwater, insects, plants, animals); personal contacts; history of similar signs and symptoms in other family members, fellow travelers, or persons who have visited same areas; use of preventive measures (insect repellent, mosquito netting); and any known recent outbreaks or diseases en-

TABLE 207-1
Summary of Helminths Included in This Chapter

Helminth(s)	Disease	Portal of Entry	Source of Infection
Ancylostoma braziliense, other	Cutaneous larva migrans	Skin	Larvae from animal feces in soil
A. duodenale, Necator americanus	Hookworm	Skin, usually feet	Larvae in soil
Ascaris lumbricoides	Ascariasis	Gastrointestinal[a]	Eggs from contaminated food, soil
Dirofilaria sp.	Dirofilariasis	Skin	Larvae in mosquito
Dracunculus medinensis	Dracunculiasis	Gastrointestinal[a]	Infective copepods in water
Echinococcus sp.	Echinococcosis	Gastrointestinal[a]	Eggs from animal (usually dog) feces
Enterobius vermicularis	Enterobiasis (pinworm)	Gastrointestinal[a]	Eggs in environment
Fasciola sp.	Fascioliasis	Gastrointestinal[a]	Metacercariae on plants, in water
Gnathostoma spinigerum, other	Gnathostomiasis	Gastrointestinal[a]	Larvae in animal flesh
Loa loa	Loiasis	Skin	Infective fly
Onchocerca volvulus	Onchocerciasis	Skin	Infective *Simulium* fly
Paragonimus westermani, other	Paragonimiasis	Gastrointestinal[a]	Metacercariae in seafood
Schistosoma mansoni, other	Schistosomiasis	Skin	Cercariae in water
Schistosomes, nonhuman	Cercarial dermatitis	Skin	Cercariae in water
Spirometra sp.	Sparganosis	Gastrointestinal[a]	Larvae in copepod or in animal flesh
Strongyloides stercoralis	Strongyloidiasis	Skin	Larvae in soil, feces
Taenia multiceps, other	Coenurosis	Gastrointestinal[a]	Eggs (from animal feces) in food, water
T. solium	Cysticercosis	Gastrointestinal[a]	Eggs from feces
Toxocara canis, other	Visceral larva migrans	Gastrointestinal[a]	Eggs in soil
Trichinella spiralis	Trichinosis	Gastrointestinal[a]	Larvae in animal flesh
Wuchereria bancrofti, other	Filariasis	Skin	Infective mosquitoes

[a]Ingestion.

demic to geographic areas previously lived in or visited. The history should also include a thorough review of medications and other preparations (including herbal and local treatments) that the patient may have used. The dermatologic history should include initial presentation and progression of lesions, time of onset relative to potential exposures, duration of lesions, anatomic distribution, and any associated local and systemic signs and symptoms.

Laboratory and Diagnostic Evaluation

Levels of eosinophils in the blood vary according to the stage of infection. The level is typically low during the penetration phase and reaches highest levels during the invasive phase of the cycle. Thereafter it often decreases slowly and may fluctuate more or less above the normal value during the chronic phase. A transient hypereosinophilia may be observed approximately 10 days after the start of effective treatment. Serologic tests vary greatly in their sensitivity and specificity; a common problem is cross-reactivity among the various nematodes, trematodes, and cestodes.

The diagnosis of an helminthic infection is often difficult during the penetration and acute phase of the disease; diagnosis may be suspected because of associated epidemiologic and clinical findings. In the chronic phase, diagnosis is often based on identification of parasite's eggs or larvae. The delayed appearance of antibodies (beginning during the invasive phase) means that serologic tests may need to be repeated to identify a seroconversion.

Sections that follow describe key features of the most common and important helminthic infections. Details about recommended treatment and how to obtain access to unusual drugs can be found in specific listed references[7–9] and through *The Medical Letter*, which is regularly updated and can be accessed online at http://www.medicalletter.org.[10]

HUMAN NEMATODES (ROUNDWORMS)

Intestinal Nematodes

ASCARIASIS ***Synonyms.*** Roundworm infection, ascaridiasis.

Epidemiology. Ascariasis is found worldwide; global prevalence is estimated at 807 million. The highest rates of infection are in children, in hot and humid climates, and in areas with crowding and poor sanitation. Clay soils are especially suited for the survival of *Ascaris* sp.

Etiology and Pathogenesis. Ascariasis is caused by *Ascaris lumbricoides* and occasionally by *A. suum,* the pig roundworm.[11,12] *A. lumbricoides* is the largest intestinal nematode (female measures 20 to 35 cm in length and 3 to 6 mm in thickness; male measures 11 to 22 cm in length). Humans become infected with *A. lumbricoides* by ingesting infective eggs in soil contaminated with human feces (e.g., contaminated fruits, vegetables, water, and hands).

Clinical Findings. **Related Physical Findings.** Pulmonary symptoms, urticaria, and eosinophilia may begin 10 to 14 days after ingestion of *A. lumbricoides* eggs. Gastrointestinal symptoms may precede the shedding of eggs in feces, which begins 50 to 75 days after ingestion of infective eggs. Initial symptoms may be noted weeks or months after onset of infection. Most adult worms survive 8 to 12 months; occasionally, as long as 24 months.

Cutaneous Lesions. Urticaria occurs only during the invasive phase of the disease and may be associated with the pulmonary manifestations of Loeffler

TABLE 207-2
Helminthic Causes of Migratory Dermatologic Lesions

DISEASE	HELMINTH(S)	COMMENTS
Cutaneous larva migrans	Primarily *Ancylostoma braziliense* and *A. caninum*	Larvae of dog and cat hookworms
Dirofilariasis	*Dirofilaria immitis* and other *Dirofilaria* sp.	Usually a discrete nodule
Dracunculiasis	*Dracunculus medinensis*	Movement of worm just below dermis before eruption
Fascioliasis	*Fasciola hepatica* and *F. gigantica*	Migratory areas of inflammation, especially with *F. gigantica*
Gnathostomiasis	*Gnathostoma spinigerum* and other *Gnathostoma* sp.	Migratory inflammatory lesions, 1 cm/hr or faster when subcutaneous
Loiasis	*Loa loa*	Migratory inflammatory swellings; worm may be visible crossing conjunctivae
Paragonimiasis	Primarily *Paragonimus westermani*	Subcutaneous migratory swelling or subcutaneous nodules
Sparganosis	*Spirometra erinacei, S. mansoni, S. mansonoides,* and *S. proliferum*	Occasionally migratory; larval movement
Strongyloidiasis	*Strongyloides stercoralis*	Migratory, serpiginous lesions (larva currens), 5–10 cm/h

syndrome (cough, wheezing, dyspnea), fever, and vague gastrointestinal symptoms. It disappears spontaneously at the end of this phase.

Laboratory Tests. A peripheral eosinophilia may accompany the invasive stage.

The diagnosis is made by finding eggs in feces, which does not occur until after the dermatologic manifestations of the invasive stage have disappeared. The diagnosis is also rarely made based on the identification of the adult worm in stool, pharynx, or an operative specimen or by finding larvae in sputum or gastric lavage. Transient bilateral infiltrates on chest x-ray films are seen early in infection.

Differential Diagnosis. For the skin lesions, differential diagnosis includes the causes of acute urticaria (see Chap. 37).

Complications.

Treatment. Treatment options include albendazole, mebendazole, pyrantel pamoate, or levamisole (Box 207-1).[12]

Prevention. Proper waste disposal and avoidance of ingestion of fecally contaminated soil prevents ascariasis. The embryonated eggs of *A. lumbricoides* can remain viable in soil for years.

ENTEROBIASIS ***Synonyms.*** Threadworm, pinworm, or seatworm infection, oxyuriasis.

Epidemiology. Enterobiasis is found worldwide and is the most common helminthic infection in industrialized countries. The highest rates of infection are among children.

Etiology and Pathogenesis. Enterobiasis is caused by *Enterobius vermicularis*.[13]

Humans, the only host for the parasite, become infected by ingesting infective *E. vermicularis* eggs (e.g., direct anus-to-mouth transfer by fingers or sexual activities, contact with contaminated objects, such as bed linens, clothing, bathroom fixtures) and the inhalation and ingestion of airborne eggs in dust. Eggs become infective within a few hours of being deposited by the female worm in the perianal area.

Clinical Findings. Nocturnal anal and perianal pruritus is the primary clinical feature. The worm may be seen around the anus. The skin may become impetiginized and give rise to cellulitis. In females, vulvovaginitis may occur, and a nodular lesion of the vulva has been described.[14]

Laboratory Tests. The results of laboratory studies are usually normal. Eosinophilia occurs only during tissue invasion.

Special Tests. Enterobiasis is diagnosed by identification of *E. vermicularis* eggs in the perianal area. This is most effectively done by pressing transparent tape on a glass slide to the skin in the perianal area, then reviewing it under a microscope for identification of the eggs. Eggs may also be found in stool (less than 5 percent) and in subungual material. Occasionally, the adult worm (white, up to 4 mm in length) is found in the perianal area, vulva, vagina, or underclothes. When ectopic sites are involved, the parasite may be identified in tissue sections.

Differential Diagnosis. Irritant and allergic contact dermatitis, atopic dermatitis, neurodermatitis, and strongyloidiasis are part of the differential diagnosis.

Complications.

Treatment. (See Box 207-1)

Prevention. Treatment of infected cases and good personal hygiene are the most effective preventive measures.

HOOKWORM DISEASE ***Synonyms and Diseases.*** New World hookworm disease, American hookworm disease, uncinariasis, or necatoriasis (for disease caused by *Necator americanus*); Old World hookworm infection or ancylostomiasis (for disease caused by *Ancylostoma duodenale*).[12,15]

Epidemiology. The various species that cause hookworm disease have distinct, but overlapping, geographic distributions. Hookworm disease is most common in rural tropical and sub-tropical areas but can also occur in temperate areas when sanitation is poor. The global prevalence is estimated at 576 million. The majority of persons who harbor hookworms have no or few symptoms.

Etiology and Pathogenesis. The major causes of human hookworm disease are *A. duodenale* and *N. americanus*. Eggs embryonate and hatch in the soil and develop into infective larvae over 5 to 10 days. Humans are the main reservoir host for *A. duodenale* and *N. americanus*. Humans usually acquire infection via penetration of intact skin by *A. duodenale* larvae (e.g., skin contact with fecally contaminated soil, such as occurs when walking barefoot). Transmammary infection of nursing infants is possible with *A. duodenale*.

Clinical Findings. **RELATED PHYSICAL FINDINGS.** Systemic symptoms of the invasive phase are less frequent than in ascariasis. Pulmonary symptoms (cough, wheezing, and shortness of breath) may occur 1 to 3 weeks after percutaneous penetration in association

Box 207-1

Treatment for Parasitic Infections Discussed in This Chapter

INFECTION	DRUG	ADULT DOSAGE
Ascariasis		
Drug of choice	Albendazole[a]	400 mg once
or	Mebendazole	100 mg bid × 3 days or 500 mg once
or	Pyrantel pamoate[a]	11 mg/kg once (maximum, 1 g)
Coenurosis		
Treatment of choice	Surgical excision of the nodule.	
Cutaneous larva migrans		
Drug of choice	Albendazole[a]	400 mg daily × 3 days
or	Ivermectin[a]	200 μg/kg daily × 1–2 days
or	Thiabendazole topically	
Cysticercosis*		
Treatment of choice	Initial therapy of parenchymal disease with seizures should focus on symptomatic treatment with anticonvulsant drugs. Treatment of parenchymal disease with albendazole and praziquantel is controversial, and randomized trials are inconclusive. Any cysticercocidal drug may cause irreparable damage (even when given with glucocorticoids) when used to treat ocular or spinal cysts. A pre-treatment ophthalmic examination must be done to diagnose intraocular cysts.	
Alternative	Albendazole	400 mg bid × 8–30 days, may be repeated as necessary
or	Praziquantel[a]	50–100 mg/kg/day in 3 divided doses × 30 days
Dirofilariasis		
Treatment of choice	Surgical excision of the nodule.	
Dracunculiasis		
Treatment of choice	Extraction of the worm by slowly winding the worm around a stick.	
Drug of choice	Metronidazole[a]	250 mg tid × 10 days
This dose decreases inflammation and facilitates removal of worm but is not curative. Mebendazole, 400–800 mg/day for 6 days, has been reported to directly kill the worm.		
Echinococcosis*		
Echinococcus granulosus		
Drug of choice	Albendazole	400 mg bid × 1–6 mo
Patient may benefit from or require surgical resection of cysts. Praziquantel is useful preoperatively or in case of spill during surgery. PAIR (percutaneous aspiration-injection-reaspiration with ultrasound guidance) plus albendazole therapy has been effective for the management of hepatic hydatid cyst disease.		
E. multilocularis		
Treatment of choice	Surgical excision is the only reliable means of cure. Reports have suggested that in nonresectable cases, the use of albendazole or mebendazole can stabilize and sometimes cure infection.	
Enterobiasis		
Treatment of all household members is recommended because all are usually infected.		
Drug of choice	Pyrantel pamoate	11 mg/kg once (maximum, 1 g), repeat in 2 wk
or	Mebendazole	100 mg once, repeat in 2 wk
or	Albendazole[a]	400 mg once, repeat in 2 wk
Fascioliasis*		
Drug of choice	Triclabendazole[b]	10 mg/kg once or twice
Alternative	Bithionol[c]	30–50 mg/kg on alternate days × 10–15 doses
Unlike other fluke infections, *Fasciola hepatica* infection may not respond to praziquantel. Triclabendazole, a veterinary fasciolide, may be safe and effective, but the data are limited. Triclabendazole should be taken with food for better absorption.		
Filariasis, lymphatic*		
Endosymbiotic *Wolbachia* bacteria may play a role in filarial development and host response and may represent a new target for therapy. Doxycycline, 100 mg PO qd × 6 wk, has resulted in a decrease in *Wolbachia* and a block in microfilaria production.		
Wuchereria bancrofti, Brugia malayi, B. timori		
Drug of choice	Diethylcarbamazine[c]	6 mg/kg/day divided in 3 doses × 14 days
In patents with microdilaria in the blood, it is advisable to start with a lower dose and scale up. A full dose may be given on day 1 provided that patient is without blood microfilariae.		
Antihistamines or glucocorticoids may be required to reduce the allergic reaction secondary to microfilariae disintegration during the treatment of filarial infections.		
Most symptoms are caused by the adult worm. Single-dose combination of albendazole, 400 mg, with either ivermectin, 200 μg/kg, or diethylcarbamazine, 6 mg/kg, is effective for reduction or suppression of *W. bancrofti* microfilaremia.		
Gnathostomiasis*		
Drug of choice	Albendazole[a]	400 mg bid × 21 days
or	Ivermectin	200 μg/kg/d × 2 days
with or without	Surgical removal	

(continued)

Box 207-1

Treatment for Parasitic Infections Discussed in This Chapter (Continued)

INFECTION	DRUG	ADULT DOSAGE
Hookworm infection		
Drug of choice	Albendazole[a]	400 mg once
or	Mebendazole	100 mg bid × 3 days or 500 mg once
or	Pyrantel pamoate[a]	11 mg/kg once (maximum, 1 g) × 3 days
Loiasis*		
Drug of choice	Diethylcarbamazine[c]	6 mg/kg in 3 doses × 14 days
In patients with microfilariae in the blood, treatment should begin with low dose and then scaled up. A full dose may be given on day 1 provided the patient is without blood microfilariae.		
Antihistamines or glucocorticoids may be required to reduce the allergic reaction secondary to microfilariae disintegration during the treatment of filarial infections, particularly in loiasis.		
In heavy *Loa loa* infections, rapid killing of microfilariae may provoke an encephalopathy. Apheresis has been reported to be effective in decreasing microfilarial counts in patients who are heavily infected with *Loa loa*. Albendazole or ivermectin have also been used to reduce microfilaremia. Albendazole is preferred given its slower onset of action. Albendazole may be useful for the treatment of loiasis when diethylcarbamazine is ineffective or cannot be used but repeated courses may be necessary. Diethylcarbamazine, 300 mg PO qwk, has been recommended for loiasis prevention.		
Onchocerciasis*		
Endosymbiotic *Wolbachia* bacteria may play a role in filarial development and host response, and may represent a new target for therapy. Doxycycline, 100 mg PO qd × 6 wk, has been associated with block of microfilariae production in onchocerciasis.		
Drug of choice	Ivermectin	150 μg/kg once, repeated every 6–12 mo until asymptomatic
Annual treatment with ivermectin, 150 μg/kg, can prevent blindness due to ocular onchocerciasis.		
Paragonimiasis*		
Drug of choice	Praziquantel[a]	75 mg/kg/day divided in three doses × 2 days
Alternative	Bithionol[c]	30–50 mg/kg on alternate days × 10–15 doses
or	Triclabendazole	May be effective in dosages 5 mg/kg qd × 3 days or 10 mg/kg bid × 1 day. Triclabendazole should be taken with food for better absorption.
Schistosomiasis*		
Schistosoma haematobium		
Drug of choice	Praziquantel	40 mg/kg/day divided in two doses × 1 day
S. japonicum		
Drug of choice	Praziquantel	60 mg/kg/day divided in three doses × 1 day
S. mansoni		
Drug of choice	Praziquantel	40 mg/kg/day divided in two doses × 1 day
Alternative	Oxamniquine	15 mg/kg once
In East Africa, the oxamniquine dose should be increased to 30 mg/kg. In Egypt and South Africa, the dose should be increased to 30 mg/kg/day × 2 days. Oxamniquine has been effective in some areas where praziquantel is less effective. Oxamniquine is contraindicated in pregnancy.		
S. mekongi		
Drug of choice	Praziquantel	60 mg/kg/day divided in three doses × 1 day
Sparganosis		
Treatment of choice	Surgical excision of the nodule.	
Strongyloidiasis		
Drug of choice	Ivermectin	200 μg/kg/day × 2 days
In immunocompromised patients or disseminated disease, it may be necessary to prolong or repeat therapy or use other agents. A veterinary parenteral formulation of ivermectin has been used in one patient.		
Alternative	Albendazole 400 mg bid × 7 days or thiabendazole	50 mg/kg/day in two divided doses (maximum, 3 g/day) × 2 days
This dose is likely to be toxic and may need to be decreased.		
Trichinosis		
Drugs of choice	Glucocorticoids for severe symptoms plus	
	Mebendazole[a]	200–400 mg tid × 3 days then 400–500 mg tid × 10 days
Alternative	Albendazole[a]	400 mg bid × 8–14 days
Visceral larva migrans		
Drugs of choice	Albendazole[a]	400 mg bid × 5 days
	Mebendazole[a]	100–200 mg bid × 5 days
Optimal duration of therapy is unknown. Some consultants recommend treating for up to 20 days. In addition, glucocorticoids may be used for severe symptom or ocular involvement.		

p.c. = after a meal.
[a]Although this is a U.S. Food and Drug Administration–approved drug, the FDA considers this drug to be investigational for this disease.
[b]In the United States, this drug is available only from the manufacturer.
[c]Available under an Investigational New Drug (IND) protocol from the CDC Drug Service. http://www.cdc.gov/ncidod/srp/drugs/drug-service.html. *Consultation with tropical medicine specialist advised.

with urticaria. Gastrointestinal symptoms occur 1 month after penetration.

CUTANEOUS LESIONS. Cutaneous manifestations may be seen during the penetration phase and the invasive phase of the disease. Within 1 to 2 days after contact, the area of skin penetrated by the larvae may have localized erythema, edema, and papular or papulovesicular lesions.[17] This eruption, known as *ground itch*, is most commonly located on the feet and lasts 1 to 2 weeks. The pulmonary migration phase, seen in a minority of patients, may be associated with generalized urticaria, which disappears spontaneously at the end of this phase.

Laboratory Tests. A peripheral eosinophilia begins as early as 2 to 3 weeks after skin penetration by the infective larvae and may be high grade during the invasive phase. Chest x-ray films may reveal transient pulmonary infiltrates during pulmonary migration. In chronic infection, abnormal laboratory values include iron deficiency anemia, hypoalbuminemia, and gross or occult blood in feces.

Special Tests. Infection is diagnosed by finding characteristic eggs on stool examination (not found until 4 to 6 weeks after exposure). At the time a patient presents with ground itch or the later urticarial and pulmonary manifestations, the results of stool examinations will be negative. The eggs of *A. duodenale* and *N. americanus* are indistinguishable by routine light microscopy.

Differential Diagnosis. For ground itch, the differential diagnosis includes infectious cellulitis, cellulitis-like reaction after arthropod bite or sting, and folliculitis. For the causes of acute urticaria (seen during the invasive phase), see Chap. 37.

Complications.

Treament. (See Box 207-1) Albendazole appears to be more effective than mebendazole, which has been suggested as an alternative.[12] Ivermectin is not effective in human hookworms in contrast to animal hookworm.

Prevention. The sanitary disposal of human feces can prevent hookworm infections.

STRONGYLOIDIASIS

Synonyms. Strongyloidosis, strongyloidal ground itch, larva currens.

Epidemiology. Although the parasite is widely distributed, it is most common in tropical and sub-tropical areas.[18] *Strongyloides fuelleborni* is endemic in parts of tropical Africa and Asia. Rates of infection are as high as 80 percent in some populations in tropical areas. High rates of infection are reported in institutionalized mentally impaired persons, in former prisoners of war, and in refugees and immigrants from some tropical areas. The risk of infection is high for persons with frequent soil contact (e.g., going barefoot) in warm, moist areas where human feces frequently contaminate the soil. Persons who are infected with human T-cell lymphotrophic virus type 1 are at increased risk for complications from strongyloidiasis. Immunosuppressive therapy in chronically infected persons can be associated with hyperinfection.

Etiology and Pathogenesis. Strongyloidiasis results from infection by *S. stercoralis*. *S. fuelleborni,* a common parasite of primates, infects humans in limited geographic areas. Other *Strongyloides* sp. that do not mature in humans and affect the skin only are a cause of the CLM syndrome (see the section Hookworm-Related Cutaneous Larva Migrans).

Under appropriate conditions, the parasite can multiply for several generations in the soil. Humans are the main reservoir host for human infection. Humans become infected when infective larvae, usually from soil, penetrate skin or mucous membranes. Transmammary infection of *S. fuelleborni* may account for some infections in infants. Transmission also occurs via oral-anal sexual intercourse.

Clinical Findings. **RELATED PHYSICAL FINDINGS.** The signs and symptoms of strongyloidiasis occur irregularly with prolonged asymptomatic intervals. The penetration phase does not give rise to cutaneous signs. Skin and pulmonary manifestations can begin within days of exposure. Because autoinfection can occur, infection can persist indefinitely, although infection may first be recognized years, even decades, after it was acquired.

CUTANEOUS LESIONS. Cutaneous manifestations may be seen during the invasive and chronic phases of infection and with the hyperinfection syndrome.

During the invasive phase of the infection, transient pulmonary manifestations (cough, wheezing, infiltrates) are manifestations of pulmonary migration and may be associated with urticaria.

Chronic strongyloidiasis gives rise to non-specific gastrointestinal complaints (abdominal pain, nausea, vomiting, diarrhea, constipation, malabsorption, weight loss) and a pathognomonic skin manifestation known as *larva currens*. The filariform larvae invade the perianal skin and travel within the skin, resulting in a creeping eruption (see Fig. 207-1). Larva currens is associated with intense pruritus. This transient eruption is unique in that it migrates at a rate of up to 5 to 10 cm per hour and disappears within a few hours, but may recur over the course of weeks to years. Anatomic locations commonly include the buttocks, groin, and trunk. Persons chronically infected with *Strongyloides* may also experience pruritus ani and chronic urticaria, which may be complicated by prurigo nodularis or lichen simplex chronicus.[19]

The dermatologic manifestation of hyperinfection and disseminated strongyloidiasis is a rapidly and progressively diffuse petechial and purpuric eruption caused by massive filariform larvae dissemination to the skin (Fig. 207-2). The eruption typically involves the trunk and proximal extremities.[20] The "thumbprint sign," seen in disseminated strongyloidiasis, is a unique pattern of periumbilical purpura that resembles multiple thumbprints.[21]

Laboratory Tests. Peripheral eosinophilia is common and may be high grade during larval migration. During the chronic phase, the eosinophil level fluctuates and is often mildly elevated (mild to moderate increase) but may be normal. The absence of eosinophilia does not rule out the diagnosis. Eosinophilia is often absent in patients who are on glucocorticoids or are severely immunocompromised.

Special Tests. The identification of larvae in the stool, small bowel contents, and, rarely, in other body fluids confirms the diagnosis. Multiple stool examinations are often necessary to make the diagnosis. Larvae first appear in the stool 2 to 4 weeks after exposure. Serologic testing by enzyme-linked immunosorbent assay (ELISA) has a sensitivity of approximately 90 percent and may be useful when the diagnosis is suspected, although serologic tests lack specificity.

Diagnosis of larva currens is made by its characteristic clinical features. Skin biopsy of the larva currens eruption often fails to reveal larvae. Biopsy of the purpuric and petechial eruption of hy-

▲ **FIGURE 207-2** Non-palpable purpura secondary to disseminated strongyloidosis. (Reprinted with permission from Grossman ME, Roth J: *Cutaneous Manifestations of Infection in the Immunocompromised Host.* Baltimore, Williams & Wilkins, 1995.)

perinfection and disseminated strongyloidiasis may reveal larvae.

Differential Diagnosis. For larva currens, the differential diagnosis includes all of the causes of creeping eruption (see Table 207-2); for acute and chronic urticaria, see Chap. 37.

For the petechial and purpuric eruption, the differential diagnosis includes sepsis and causes of diffuse bleeding.

Complications.

Prognosis and Clinical Course. The mortality rate is high in disseminated strongyloidiasis.

Persons with a history of prior residence or activities that place them at an increased risk for strongyloides infection should be evaluated for presence of strongyloides infection. If infected, they should be treated, even if asymptomatic. This is especially important in persons who receive treatment that causes immunosuppression.

Treatment. (See Box 207-1)

Prevention. Sanitary waste disposal and avoiding skin-soil contact in endemic areas reduces risk of infection.

Filarial Parasites (Table 207-3)

LYMPHATIC FILARIASIS ***Synonyms and Diseases.*** Malayan filariasis (*Brugia malayi*), Timor filariasis (*B. timori*), Bancroft filariasis, filariasis bancrofti, and wuchereriasis (*Wuchereria bancrofti*). Some of these parasites can cause elephantiasis and tropical pulmonary eosinophilia.[23]

Epidemiology. Lymphatic filariases are widely distributed in tropical and subtropical areas, with the largest number of infections occurring in India, South Asia, East Asia and Pacific Islands, and sub-Saharan Africa. eFig. 207-2.1 in the on-line edition shows the geographic distribution of *W. bancrofti, B. malayi,* and *B. timori* in the Southeast Asian and Western Pacific regions. *W. bancrofti* occurs in the northern part of South America (Guyana, Surinam, and some coastal regions of Brazil). In the United States infections are seen primarily in immigrants and persons with prolonged visits to endemic areas.

Etiology and Pathogenesis. Lymphatic filariasis is caused by three filarial nematodes: *B. malayi, B. timori,* and *W. bancrofti*, parasites transmitted by infective mosquitoes.

The incubation period is 5 to 18 months, although *B. malayi* microfilaremia may occur as early as 2 to 3 months after exposure. *W. bancrofti* microfilariae first appear in peripheral blood 8 to 12 months after exposure, but symptoms can begin as early as 1 to 3 months after exposure. Adult worms live an average of 10 to 15 years; the microfilariae, probably 6 to 12 months. Symptoms and sequelae can persist after the death of all parasites.

Clinical Findings. Lymphatic filariasis was generally thought to occur mainly as a seriously handicapping disease of adults, being sporadically observed in children. However, new highly sensitive diagnostic tests have revealed that it is first acquired in childhood, often with as many as one-third of children infected before the age of 5 years in endemic areas.[25] Initial lymphatic damage generally remains sub-clinical for years or gives rise only to recurrent lymphangitis or non-specific presentations of adenitis/adenopathy. It takes years for the characteristic clinical features of chronic filariasis to appear. In endemic areas, the prevalence of clinical manifestations increases after age 20. The clinical course ranges from asymptomatic to severely disabling manifestations (less than 1 percent of those infected). Manifestations may be acute, chronic, or recurrent.[26]

CUTANEOUS LESIONS. Early findings are lymphangitis with a characteristic retrograde progression, lymphadenitis, orchi-

TABLE 207-3
Summary of Filarial Parasites[a]

SPECIES	GEOGRAPHIC DISTRIBUTION	MANIFESTATIONS
Brugia malayi	Southeast Asia	Lymphangitis, lymphadenitis, lymphedema, hydrocele, elephantiasis, tropical pulmonary eosinophilia
B. timori	Indonesia	Same as above
Loa loa	Africa	Angioedema, pruritic migratory swellings; migration of worm across eye
Mansonella ozzardi	Central and South America	Pruritus
M. perstans	Africa, South America	Pruritus, angioedema
M. streptocerca	Africa	Pruritus, papular rash, lichenification
Onchocerca volvulus	Africa, Central and South America	Pruritic papules, nodules, lichenification; keratitis, retinitis, blindness
Wuchereria bancrofti	Tropics worldwide	Lymphangitis, lymphadenitis, lymphedema, hydroceles, chyluria, elephantiasis, tropical pulmonary eosinophilia

[a]Dracunculiasis and dirofilariasis, which are also filarial infections, are covered in separate sections. All filarial infections are transmitted by biting insects, except for dracunculiasis.

tis, epididymitis, and, sometimes, fever. During the resolution of the acute phase of *W. bancrofti* filariasis, there may be extensive exfoliation of the skin of the affected limb. Lymphangitis is typically recurrent with 6 to 10 episodes per year, usually lasting 3 to 7 days each; the affected body part clinically appears normal between early episodes. Intermittent fevers and lymphangitis can recur for as long as 20 years, the lifetime for the adult worm, after an infected person leaves the endemic area.

After 10 to 15 years of infection, chronic disease is evident in sequelae of lymphatic obstruction including lymphedema, elephantiasis, hydrocele, and chyluria. The skin over the involved area is hypertrophic, verrucous, and fibrotic with redundant folds of skin (Fig. 207-3). Fissures, ulceration, and gangrene may occur. Secondary bacterial infection is common. The anatomic locations most commonly afflicted with elephantiasis include the lower extremity, scrotum, and penis. Less commonly, the upper extremity, breast, and vulva are involved. Treatment does not reverse the late findings of scarring and lymphatic obstruction. *W. bancrofti* has been reported to cause a skin nodule on the breast.

Travelers to endemic areas have a hyper-responsive clinical presentation, with more intense inflammatory reactions to filarial parasites. The clinical findings may include lymphangitis, lymphadenitis, and groin pain from the associated lymphatic inflammation, urticaria, and a peripheral eosinophilia.

▲ **FIGURE 207-3** Lymphatic filariasis secondary to *Wuchereria bancrofti*. (Used with permission from Jay S. Keystone, MD, FRCPC.)

RELATED PHYSICAL FINDINGS. Tropical pulmonary eosinophilia develops in some patients with filarial infections.

Laboratory Tests. Patients with lymphatic filariasis have a peripheral eosinophilia, which may be high grade, and an elevated IgE. Persons with tropical eosinophilic syndrome have pulmonary infiltrates on chest x-ray films.

Special Tests. Diagnosis is made by demonstrating microfilariae, preferably at night (midnight), in blood, urine, and other body fluids, and tissue. However, persons with active filarial infection may not be microfilaremic. The demonstration of the adult worm in lymphatics is possible, but biopsy of adenopathy is contraindicated. The usefulness of serologic tests has been limited by cross-reactions with other nematodes, but newer tests such as polymerase chain reaction (PCR) and antigen detection with better specificity are becoming available.

Differential Diagnosis. The stage of the infection determines the differential diagnosis. Acute infection may resemble bacterial lymphangitis and other causes of nodular lymphangitis, such as sporotrichosis and leishmaniasis.

The differential diagnosis for the chronic stage includes the other causes of lymphedema and elephantiasis (see Chap. 175).

Treatment. (See Box 207-1) Treatment is suboptimal because drugs are only partially effective against adult worms in lymphatic ducts, the cause of the cutaneous manifestations. Of the four classic drugs with an antifilarial activity, diethylcarbamazine (DEC) and ivermectin are partially effective against adult worms, and albendazole is effective only with high dosages, which may induce severe adverse events. Recent studies document that a 6- to 8-week course of daily doxycycline can reduce the longevity or the reproductive capacity of these parasites[27] by eliminating bacterial (*Wolbachia*) endosymbiots present in the lymphatic filariae. To be effective against microfilariae, treatment needs to combine doxycycline with either two doses of ivermectin, one at the end of the doxycycline course and the other 3 to 6 months later, or one single dose of DEC.[28]

When treating filariasis with DEC, clinicians may use antihistamines or glucocorticoids to decrease the allergic reaction that may result from disintegration of microfilariae. Severe reactions may follow the administration of DEC to persons co-infected with filariasis and loiasis or onchocerciasis (a reason to prefer ivermectin instead of DEC in loiasis-endemic areas).

Management strategies for patients with lymphedema include elevation of the affected body part, compression stockings, skin care of the affected area, treatment of superficial fungal infections, as well as protection of the affected area from trauma and prompt antibiotic therapy for bacterial infections of the area. Surgical treatment includes debulking of the affected area, wide excision of chronic draining areas, and lymphatic shunts. Effectiveness varies, depending on the location of lymphedema.

Prevention. The avoidance of mosquito bites in endemic areas is the primary means of prevention. Treatment of microfilaremic persons will reduce reservoir of parasites.

LOIASIS

Synonyms. Calabar swellings, fugitive swellings, *Loa loa* filariasis, African eyeworm infection.

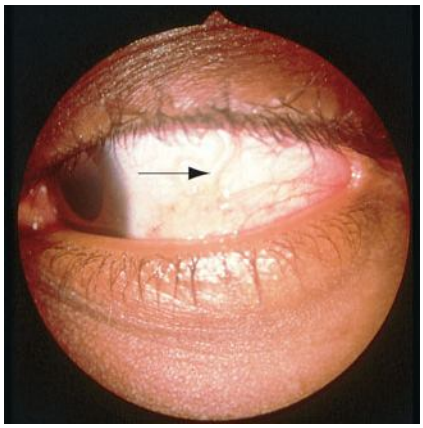
Epidemiology. Loiasis is endemic in Central and West Africa and is estimated to affect 3 to 13 million residents.

Etiology and Pathogenesis. The filarial nematode, *Loa loa,* is transmitted by *Chrysops* (a type of fly).[29] The day-biting fly ingests microfilariae along with the blood meal when it bites an infected human. The microfilariae develop into larvae, which are transmitted when the fly bites another human.

Symptoms usually begin a mean of 24 months after exposure, although first findings can appear as early as 4 months or as late as a decade or more after the acquisition of infection. Microfilariae first appear in the bloodstream 5 to 6 months after the person becomes infected. The adult worm can live longer than 20 years in the human host.

Clinical Findings. Loiasis is manifested by pruritus, migration of the worm under the skin or across the eye (Fig. 207-4), and Calabar swellings.[30]

CUTANEOUS LESIONS. Calabar swelling is the characteristic manifestation of loiasis (Fig. 207-5). These are localized areas of angioedema associated with the migration of the adult worms through the subcutaneous tissues. Calabar swellings range from 5 to 20 cm in diameter.



▲ **FIGURE 207-4** Loiasis. Adult worm crossing eye (*arrow*). (Used with permission from Murray Wittner, MD, PhD.)

They may be associated with pruritus or pain; generally last 2 to 4 days (occasionally weeks), and may recur multiple times. They occur predominantly on the extremities (upper more commonly than lower), especially around joints such as the wrist or knee. Fatigue, myalgias, arthralgias, and fever are uncommonly associated with the lesions. Adult worms may also migrate under the skin, causing a creeping eruption (see the following section, Related Physical Findings). It is characterized by a serpiginous or linear erythematous cutaneous trail that is less than 10 cm long and advances rapidly (1 cm per minute) and lasts no more than a few hours (for other causes of migratory lesions, see Table 207-2).

Related Physical Findings. A migrating adult worm may be seen crossing the conjunctivae or the bridge of the nose; see Fig. 207-4). This is associated with conjunctivitis and, occasionally, swelling on the face, particularly of the periorbital region.

Laboratory Tests. Findings include a peripheral eosinophilia (may be high grade), leukocytosis, and elevated IgE. *Loa loa*–specific IgG4 is elevated.

Special Tests. Diagnosis is based on identification of microfilariae in blood (during the day) or the identification of an adult worm removed from the eye or other tissues. Calcified worms may be seen on x-ray films. Although the usefulness of older serologic tests is limited by cross-reactivity with other parasites, newer approaches are being developed, including the use of PCR-based testing.

Differential Diagnosis. The differential diagnosis includes all the causes of migratory lesions (see Table 207-2) and angioedema of the extremities (gnathostomiasis, trichinosis, eosinophilic cellulitis).

Complications.

Treatment. The surgical removal of the worm from the eye or other tissue, if feasible, is therapeutic, but patients are usually infected with multiple worms (usually not more than 10 to 20 adult worms).

As the manifestations of loiasis are due to adult worms, DEC is currently the drug of choice because it is effective against the adult worm *Loa loa* (in contrast to other filariasis) as well as microfilariae (see Box 207-1). Side effects from treatment are common and are occasionally severe, especially in patients with high circulating levels of microfilariae. One approach has been to gradually increase the dose of DEC and to pre-treat with antihistaminics and corticosteroids, though this does not always prevent encephalitis.[33] Repeat courses of treatment are necessary in 50 percent or more of patients.

Ivermectin and albendazole are ineffective against the adult worms but can be useful because they reduce microfilarial levels, the risk factor for adverse reactions.[34] In addition, for the rare patient who has an infection refractory to DEC, albendazole may be effective.[35] In patients with heavy infections, approaches include the use of single dose ivermectin or albendazole (for 21 days) or cytapheresis to reduce microfilarial levels.[32]

Prevention. Prevention includes avoiding bites from *Chrysops* in endemic areas and treatment of infected humans to reduce source of parasites.

Chemoprophylaxis with a weekly 300-mg dose of DEC is effective for preventing *Loa loa* in long-term travelers to endemic regions who expect to have frequent exposures to biting flies.[36]

MANSONELLIASIS

ONCHOCERCIASIS

Synonyms. Onchocercosis, blinding filariasis, river blindness, coastal erysipelas, erysipela de la costa (Mexico and Guatemala), onchocercomata, onchodermatitis, sowda (Arabic speaking areas), craw-craw (West Africa).

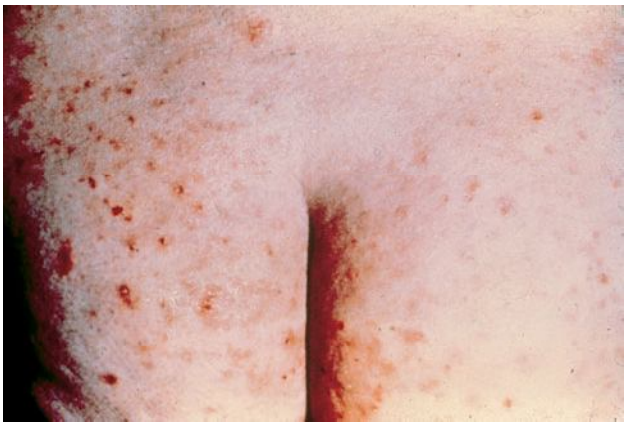
Epidemiology. The greatest concentration of *Onchocerca volvulus* infections is in equatorial Africa. Endemic foci also exist in Latin America and the Arabian peninsula. An estimated 18 million persons are infected. eFig. 207-5.1 in the on-line edition shows the geographic distribution of onchocerciasis in Africa and the Arabian peninsula. eFig. 207-5.2 in the on-line edition shows the geographic distribution of endemic onchocerciasis in the Americas.

Etiology and Pathogenesis. Onchocerciasis is caused by the filarial nematode *O. volvulus*[37] and is transmitted by blackflies of the genus *Simulium.* The microfilariae develop into infective larvae within the blackfly, which passes larvae to another human when taking a blood meal. In the human, the infective larvae mature to adult worms that are encapsulated in fibrous tissue and reside in nodules in the subcutaneous tissue and deep fascia.

Microfilariae from an infected mother can infect the fetus, and microfilariae can potentially be transmitted by blood transfusion.

The incubation period is usually 1 to 2 years with a range of months to several years. Microfilariae may first appear 3 to 15 months after exposure. The initial symptoms can precede the presence

▲ **FIGURE 207-5** Calabar swelling of loiasis. (Used with permission from Jay DS. Keystone, MD, FRCPC.)



▲ **FIGURE 207-6** Onchocercal dermatitis. (Used with permission from Herman Zaiman, MD.)

of microfilariae in tissue, but often develop only after months or years of infection. The microfilariae can survive in humans for up to 2 to 3 years, the adult worms, for 10 to 15 years.[38]

Clinical Findings. Persons with onchocerciasis may be asymptomatic, or they may have a severe impairment, including loss of vision.[39] The skin and the eye are the two most commonly involved organ systems.

CUTANEOUS LESIONS. Clinical manifestations differ between long-term residents of endemic areas and short-term visitors from nonendemic regions, whose infection may be associated with acute symptoms and immune hyper-responsiveness, despite low levels of parasites.[40] The most common presentations in visitors to endemic areas are pruritus and rash (Fig. 207-6).[41] Skin nodules (Fig. 207-7) and eye involvement are usually absent, and microfilariae are absent or found in low numbers in the skin. After exposures in West and Central Africa, travelers and expatriates may have an acute form of onchocerciasis characterized by acute pruritic and erythematous swelling of a limb known as *gros bras camerounais*[42] or onchocerciasis-associated limb swelling.[43] In contrast to other clinical forms of onchocerciasis, onchocerciasis limb swelling is a disease of the forested areas, not the savanna.[42]

Other skin manifestations of onchocerciasis are the consequences of itching, which is chronic and severe. Six different patterns of skin changes have been described: acute papular onchodermatitis, chronic papular onchodermatitis (see Fig. 207-6), lichenified onchodermatitis, atrophy, depigmentation (see Chap. 73, Fig. 73-9), and palpable onchocercal nodules (see Fig. 207-7). More than one pattern of skin involvement may be present simultaneously, or one pattern of skin involvement may evolve into another pattern. Pruritus is often the first symptom of infection. Acute papular onchodermatitis, which most often involves the face, extremities, and trunk, includes widespread small pruritic papules, vesicles and pustules, sometimes with associated erythema and edema. Ivermectin and DEC therapy of infected persons can precipitate a rash similar to acute papular onchodermatitis.

The skin lesions of chronic papular onchodermatitis are macules and lichenoid papules varying in diameter from 3 to 9 mm. Pruritus is common, and post-inflammatory hyperpigmentation may be present. The most commonly affected anatomic areas are the buttocks, shoulders, and waist (see Fig. 207-6).

▲ **FIGURE 207-7** Onchocercal nodule over iliac crest. (Used with permission from Jay S. Keystone, MD, FRCPC.)

RELATED PHYSICAL FINDINGS. Palpable onchocercal nodules containing the adult worm involve the deep dermis and subcutaneous tissue (see Fig. 207-7). Typically asymptomatic, the nodules occur over bony prominences such as the skull, iliac crest, knee, rib, sacrum, scapula, and trochanter.

Laboratory Tests. Peripheral eosinophilia and elevated IgE levels are common findings.

Special Tests. Onchocerciasis is most commonly diagnosed by the identification of microfilariae in a skin snip or of an adult worm in an excised nodule. Microfilariae may be clearly visible in the anterior chamber of the eye on slit-lamp examination. Antibody testing lacks specificity; PCR testing is generally available only through research laboratories.[44]

Differential Diagnosis. The differential diagnosis depends on the skin findings at the time of presentation. Pruritus may suggest scabies. Acute papular onchodermatitis may resemble miliaria, insect bites, or eczema. Chronic papular onchodermatitis may resemble a chronic or lichenoid eczema or atopic dermatitis. The differential diagnosis for lichenified onchodermatitis is broad and includes essentially any diagnosis that involves significant pruritus or rubbing of the involved area. Atrophy associated with onchocerciasis resembles that associated with aging. Onchocercal depigmentation may be confused with post-inflammatory hypopigmentation or depigmentation. The differential diagnosis for onchocercal nodules includes the other parasitic causes of nodules (Table 207-4) and epidermal inclusion cysts.

Treatment. (See Box 207-1) DEC should not be used in patients with proven onchocerciasis due to its lack of efficacy on adult worms and the severity of ocular reaction it may induce. A single 50-mg dose of DEC can be administered as a diagnostic tool for unproven onchocerciasis (Mazzotti test) in areas where loiasis is not endemic. In such a case, it provokes (often within 3 hours) an increase in the cutaneous manifestations; as a consequence microfilariae may appear in the dermis, and a biopsy may then confirm the diagnosis.

The drug of choice in the treatment of onchocerciasis is ivermectin. Ivermectin (single dose, 150 μg/kg) causes a dramatic decrease of the microfilarial load

TABLE 207-4
Helminthic Causes of Dermatologic Nodules and Cysts

DISEASE	HELMINTH(S)	COMMENTS
Coenurosis	Several species of *Multiceps*	Solitary cyst
Solitary cyst cutaneous larva migrans	Primarily *Ancylostoma braziliense* and *A. caninum*	Larvae of dog and cat hookworms
Cysticercosis	*Taenia solium*	May be multiple
Dirofilariasis	*Dirofilaria immitis* and other *Dirofilaria* sp.	Usually single
Dracunculiasis	*Dracunculus medinensis*	Localized swelling
Echinococcosis	*Echinococcus granulosus* and *E. multilocularis*	—
Fascioliasis	*Fasciola hepatica* and *F. gigantica*	Painful, pruritic
Filariasis, lymphatic	*Brugia malayi, B. timori,* and *Wuchereria bancrofti*	Mass in scrotum
Gnathostomiasis	*Gnathostoma spinigerum* and other *Gnathostoma* sp.	Migratory swelling
Loiasis	*Loa loa*	Inflammatory swellings
Onchocerciasis	*Onchocerca volvulus*	Painless, mobile, dermal nodules
Paragonimiasis	Primarily *Paragonimus westermani*	Subcutaneous nodule
Schistosomiasis	*Schistosoma haematobium, S. intercalatum, S. japonicum, S. mansoni,* and *S. mekongi*	Verrucous, vegetating
Sparganosis	*Spirometra erinacei, S. mansoni, S. mansonoides,* and *S. proliferum*	Slow growing

in the skin of patients with onchocerciasis and thus leads to a clinical improvement of the symptoms.[45,46] However, when used as a single annual or semiannual dose, ivermectin has no effect on the adult female worm, which can survive 14 years or longer. Thus, for optimal benefit, ivermectin must be given repeatedly throughout the life span of the parasite[38] or be combined with doxycycline. Long-term treatment with doxycycline (6 weeks) kills the endosymbiotic *Wolbachia* in adult worms and interrupts production of microfilariae for 18 months or longer.[47] Another option is to increase the frequency of ivermectin dosing to every 3 months, which decreases the fecundity of the adult female parasite two- to threefold.[48]

Prevention. The primary means of preventing onchocerciasis is through vector control and mass treatment with ivermectin of the population in endemic areas.

Other Human Nematodes

DRACUNCULIASIS

Synonyms. Dracunculosis, dracontiasis, Guinea worm disease, Medina worm infection, dragon worm disease, serpent worm disease.

Epidemiology. As a consequence of an eradication program, the number of endemic countries (all in sub-Saharan Africa) in 2005 dropped to 9, down from 20 in 1980. Ghana and Sudan reported 89 percent of total global cases; and Niger, Mali, Niger, and Togo each reported more than 100 cases in 2004.[50]

Etiology and Pathogenesis. The nematode *Dracunculus medinensis* causes dracunculiasis (Fig. 207-8). The female is 70 to 80 cm in length and rarely exceeds 100 cm.

Larvae are released directly through leg ulcers into water from an infected human and ingested by copepods (tiny aquatic arthropods), in which they develop. Humans ingest the infective copepods (*Cyclops*) in contaminated drinking water and are the definitive host and main reservoir of infection.

Clinical Findings. **RELATED PHYSICAL FINDINGS.** Symptoms associated with the migration of the worm may precede the emergence of the worm. The adult worm typically dies (or is removed) after reaching the skin and releasing larvae.

CUTANEOUS LESIONS. The characteristic clinical findings include a bulla, 2 to 7 cm in size, that progresses over 1 to 3 days to an ulcer after contact with water and release of larvae. At this stage, the adult worm may be palpated, sometimes seen, under the skin, appearing as a cutaneous trail of 55 cm to 80 cm long, but usually is obscured by the local swelling

▲ **FIGURE 207-8** Dracunculiasis. (Used with permission from Jay S. Keystone, MD, FRCPC.)

Rupture of the worm in tissues provokes an intense inflammatory response and cellulitis, and may lead to abscess formation (see Fig. 207-8). Disruption of the skin by the worm predisposes to secondary bacterial infection, including tetanus. Most infected persons have one or a small number of worms (usually fewer than six). In 85 percent to 90 percent of cases the lesion is on the lower extremity, but the worm may emerge on the hands, arms, trunk, and even jaw. Non-specific symptoms may precede the skin lesion by a few hours and disappear once the larvae are ejected.

Laboratory Findings. Peripheral eosinophilia is uncommon.

Diagnosis. Visualization of the parasite as it emerges (see Fig. 207-8) and identification of the discharged motile larvae confirm the diagnosis. Calcified dead worms may be seen on x-ray.

Differential Diagnosis. The differential diagnosis includes causes of localized cutaneous bullae, ulcers, carbuncle, limb swelling (cellulitis associated with bacterial infection, onchocerciasis, loiasis) and creeping eruption (though the cutaneous trail does not advance from one day to the next; see Table 207-2).

Complications.

Treatment. Treatment of dracunculiasis includes slow extraction of the worm combined with wound care.

Prevention. Water from potentially infected sites should be filtered (e.g., through cloth to remove copepods).

Infected individuals should be prevented from contaminating wells and other drinking water sources when larvae are emerging.

ANIMAL NEMATODES

Infections in Humans

TOXOCARIASIS

GNATHOSTOMIASIS

Synonyms. Yangtze River edema (China), tau-chid (Thailand), choko-fushu (Japan), wandering swelling, Consular disease (Nankung), Shanghai rheumatism, nodular eosinophilic panniculitis (Ecuador), Woodbury bug (Australia).

Epidemiology. Human gnathostomiasis is endemic in Southeast Asia, especially Thailand and Japan. Since the 1970s, the prevalence of gnathostomiasis has increased in Peru, Ecuador, and Mexico. Imported fish and other animal flesh can be a source of infection outside of endemic areas. Sporadic cases have been reported in the Americas, Africa, Europe, and Australia. In the last two decades, an increase has been noted in the cases in travelers returning from endemic countries.[57]

Etiology and Pathogenesis. The nematode *Gnathostoma spinigerum* and, less frequently, *G. hispidum, G. nipponicum,* and *G. doloresi* cause gnathostomiasis.[58]

The adult worm lives in the stomachs of the definitive hosts, cats and dogs. Eggs from animal feces hatch in water. The larvae are ingested by *Cyclops* (a type of copepod, which are small aquatic arthropods) that are eaten by fish, frogs, and snakes, and sometimes domestic pigs and chickens. In these hosts, the larvae develop into third-stage larvae. Humans ingest the third-stage larvae in undercooked or raw flesh of infected animals. Transmission may also occur by ingestion of infective copepods in water or by skin penetration when handling infected fish.

Soft tissue swellings usually begin 3 to 4 weeks after exposure, but may not develop months or years later. The parasite can survive in the human for 10 years or longer. One report documents recurrences for 20 years.

Clinical Findings. **Related Physical Findings.** The signs and symptoms of gnathostomiasis range from mild to severe and depend on the location of larvae.

Cutaneous Lesions. The signs of the penetration phase occur within 1 to 2 days after ingestion of the larvae and include acute urticaria and fever, malaise, anorexia, nausea, vomiting, diarrhea, and epigastric pain. These signs disappear spontaneously within 2 days.[59] Migration of the larvae in the skin and subcutaneous tissue causes migratory swellings (eosinophilic panniculitis), creeping dermatitis, papules, and nodules.[60] Migratory swellings are intermittent and associated with erythema, pruritus, and pain (Fig. 207-9). The lesions may be single or multiple, and up to several centimeters in diameter. The swellings develop rapidly, persist for 1 to 4 weeks, then resolve, only to reappear in a different anatomic location after an asymptomatic interval of a week to months. Over time, episodes become less frequent, less intense, and shorter in duration. However, cutaneous gnathostomiasis may continue for months to years. Gnathostomiasis may present as a creeping eruption (1 cm/hour) (see Table 207-2) and, rarely, as a skin papule or nodule or limb swelling of the extremities (see Fig. 207-9). The most common anatomic locations include the trunk, upper body, and thighs.

Laboratory Tests. Peripheral eosinophilia may be high grade during larval migration. When the infection involves the central nervous system (CNS), the cerebrospinal fluid may be bloody or xanthochromic and contains eosinophils.

Special Tests. The characteristic morphology of larvae in surgical specimens or at autopsy confirms the diagnosis. Nonetheless, the diagnosis of gnathostomiasis is rarely confirmed by the identification of the larva in the skin or viscera. Most often the diagnosis relies on epidemiologic, clinical, and laboratory findings (hypereosinophilia, positive serologic test). Serologic tests are available in a few laboratories but are limited by cross-reactivity.[61]

Differential Diagnosis. The differential diagnosis of cutaneous gnathostomiasis include all the causes of migratory lesions (see Table 207-2), panniculitis, limb swelling (e.g., loiasis, onchocerciasis, eosinophilic cellulitis, other), and skin nodules (see Table 207-4).

The differential diagnosis of visceral gnathostomiasis varies according to the localization.

Complications.

Treatment. (See Box 207-1) Surgical excision plus albendazole is the treatment of choice. Even if surgery is not possible, treatment is recommended (e.g., albendazole, 400 mg twice a day for 21 days). Ivermectin (one to two doses of 200 μg/kg) has also been shown to be effective.[62,63] Late relapses may occur (up to 24 months after apparent cure),[60] so long-term follow-up is advised.

Prevention. Infection can be prevented by avoiding raw and undercooked flesh of fish, eel, chicken, duck, pork, snake, dogs, cats, and frog; drinking only treated water; and wearing gloves when handling potentially infected flesh.

TRICHINOSIS

Synonyms. Trichinellosis, trichiniasis, trichinelliasis.

▲ **FIGURE 207-9** Subcutaneous swellings of gnathostomiasis. (Used with permission from Jay S. Keystone, MD, FRCPC.)

Epidemiology. Trichinosis is present in most countries, but there is marked variation in the incidence. The parasite is thought to be absent from Australia and many South Pacific islands. Sporadic infections occur worldwide via shipped meat. Human infection tends to be sporadic and epidemic.

Etiology and Pathogenesis. *Trichinella spiralis* is the cause of trichinosis.[64]

Animals ingest muscle containing infective larvae and become infected. Humans become infected by eating raw or undercooked flesh of animals infected with *Trichinella*. Sources of infection include swine, bears, wild boars, cougars, walruses, horses, dogs, and cats. Humans are incidental dead-end hosts.

Symptoms occur during larval migration, before encystment. The encysted larvae may remain viable for 5 to 10 years.

Clinical Findings. The severity of trichinosis ranges from asymptomatic to fatal. The case fatality rate is 1 percent to 2 percent for recognized infections, usually related to complications of CNS or cardiac involvement.

Related Physical Findings. Abdominal pain, diarrhea, and vomiting occur during the first week of infection. Ten days after the ingestion of larvae, the signs and symptoms include fever (90 percent of the cases), fatigue, severe myalgia, and cutaneous signs. Headache, cough, and shortness of breath may be reported.

Cutaneous Lesions. Cutaneous manifestations are seen in about 75 percent of cases of symptomatic trichinosis,[65] the most frequent being periorbital and facial edema (75 percent to 95 percent of the cases), conjunctivitis (50 percent) and a macular or papular (sometimes urticarial) rash (15 percent). Hand swelling and volar surface erythema followed by desquamation have been reported.[66] Subconjunctival and splinter hemorrhages are less common (see eFig. 207-9.1 in online edition).

Laboratory Findings. A peripheral eosinophilia may be marked and may persist for months. Muscle enzymes (creatine phosphokinase) are increased.

Special Tests. The diagnosis usually relies on the association of epidemiological data (ongoing epidemic, at risk meal consumption), the clinical triad (fever, facial edema, myalgias), and laboratory findings (eosinophilia, increased muscle enzymes). A definitive diagnosis is possible after the seventeenth day and relies on the identification of the parasite in tissue, on muscle biopsy (see eFig. 207-9.2 in on-line edition). Serologic testing with ELISA or indirect immunofluorescence is not useful in early infection.[67] Antibody levels become positive after the twentieth day and can confirm the diagnosis.

Differential Diagnosis. The differential diagnosis includes allergic reactions, dermatomyositis (see Chap. 157), vasculitis, the parasitic causes of urticaria and eosinophilia-myalgia syndrome (see Chaps. 68 and 158).

Complications.

Treatment. (See Box 207-1)

Prevention. Cooking the meat to a temperature of 77°C (170°F) destroys the trichinae. Smoking and drying meat does not kill the infective larvae. Salt curing solutions may kill the trichinae, but the temperature and duration are important factors in this method. Swine should not be fed uncooked garbage and offal.

HOOKWORM-RELATED CUTANEOUS LARVA MIGRANS

Synonyms. Creeping eruption, creeping verminous dermatitis, sandworm eruption, plumber's itch, duck hunter's itch. These terms describe a sign (itching and creeping dermatitis) caused by several different parasites (see Table 207-2).[68]

Epidemiology. Cutaneous larva migrans (CLM) is widely distributed and most commonly found in tropical and subtropical areas, especially the southeastern United States, Caribbean, Africa, Central and South America, India, and Southeast Asia. Activities that pose a risk include contact with sand or soil contaminated with animal feces, such as playing in a sandbox, walking barefoot on a beach, and working in crawl spaces under houses.

Etiology and Pathogenesis. Most often, the larvae of animal hookworms cause hookworm-related CLM (HrCLM). *Ancylostoma braziliense* is the most common cause. Other skin-penetrating hookworm larvae that produce similar disease include *A. caninum, Uncinaria stenocephala* (hookworm of European dogs), and *Bunostomum phlebotomum* (hookworm of cattle). *A. caninum* causes eosinophilic enteritis as well as cutaneous disease. Cats and dogs are hosts for *A. ceylanicum* and *A. caninum*.

The human is an aberrant, dead-end host who acquires the parasite from an environment contaminated with animal feces. The infective larvae may remain viable in soil for several weeks. Third-stage larvae penetrate human skin and migrate up to several centimeters a day, usually between the stratum germinativum and stratum corneum. This induces a localized eosinophilic inflammatory reaction. Most larvae are unable to undergo further development or to invade deeper tissues and die after days to months.

Clinical Findings. The time from exposure to onset of symptoms is usually a few (1 to 6) days. Skin changes are the most prominent findings.

Related Physical Findings. Systemic signs and symptoms (wheezing, dry cough, urticaria) have been reported in some patients.[69]

Cutaneous Lesions. The characteristic lesion of HrCLM is an erythematous, raised, and vesicular, linear, or serpentine cutaneous trail (Figs. 207-10 and

▲ **FIGURE 207-10** Cutaneous larva migrans. (Used with permission from Jay S. Keystone, MD, FRCPC.)

▲ **FIGURE 207-11** Cutaneous larva migrans. Note vesicular and bullous lesions. (Used with permission from Jay S. Keystone, MD, FRCPC.)

207-11).[68] Lesions are approximately 3 mm wide and may reach 15 to 20 cm in length. Lesions can be single or multiple, are intensely pruritic, and may be painful. The hookworm larvae advance a few millimeters to a few centimeters daily. The most common anatomic sites (usually 3 to 4 cm from the penetration site) include the feet and buttocks. The oral mucosa has been involved. Excoriation and impetiginization are uncommon (10 percent of the cases).

Another clinical presentation is hookworm folliculitis.[70] The patients usually present with pruritic folliculitis and creeping eruption. The folliculitis consists of 20 to 100 follicular papules and pustules, confined to a particular area of the body, usually the buttocks. Two to 10 serpiginous or linear burrows 1 to 5 cm long may be located in the same or different area. The eruption usually lasts between 2 and 8 weeks, though rarely it has been reported to last up to 2 years.

Laboratory Findings. There may be a transient peripheral eosinophilia.

Special Tests. Characteristic creeping eruption, as well as known epidemiologic exposure, are the basis for the diagnosis of HrCLM.

The diagnosis of hookworm folliculitis is based on clinical findings alone when pruritic folliculitis is associated with creeping eruption. Otherwise, histologic studies are necessary, and show nematode larvae trapped within the follicular canal, the stratum corneum, or the dermis together with an inflammatory eosinophilic infiltrate.[70] In contrast to creeping dermatitis, skin scrapings in patients with folliculitis may reveal live and dead nematode larvae when examined by light microscopy with mineral oil; nematode larvae may also be seen in the dermis on sections of skin biopsy specimens.

Differential Diagnosis. There is a confusion between the terms *creeping eruption* (a sign) and *cutaneous larva migrans* (CLM, a syndrome), both of which have been used to name a disease, animal HrCLM.[68]

Cutaneous Larva Migrans Syndrome. CLM should only refer to the infection by animal nematodes in which the infected human is a dead-end host. These nematodes include animal hookworms (HrCLM), *Gnathostoma* sp. (cutaneous gnathostomiasis), animal filarial nematodes (Spirurina X),[71] *Pelodera strongyloides*, and various zoonotic species of *Strongyloides*. By definition, CLM syndrome does not include diseases in which creeping eruption is due to (1) nonlarval forms of parasites (migratory myiasis, dracunculiasis, loiasis, and scabies); (2) larval forms of human nematodes such as *S. stercoralis* (larva currens); or (3) larval forms of trematodes such as *Fasciola gigantica*.

Clinically, the hallmark of CLM is a creeping eruption but other cutaneous signs related to the subcutaneous migration of nematode's larvae have been described, such as migratory panniculitis and limb swelling.

Creeping Eruption. The different helminthic diseases causing creeping eruption can be distinguished on the basis of the duration of the disease, the characteristics of the cutaneous trail(s) (number, width and length, and serpiginous or linear nature), the location of the trail and other clinical signs, in addition to classical epidemiologic and laboratory findings (see Table 207-2). Correct diagnosis is required for appropriate treatment.

Treatment. (See Box 207-1) First-line treatment for HrCLM is a single dose of ivermectin or a three-day course of albendazole.[72] Cure rates approach 100 percent. Topical therapy with thiabendazole is also an option. The topical application of 10 percent albendazole cream twice a day during 10 days is effective, but it is not available in all countries.[73] There should be no attempt to extract the worm, because it has already migrated beyond the visible lesion by the time it is identified.

Prevention. Infection with animal hookworms is prevented by avoiding direct skin contact with fecally contaminated soil.

DIROFILARIASIS

Synonyms. Dog heartworm infection.

Epidemiology. Widespread in dogs, *Dirofilaria immitis* is thought to be most prevalent in North and South America, Australia, Europe, Japan, India, and China. Sporadic infections with other *Dirofilaria* sp. have been reported from all continents.

Etiology and Pathogenesis. The organisms responsible for dirofilariasis include the filarial nematodes of several species of the genus *Dirofilaria*. These include, most importantly, *D. immitis* (the dog heartworm), as well as *D. tenuis* (raccoon), *D. repens* (dog), and *D. ursi* (bear).[74] *D. immitis* causes pulmonary disease and, rarely, soft-tissue infection.

The parasite occasionally survives for years. Rarely, mature worms have been found in the heart. Dead and calcified worms may be found years after the disease was acquired.

Clinical Findings. The interval between exposure and development of symptoms is usually at least 2 to 3 months. Several dirofilarial species can cause skin lesions.

Related Physical Findings. Pulmonary dirofilariasis can cause cough, chest pain, and, rarely, hemoptysis and low-grade fever. More than 50 percent of persons with pulmonary dirofilariasis are asymptomatic.

Cutaneous Lesions. Soft-tissue dirofilariasis is characterized by erythematous to skin-colored, well-defined, firm subcutaneous nodules or a mass that is usually single.[75] The lesion is typically 1 to 5 cm in diameter and may be tender. There may be initial soft-tissue swelling, which evolves into a well-circumscribed nodular lesion. Occasionally, lesions are migratory.[76] The most common anatomic sites are the head, neck, breast, arm, leg, and scrotum. Parasites may appear in the conjunctiva and oral cavity. Subcutaneous dirofilariasis has been associated with acute arthritis.

Laboratory Findings. Peripheral eosinophilia is usually absent. Chest x-ray

films of pulmonary dirofilariasis show a coin lesion that is usually single and may be calcified.

Special Tests. The definitive diagnosis of dirofilariasis comes from surgical excision of the nodule and identification of the worm. Serologic studies using ELISA may be positive in 75 percent of patients with pulmonary dirofilariasis. However, cross-reaction with other helminthic infections (strongyloidiasis, toxocariasis, schistosomiasis, and filariasis) may limit the usefulness of ELISA, particularly in tropical locations.

Differential Diagnosis. Cutaneous cysticercosis, onchocercosis (onchocercoma), paragonimiasis, as well as epidermal inclusion cyst, lipoma, or other benign tumor, and malignant tumor or metastatic disease, make up the differential diagnosis of subcutaneous dirofilariasis (see Table 207-4).

Treatment. Surgical excision of the nodule containing the worm is curative.

Prevention. Dirofilariasis caused by *D. immitis* can be prevented by controlling heartworm infection in dogs. Prevention of other dirofilarial infections requires avoiding bites of arthropods with infective larvae.

TREMATODES

Schistosomes

CERCARIAL DERMATITIS (See Chap. 209)

SCHISTOSOMIASIS ***Synonyms.*** Bilharziasis, snail fever, Katayama fever.

Epidemiology. An estimated 200 million people are infected globally and more than half a billion live in at-risk areas. eFigs. 207-11.1 and 207-11.2 in the online edition show the geographic distribution of schistosomiasis. Humans are the only important reservoir for *Schistosoma haematobium*. In parts of Africa, baboons are important hosts for *S. mansoni*. Animals (e.g., cows, dogs) are important hosts for *S. japonicum*.

Infection can be acquired after a brief exposure in an endemic area, and many outbreaks have been reported in travelers,[82,83] typically after swimming, wading, rafting, and bathing in infested water in endemic areas. Attack rates in nonimmune exposed persons, such as travelers, can be as high as 69 percent to 100 percent. Pools, ponds, shores of lakes, and small dams pose a greater risk than rapidly flowing streams. Invasive schistosomes are not found in saltwater. Chlorination, iodination, and boiling eliminate infective cercariae.

Etiology and Pathogenesis. Schistosomiasis is caused by trematodes (flukes) that, in the adult stage, live in blood vessels.[84–86] These include primarily *S. mansoni, S. japonicum, S. haematobium, S. mekongi,* and *S. intercalatum* (see the section Cercarial Dermatitis for a discussion of disease caused by nonhuman schistosomes in the on-line edition and Chap. 209). Schistosome eggs excreted by a human or animal hatch in water, releasing free-swimming miracidia that penetrate the intermediate host, the snail, where they develop over 4 to 6 weeks, then emerge as free-swimming cercariae. Cercariae penetrate the skin of a human or other vertebrate host over 30 seconds to 10 minutes, become schistosomulae, and may elicit a local inflammatory response (penetration phase). Schistosomulae enter venules and reach pulmonary capillaries in 1 week after skin penetration. Worms mature in the hepatic sinusoids after several weeks, mate, and migrate to the mesenteric venules (*S. intercalatum, S. japonicum, S. mansoni, S. mekongi*) or rectovesical plexus and branches of the vesical plexus (*S. haematobium*). The migration of the larvae (schistosomulae) in the body leads to an acute parasitic toxemia with hypersensitivity reaction and circulating immune complexes. This invasive stage occurs generally 2 to 6 weeks after the exposure (invasive or acute phase). The mature worm pairs begin to produce eggs 1 to 3 months after infection began.

Mature adult females lay eggs daily, of which 60 percent remain in tissues or enter the bloodstream (chronic phase). The rest of the eggs reach the bowel or bladder and are excreted. The response to eggs is characterized by granulomas with epithelioid cells, foreign body giant cells, and many eosinophils. Necrosis, fibrosis, and calcification occur late in the disease. Worms do not multiply in the human host.

Clinical Findings. **RELATED PHYSICAL FINDINGS.** Clinical features range from inapparent to fatal,[87] although serious sequelae develop only in a small percentage of infected persons—occasionally during the acute phase (especially in nonimmunes) and often after many years of infection. Symptoms of acute schistosomiasis (Katayama fever or Katayama syndrome), are most prominent in primary infection in nonimmune persons, and include fever, myalgia, and headache that may persist for 2 to 10 weeks, sometimes longer.[82,86] Patients may also have cough, lymphadenopathy, abdominal pain, anorexia, and diarrhea. This invasive phase has historically been described with *S. japonicum* (Katayama fever, sensu stricto), *S. mansoni,* and, to a lesser extent, with *S. haematobium*.

Symptoms of the chronic phase may begin after years of infection. The usual life span of the adult worm within the human is 3 to 10 years, but survival of more than 30 years has been documented.

CUTANEOUS LESIONS. Cutaneous manifestations can be seen at every phase of the infection.[88]

Penetration phase: The skin manifestations of infection begin within minutes of bathing and reflect hypersensitivity response to the cercariae. An urticarial and erythematous papular eruption associated with pruritus develops in persons who have been previously sensitized. The rash usually resolves over 1 week. The first exposure to cercariae typically results in erythema and pruritus that resolve within hours.

Invasive phase: In initially nonimmune infected persons, the invasive phase becomes symptomatic in 50 percent to 100 percent of the cases as immunity develops. Skin manifestations during the invasive phase include urticaria, purpura, subungual hemorrhage, and edema of the face, the extremities, genitals, and trunk.

Chronic phase: Late cutaneous manifestations (bilharziasis cutanea tarda) result from the granulomatous, inflammatory reaction to the deposition of eggs in the dermis (Fig. 207-12). It is seen primarily in persons who live in endemic regions. Lesions are skin-colored or slightly pigmented, 2- to 4-mm firm, pruritic, oval papules that may form clusters. The lesions appear in crops and, without treatment, remain unchanged. The trunk, particularly the periumbilical region, is the most common anatomic location for the lesions.

Lesions also appear in the genital and buttocks areas, especially on the vulva in women and the scrotum and penis in men. Early in the disease, the lesions

▲ **FIGURE 207-12** Ectopic deposition of *Schistosoma mansoni* ova.

may also manifest as papules or nodules. Late in the disease, lesions include painless, skin-colored, pink or brown eroded papules and warty, vegetative, polypoid lesions that may be ulcerated and necrotic, with fistulous tracts. Lymphedema and elephantiasis can occur. These lesions may be complicated by secondary bacterial infection and squamous cell carcinoma.

Laboratory Findings. Prominent eosinophilia may be present in early infection. It is the highest during the invasive phase and subsequently fluctuates more or less above the normal value during the chronic phase. Development of eosinophilia may lag behind appearance of clinical symptoms and is usually present by 6 weeks after exposure.

Special Tests. During the chronic phase infection is diagnosed by identifying viable eggs in the stool (*S. japonicum* and *S. mansoni*), urine (*S. haematobium*), or biopsy of rectal, bladder, or other tissue. Serologic tests can also be used , although they vary in their sensitivity and specificity.[89]

Diagnosis is much more difficult to establish during the invasive phase when worms are not yet producing eggs. Serologic tests become positive only 6 weeks after exposure and approximately 3 weeks after the beginning of the acute phase.[82] At this stage, the diagnosis can be suspected based on a history of exposure in endemic area, a history of cercarial dermatitis, and compatible clinical signs. Diagnosis can be confirmed later by finding specific antibodies (seroconversion) and eggs of schistosomiasis.

Differential Diagnosis. For acute invasive schistosomiasis, the differential diagnosis of skin lesions includes all the helminthic causes of acute urticaria.

The differential diagnosis of bilharziasis cutanea tarda of the genital and buttocks area includes atypical syphilis or condyloma latum, condyloma acuminatum, elephantiasis and its causes, amebiasis, other granulomatous diseases, malignancy, and hemorrhoids.

Complications.

Treatment. (See Box 207-1) Praziquantel is the treatment of choice for *S. haematobium, S. japonicum, S. mansoni,* and *S. mekongi* infections. Oxamniquine is an alternative treatment for *S. mansoni* infection. Drugs are not effective during the acute invasive phase and can worsen clinical symptoms.[82] Steroids may be helpful in severe acute schistosomiasis.

Prevention. Avoiding contact with infested water in endemic areas, as well as snail control in those areas, can prevent schistosomiasis. Feces and urine of infected humans should be eliminated in a way that precludes contamination of freshwater.

Flukes Other Than Schistosomes

LIVER FLUKES, FASCIOLIASIS ***Synonyms.*** Sheep liver fluke disease.

Epidemiology. *F. hepatica* is found worldwide in sheep- and cattle-raising areas.[90,91] Sporadic human infections have been reported from all continents.

Etiology and Pathogenesis. Trematodes (flukes) causing fascioliasis include *F. hepatica,* the sheep liver fluke, and *F. gigantica* (rare in humans).[92]

LUNG FLUKES, PARAGONIMIASIS ***Synonyms.*** Lung fluke infection, oriental lung fluke disease

Epidemiology. *Paragonimus westermani* is widely distributed in East and Southeast Asia and Africa. Other species of *Paragonimus* are found in Asia, Africa, and the Americas. Worldwide, an estimated 10 million persons are infected with paragonimiasis. The rates of infection are high in parts of Asia, where raw, undercooked, salted, pickled, or marinated crustaceans are frequently eaten.

Etiology and Pathogenesis. The trematode (fluke) *P. westermani* and more than 10 species of *Paragonimus* infect humans.[92,97]

CUTANEOUS LESIONS. Urticaria may occur early and migratory subcutaneous nodules may appear as early as 2 weeks. Ten percent of patients with *P. westermani* infection and 20 percent to 60 percent of patients with *P. skrjabini* and *P. szechuanensis* infection have subcutaneous swelling or nodules (containing immature flukes). These lesions may be up to 6 cm in diameter, migratory, firm, slightly mobile, and tender to palpation. The lesions are most commonly located on the lower abdomen and inguinal region.

Laboratory Tests.

Treatment. The drug of choice is praziquantel. Bithionol is an alternative therapy (available under an Investigational New Drug protocol from the Centers for Disease Control Drug Service).

Prevention. Paragonimiasis may be prevented by eating only well-cooked crustaceans.

CESTODES (TAPEWORMS)

Major Tapeworms in Humans

ECHINOCOCCOSIS ***Synonyms.*** For disorders associated with *Echinococcus granulosus*—unilocular echinococcosis, hydatid disease caused by *E. granulosus,* classic cystic hydatid disease; for disorders associated with *E. multilocularis*—multilocular echinococcosis, alveolar hydatid disease.

Epidemiology. *E. granulosus* is present on all continents except Antarctica. Infections are sporadic in North America, Central America, northern South America, northern Europe, Australia, and New Zealand. There is a high prevalence of infection in southern South America, focal parts of southern Europe, parts of the former Soviet Republics, Middle Eastern countries, and northern and East Africa. The infection is present in most Asian countries.

E. multilocularis is more limited in distribution; cases have been documented in North America, Europe, Asia, India, and Iran.

Etiology and Pathogenesis. The larval stages of the cestodes (tapeworms) *E. granulosus* and *E. multilocularis* cause most cases of human echinococcosis.[98] Humans are incidental intermediate hosts.

Clinical Findings. Most infections with *E. granulosus* are asymptomatic and go unrecognized. The clinical features of in-

fection with *E. granulosus* are highly variable and reflect the location and size of cysts. Cysts are usually single, although they can be multiple (25 percent). Body location includes the liver (50 percent to 75 percent), lung (20 percent to 30 percent), and other sites: kidney, spleen, heart, bones, muscles, and CNS (less than 2 percent). Within the abdomen, the cyst may reach a large size before symptoms develop.

Related Physical Findings. The signs and symptoms of *E. multilocularis* infection are epigastric and right upper quadrant pain, a palpable mass, jaundice, and hepatomegaly. Initial symptoms occasionally are related to metastatic lesions in the CNS and lung. The interval between acquisition of infection and onset of symptoms is usually years and may be decades for *E. granulosus*.
